Turbulence and Stress Owing to Gravity Wave and Tidal Breakdown

R. S. LINDZEN

Naval Research Laboratory, Washington, D. C. 20390
Center for Earth and Planetary Physics, Harvard University, Cambridge, Massachusetts 02139

It has been suggested (Lindzen, 1967, 1968*a, b;* Lindzen and Blake, 1971; Hodges, 1969) that turbulence in the upper mesosphere arises from the unstable breakdown of tides and gravity waves. Crudely speaking, it was expected that sufficient turbulence would be generated to prevent the growth of wave amplitude with height (roughly as (basic pressure)$^{-1/2}$). This work has been extended to allow for the generation of turbulence by smaller amplitude waves, the effects of mean winds on the waves, and the effects of the waves on the mean momentum budget. The effects of mean winds, while of relatively small importance for tides, are crucial for internal gravity waves originating in the troposphere. Winds in the troposphere and stratosphere sharply limit the phase speeds of waves capable of reaching the upper mesosphere. In addition, the existence of critical levels in the mesosphere significantly limits the ability of gravity waves to generate turbulence, while the breakdown of gravity waves contributes to the development of critical levels. The results of the present study suggest that at middle latitudes in winter, eddy coefficients may peak at relatively low altitudes (50 km) and at higher altitudes in summer and during sudden warmings (70–80 km), and decrease with height rather sharply above these levels. Rocket observations are used to estimate momentum deposition by gravity waves. Accelerations of about 100 m/s/day are suggested. Such accelerations are entirely capable of producing the warm winter and cold summer mesopauses.

1. INTRODUCTION

The possibility of breaking waves generating turbulence in the mesosphere was noted some years ago by *Lindzen* [1967; 1968*a*] and *Hodges* [1969] for tides and gravity waves, respectively. The idea, in these papers, was simply that vertically propagating gravity waves that, in the absence of damping, grow in amplitude as $p_0^{-1/2}$ (where p_0 is the basic unperturbed pressure) could at some height reach amplitudes for which the wave fields themselves would be strongly unstable (i.e., the combination of mean and wave fields would have a negative static stability or at least its Richardson number would drop below 0.25). Above such a height it was suggested that the waves would generate sufficient turbulence, on the average, to prevent further wave growth with height. Theoretical results implied that among tidal modes, only the first propagating diurnal mode would prove important in this respect. *Lindzen and Blake* [1971] estimated that this mode would break down between 80 and 90 km, generating turbulence up to a height of about 108 km above which molecular viscosity and conductivity are sufficient to inhibit further wave growth. The turbulence generated by this tidal mode is restricted to within about 30° latitude of the equator as is the mode itself. The cessation of turbulence at 108 km corresponds closely to the height usually designated for the turbopause and in a loose fashion supports the notion of tidal generation for turbulence.

The situation with respect to internal gravity waves is less certain. Structures with moderately short vertical wavelengths (0(12 km)) are commonly observed in rocket soundings, poleward of 30° (thus excluding diurnal tides, at least in some measure), especially in winter. Examples of such soundings are shown in Figure 1. On the basis of dispersion relations given by *Hines* [1960], one commonly—but arbitrarily—identified the gravity waves as oscillations of relatively short period (0(3 hours)). Observations suggested that such gravity waves also broke down, and *Hodges* [1969] estimated the resulting generation of turbulence along similar lines to those discussed in connection with the diurnal tide. Again, the turbulence was assumed to persist up to some turbopause height. These studies tended to ignore the fact that the relevant frequencies were the Doppler shifted frequencies and that intrinsic frequencies might be very different.

Lindzen [1971] presented a crude model of turbulence in the mesosphere that summarized the above mechanisms and, in addition, argued that 'turbulent' diffusion could result from nonbreaking waves (NB tidal modes are simply special cases of internal gravity waves [viz. *Lindzen,* 1970]. The specific argument was based on wave transiency, but other arguments have been advanced by *Weinstock* [1976]. This matter is discussed further in a separate note by R. S. Lindzen and J. Forbes (manuscript in preparation, 1981) wherein we consider the cascade of energy from stable waves to waves of sufficiently small vertical wavelengths to permit unstable breakdown. Returning to *Lindzen* [1971], the model of eddy diffusion presented consisted in a diffusion coefficient that increased as $(p_0)^{-1/2}$ up to a level at which wave breaking occurred, increased markedly at this level (50–90 km), and remained constant up to some turbopause level. Both the magnitude and the distribution of the diffusion coefficient were reasonably compatible with what was called for by measurements of composition [*Hunten,* 1975; *von Zahn et al.,* 1980] but the range of uncertainty was large. The notion of exponentially increasing (with height) eddy coefficients has, however, gained fairly general acceptance.

Recently, *Holton and Wehrbein* [1980] have concentrated on the momentum deposition by breaking waves, modeling this by Rayleigh friction (acting to bring zonal flow to zero). To be sure, wave breaking does lead to deposition of wave momentum flux, quite apart from the generation of diffusive turbulence; the two effects are, however, distinct as will be shown in section 2 of this paper. Moreover, in the case of breaking tides, the deposited momentum is not attempting to bring the mean flow to zero [*Fels and Lindzen,* 1974]. Nevertheless, as was noted by *Leovy* [1964] and *Lindzen* [1968*b,* 1973], if one anticipates that friction is responsible for the reversal of the latitudinal temperature gradient at the meso-

pause, then one really does need a mechanism that acts to reduce zonal velocities rather than gradients.

The purpose of the present paper is to reassess carefully, but simply, the role of wavebreaking in the mesosphere, emphasizing the role of the mean flow in determining the behavior of gravity waves. Assuming that most high latitude gravity waves originate in the troposphere, it is shown in section 3 that changes in the mean zonal flow accompanying changing seasons, sudden warmings, etc., dramatically alter the nature of gravity waves in the mesosphere. Such changes lead to simple explanations of various mesospheric observations.

2. Gravity Waves in the Mesosphere—Simple WKB Analysis

In this section, gravity waves typical of middle to high latitudes will be emphasized, though theoretical results are easily extended to tidal gravity waves. It will be assumed that the reader is familiar with the mathematical theory of internal gravity waves. Only selected results will be presented here. The following references are but a few of the references where more complete treatments are presented: *Hines* [1960], *Lindzen* [1970], *Gossard and Hooke* [1975], and *Holton* [1979].

We will begin by presenting some data relevant to our subsequent discussion. Figure 1 shows various temperature profiles over Wallops Island (38°N) taken in winter and summer by using rocket grenades [*Theon et al.*, 1967]. We will choose to interpret the pronounced waviness in these profiles as being due to internal gravity waves. Winter 1965 results appear anomalous. However, the remaining profiles suggest a fairly clear picture. Vertical wavelengths are typically 0(12 km) in both winter and summer (the coarse resolution of the grenade method leaves such estimates fairly uncertain). Below breaking levels there is uncertainty over wavelength because wave amplitudes are weak.

In winter the profiles begin to manifest neutral or even unstable lapse rates above 50 km; in summer such lapse rates are found above 70 km. Such levels are marked in Figures 1 and 3. We will identify these lapse rates with the onset of wave breaking. In Figure 2 we show the 'typical' distribution of zonal wind with the latitude and height for winter and summer (CIRA, 1972). Of course, it is by now recognized that the results in Figure 2 are not likely to be applicable to particular winters and summers. For example, in Figure 3 we show winter and summer wind profiles for the latitude band 30°–45°N based on rocket data for the period 1960–1964 [*U.S. Standard Atmosphere Supplement*, 1966]. Also shown are geostrophic winds based on observed temperatures. There is qualitative similarity to Figure 2, but the quantitative differences are obvious. In particular, Figure 3 shows wind magnitudes peaking at the levels of wavebreaking deduced from Figure 1. For our calculations we will use the results in Figure 3. For reference purposes, we show in Figure 4 standard models for the height distribution of temperature in winter and summer (CIRA, 1972). The information in Figure 4 will be needed in subsequent calculations. However, it should be noted that in the absence of wave perturbations, mean lapse rates are only 0 (± 2.4°/km) which are (for many purposes) small when compared with $(g/c_p) = 9.8°/\text{km}$.

We now proceed to use the mathematical theory of internal gravity waves to exploit the above observationally derived features. The crudeness of these features leads us to restrict ourselves to only the simplest, approximate, theoretical results. Our equation for the vertical velocity perturbation, w, associated with internal gravity waves is

$$\tilde{w}_{zz} + \left(\frac{N^2(1 + l^2/k^2)}{(\bar{u} - c)^2} - \frac{1}{4H^2} \right) \tilde{w} = 0 \tag{1}$$

where

w vertical velocity perturbation;

x west-east distance;
y south-north distance;
c phase speed in x direction;
g gravitational acceleration;
N^2 (Brunt-Vaisala frequency)$^2 = g/\bar{T}\,\Gamma$;
Γ $(\partial\bar{T}/\partial z) + (g/c_p)$;
ϕ arbitrary phase.

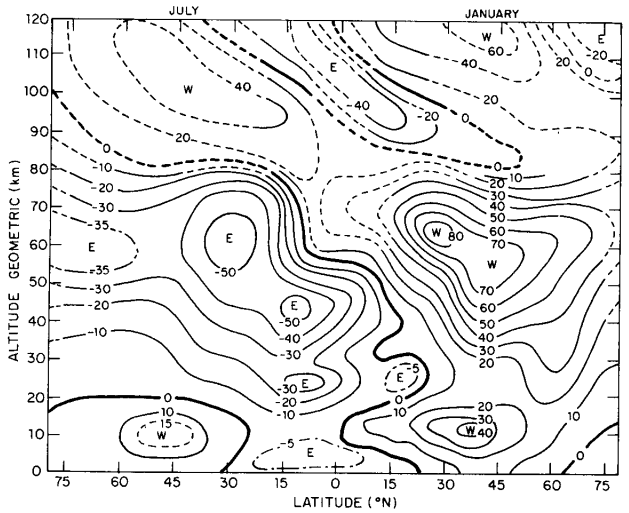

Fig. 2. Zonal wind contours as a function of height and latitude for July and January (CIRA, 1972).

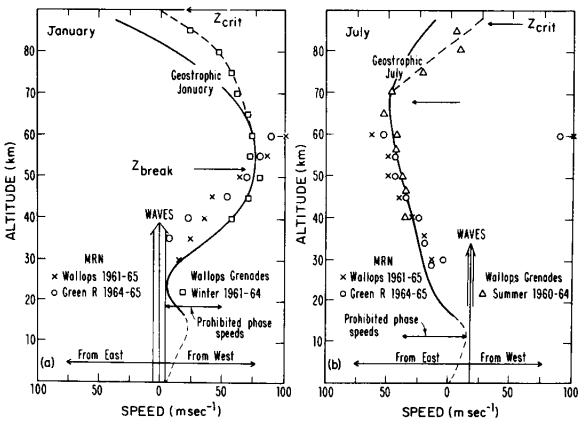

Fig. 3. Zonal wind as a function of height in the latitude belt 30°–45°N based on rocket probes. (*a*) Results for January; (*b*) results for July. Also shown are the geostrophic winds derived from temperature soundings and the phase speeds permitted and prohibited for mesospheric gravity waves of tropospheric origin.

Equation (1) assumes that $\bar{u}_{zz}$ is not too large. Equation (1) has the following approximate WKB solution [viz. *Bender and Orszag,* 1978]:

$$\tilde{w} \approx A\lambda^{-1/2} \exp\{i \int \lambda\, dz'\} \tag{3}$$

where $\lambda^2 = [N^2(1 + l^2/k^2)/(\bar{u} - c)^2] - (1/4H^2)$, and A = constant.

For the problems we are considering

$$\frac{1}{4H^2} \ll \frac{N^2(1 + l^2/k^2)}{(\bar{u} - c)^2}$$

and

$$\lambda^2 \approx \frac{N^2(1 + l^2/k^2)}{(\bar{u} - c)^2} \tag{4}$$

(2) and (3) now determine w. We next wish to obtain the temperature perturbation associated with w. From the thermodynamic energy equation one has

$$ik(c - \bar{U})\delta T \approx w\Gamma \tag{5}$$

or by using (3) and (4)

$$\delta T \approx \frac{i\Gamma^{1/2}T^{-1/2}A}{g^{1/2}k(1 + l^2/k^2)^{1/2}} \lambda^{1/2} e^{i\int\lambda dz} e^{z/2H} e^{ik(x-ct)} \cos(ly + \phi) \tag{6}$$

Equation (6) is appropriate below the level of wave breakdown. For some purposes it proves useful to allow the multiplicative constant in (6) to have a parametric dependence on latitude. It is also convenient to incorporate

$$-ig^{1/2}k\left(1 + \frac{l^2}{k^2}\right)^{1/2}$$

into the 'constant':

$$\delta T \approx A(\theta)\Gamma^{1/2}T^{-1/2}\lambda^{1/2} e^{i\int\lambda dz}\ e^{z/2H} e^{ik(x-ct)} \cos(ly + \phi) \tag{7}$$

where θ = latitude.

For the waves shown in Figure 1, the factor $e^{i\int\lambda dz}$ dominates the z variation of δT, so

$$\frac{d\delta T}{dz} \approx iA(\theta)\Gamma^{1/2}\bar{T}^{-1/2}\lambda^{3/2} e^{i\int\lambda dz}\, e^{z/2H} e^{ik(x-ct)} \cos(ly + \phi) \tag{8}$$

For simplicity, we will identify the level of wave breaking with that level at which

$$\left|\frac{d\delta T}{dz}\right| = \Gamma \tag{9}$$

or from (8)

$$A(\theta)\Gamma^{1/2}\bar{T}^{1/2}\lambda^{3/2} e^{z_{break}/2H} \approx \Gamma \tag{10}$$

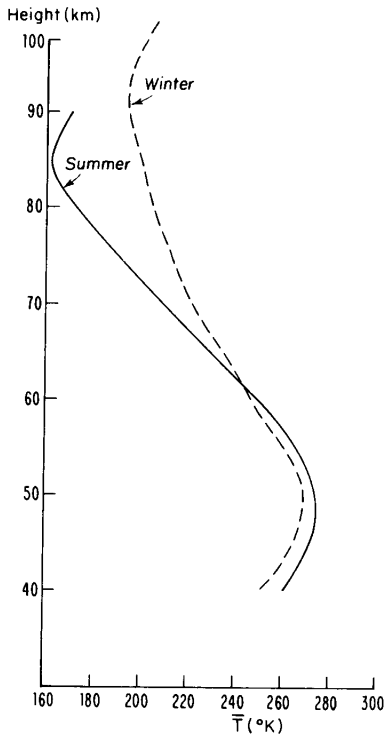

Fig. 4. Zonally averaged temperature as a function of height at 40°N for winter and summer (CIRA, 1972).

Given $A(\theta)$, (10) determines z_{break}, or, alternately, we may use z_{break} as found in Figure 1 to determine $A(\theta)$.

We now hypothesize as in *Lindzen* [1968] and *Hodges* [1969] that above z_{break}, sufficient diffusive turbulence is generated to prevent further growth of $|d\delta T/dz|$. Because of this turbulence, the momentum flux carried by the wave will also be deposited in the mean flow above z_{break}. Our determination of the turbulent eddy coefficient follows the treatment of *Hodges* [1969]. The most important factors in (8) governing the growth of $|d\delta T/dz|$ are $\lambda^{3/2}$ and $e^{z/2H}$, i.e.,

$$\left|\frac{d\delta T}{dz}\right| \alpha \lambda^{3/2} e^{z/2H} \tag{11}$$

The $\lambda^{3/2}$ factor causes growth as $|u - c| \to 0$, and diminution as $|u - c|$ increases. This factor, as a rule, is competitive with the $e^{z/2H}$ growth only as $|u - c| \to 0$. Here, $\lambda^{3/2}$ can be viewed as adding to the $1/2H$ exponential growth rate an amount given by

$$\frac{1}{\lambda^{3/2}} \frac{d\lambda^{3/2}}{dz} = -\frac{3}{2} \frac{1}{(\bar{u} - c)} \frac{d\bar{u}}{dz} \tag{12}$$

Thus, one wants to determine the value of eddy diffusion that will cancel exponential growth with a rate

$$\frac{1}{2H} - \frac{3}{2} \frac{1}{(\bar{u} - c)} \frac{d\bar{u}}{dz} \tag{13}$$

The effect of eddy diffusion is approximated, following *Pitteway and Hines* [1963], by linear damping. Thus in the equations for temperature and horizontal momentum, diffusion contributes terms of the form

$$D_{eddy} \frac{\partial^2}{\partial z^2} \begin{Bmatrix} u \\ \delta T \end{Bmatrix} \approx -\lambda^2 D_{eddy} \begin{Bmatrix} u \\ \delta T \end{Bmatrix} \tag{14}$$

The presence of the right-hand side of (14) is equivalent to including an imaginary contribution to c given by

$$kc_i \approx \lambda^2 D_{eddy} \tag{15}$$

Such a contribution leads to an imaginary contribution to the vertical wave number λ:

$$\lambda \approx \frac{N(1 + l^2/k^2)^{1/2}}{\bar{u} - c} \approx \frac{Nk(1 + l^2/k^2)^{1/2}}{k(\bar{u} - c) + i\lambda_r^2 D_{eddy}}$$

where

$$\lambda_r \approx \frac{N(1 + l^2/k^2)^{1/2}}{(\bar{u} - c)}$$

Solving for λ_i we get the following approximate expression

$$\lambda_i \approx \frac{D_{eddy}\lambda_r^3}{k(\bar{u} - c)} \approx \frac{D_{eddy}N^3(1 + l^2/k^2)^{1/2}}{k(\bar{u} - c)^4} \tag{16}$$

The condition that eddy diffusion prevent the growth of $|d\delta T/dz|$ implied by (13) is simply

$$|\lambda_i| \approx \frac{D_{eddy}N^3(1 + l^2/k^2)}{k|\bar{u} - c|^4} \approx \frac{1}{2H} - \frac{3}{2}\left(\frac{1}{\bar{u} - c} \frac{d\bar{u}}{dz}\right)$$

or

$$D_{eddy} \approx \frac{k|\bar{u} - c|^4}{N^3(1 + l^2/k^2)^{3/2}} \left[\frac{1}{2H} - \frac{3}{2}\left(\frac{1}{\bar{u} - c} \frac{d\bar{u}}{dz}\right)\right] \tag{17}$$

Here, (17) is appropriate above $z = z_{break}$. Below z_{break} we still anticipate that gravity waves can generate turbulence [viz. *Lindzen,* 1971; *Weinstock,* 1976], but at a lower rate. While we will discuss (17) in more detail in the following section, two points should be mentioned immediately:

1. If $|\bar{u} - c| \gg |\bar{u}|$ (as is the case for the diurnal tide) then we expect D_{eddy} to be almost constant above z_{break} (until molecular viscosity becomes sufficient to damp the wave, a level *Lindzen and Blake* [1971] associate with the turbopause).
2. If $|\bar{u} - c| \to 0$ above z_{break}, then we expect D_{eddy} to decrease rapidly as the critical level (where $|u - c| = 0$) is approached.

The last item in our theoretical development is the determination of the deposition of wave momentum flux. In the context of the present discussion, this is given simply by $-d/dz(\rho_0\overline{uw})$, where u and w are the wave zonal and vertical velocity components. We already have an expression for w. Moreover, u is simply related to w. For the vertical wavelengths in Figure 1 we can simplify the continuity equation to

$$\frac{\partial v}{\partial y} + \frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} \approx 0 \approx \text{horizontal divergence} + i\lambda w \tag{18}$$

Now horizontal divergence $\approx ik(1 + l^2/k^2)u$ [*Lindzen,* 1970]. Thus

$$u \approx \frac{\lambda}{k(1 + l^2/k^2)} w$$

and

$$\overline{wu} \approx \frac{1}{2} \frac{\lambda}{k(1 + l^2/k^2)} |w|^2 \tag{19}$$

From (5) and (7) we have

$$|w| \approx g^{1/2} k(1 + l^2/k^2)^{1/2} A(\theta)\lambda^{1/2} e^{z/2H} \tag{20}$$

for $z < z_{break}$, and

$$\overline{wu} \approx \frac{1}{2} gkA^2(\theta) \frac{\lambda}{|\lambda|} e^{z/H} \tag{21}$$

for $z < z_{break}$.

Equation (21) is consistent with the Eliassen-Palm Theorem, which states that $d/dz(\rho_0\overline{uw}) = 0$ in the absence of forcing, dissipation, and critical levels. As noted in connection with (10), δT and w are known at z_{break}. It is readily shown that

$$\overline{wu}|_{z=z_{break}} \approx \frac{k}{2} \frac{N^2}{\lambda^3} \tag{22}$$

Above z_{break}, diffusion essentially eliminates the exponential growth shown in (21). Thus, above z_{break}

$$\overline{wu} \approx \left.\frac{k}{2} \frac{N^2}{\lambda^3}\right|_{\text{evaluated at } z_{break}} \tag{23}$$

Acceleration of the mean zonal flow due to wave breakdown is given by

$$-\frac{1}{\rho_0} \frac{d}{dz} \rho_0 \overline{uw} \approx \left.\frac{k}{2H} \frac{N^2}{\lambda^3}\right|_{z_{break}} \approx \left.\frac{-k}{2H} \frac{(\bar{u} - c)^3}{N(1 + l^2/k^2)^{3/2}}\right|_{\text{eval at } z = z_{break}} \tag{24}$$

The acceleration will be roughly constant between z_{break} and z_{crit} or some other height beyond which wave action ceases.

While the sign of the acceleration will always be such as to bring $\bar{u}$ toward c, it is clear that the process is not properly described by Rayleigh friction. It is also clear that the mean flow acceleration does not result from approximating the effect of D_{eddy} on the mean flow. The two effects are related but separate manifestations of wavebreaking. Note that the distribution of wave acceleration cannot be fixed in space but must be determined on the basis of the particular positions of z_{break} and z_{crit} at any given time.

3. Quantitative Considerations

To evaluate the formulae in section 2, information is needed concerning the phase speeds and wave numbers of the relevant waves. Such quantities are, indeed, well known for tidal modes [*Chapman and Lindzen,* 1970]. This section, therefore, will concentrate primarily on estimating these quantities for gravity waves.

a. *Phase Speeds*

The determination of phase speeds depends, fairly obviously, on the source of gravity waves. (For tides, thermal forcing is reasonably well known [*Lindzen,* 1979; *Forbes and Garrett,* 1979], and the phase speed is essentially the linear rotation speed of the earth, ~ 465 m/s at the equator.) While the possibility of stratospheric and mesospheric origins for mesospheric gravity waves (excluding tides for the moment) exists, no explicit evidence has been found. On the other hand, we do know of very important tropospheric sources, some of which are (1) flow over fixed surface features (mountains, cities, or 'heat islands,' etc.); viz. *Queney* [1948] and many others); (2) frontal processes [*Hines,* 1968; *Peltier and Ley,* 1978]; (3) Kelvin Helmholtz instability [*Lindzen and Rosenthal,* 1976].

The last two are associated with tropospheric flow speeds, while the first is associated with zero phase speed. However, owing to the unsteadiness of the troposphere, one expects phase speeds actually to be spread somewhat about the above speeds. An explicit study of the gravity wave spectra generated goes well beyond the scope of the present study.

We will simply assume a tropospheric origin for mesospheric gravity waves, and, in light of the above remarks, we will assume the phase speeds to be limited roughly to the range of tropospheric wind speeds (i.e., from some neighborhood of zero to some neighborhood of the tropospheric flow speeds shown in Figure 2).

As concerns the mesosphere, we have an additional (and crucial) constraint. Namely, gravity waves cannot readily pass through critical surfaces (where the flow speed and phase speed are equal). Assuming the zonal flows shown in Figure 3 to be appropriate, at least for discussion purposes (and recognizing that this is not likely to be accurately true at any given time), we see that in winter only phase speeds less than 10 m/s can be transmitted, while in summer only phase speeds somewhat in excess of 20 m/s can be transmitted, at least in the neighborhood of 40°. From Figure 2 we see that lower phase speeds would be permitted at other latitudes. Recall that we do not expect the generation of waves with either large negative phase speeds or with phase speeds much in excess of 20 m/s. Intuitively, we expect much greater generation of gravity wave energy with phase speeds near zero than with phase speeds greater than 20 m/s. This is consistent with the fact that z_{break} occurs at a much greater height in summer than in winter (viz. Figure 1). On the other hand, during sudden warmings, when easterlies develop in the stratosphere, we expect a significant reduction in the transmission of gravity waves to the mesosphere and a consequent increase in z_{break}. The seasonal variations in z_{break} caused by the seasonal variation in gravity wave filtering by mean winds provides a reasonable explanation of the observed seasonal variation of height of radio reflections from 50 km in winter to 70 km in summer [*Balsley et al.,* 1980]. The above results also appear consistent with the observation of enhanced D region ionization during sudden warmings [*Koshelev,* 1976].

b. *Horizontal Wave Numbers*

It is clear from (17) and (24) that our estimates of eddy diffusion and wave-induced acceleration depend on our choice of horizontal wave numbers. Vertical wave numbers are independent of specific choices of horizontal wave numbers, but they do depend on the ratio l^2/k^2.

In the case of the main diurnal propagating mode, wave numbers are, of course, well known. From the equivalent gravity mode formulation [*Lindzen,* 1970]

$$k = 1/6400 \text{ km}$$

and

$$l \approx 6.8k$$

Taking

$$u - c \approx -c \approx 466 \text{ m/s}$$

$$\frac{\partial T}{\partial z} + \frac{g}{c_p} \approx 7.5°/\text{km}$$

and

$$T \approx 250°\text{K}$$

we get from (4)

$$\lambda \approx \left(\frac{g}{T}\left|\frac{\partial T}{\partial z} + \frac{g}{c_p}\right|\right)^{1/2}\left(1 + \frac{l^2}{k^2}\right)^{1/2} \approx 2.5 \times 10^{-4} \text{ m}^{-1} \qquad (25)$$

corresponding to a vertical wavelength of about 25 km as expected.

The situation for gravity waves at middle and high latitudes is more ambiguous. What follows are to some extent 'guesstimates.' We will attempt to find a reasonable value of $(l/k)^2$ by matching the 'observed' vertical wave lengths with those predicted by (4). For both winter and summer

$$|u - c| \sim 50 \text{ m/s}$$

$$\frac{\partial T}{\partial z} + \frac{g}{c_p} \approx 7.5°/\text{km}$$

and

$$T \sim 250°\text{K}$$

Now we want

$$\lambda \sim \frac{2\pi}{12 \times 10^3 \text{ m}} \sim 5.236 \times 10^{-4} \text{ m}^{-1}$$

Equation (4) yields

$$\lambda \sim 3.4 \times 10^{-4} \text{ m}^{-1}\left(1 + \frac{l^2}{k^2}\right)^{1/2}$$

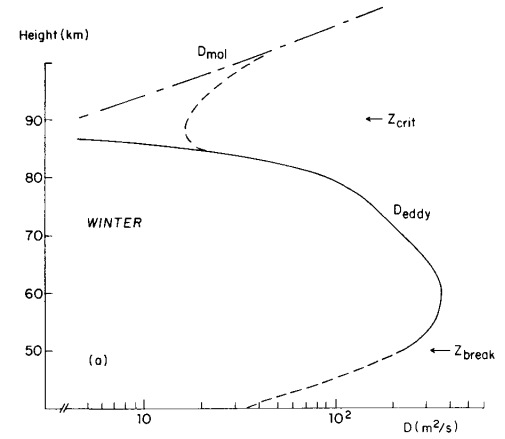

Fig. 5*a*

Fig. 5. Solid line shows predicted eddy diffusion coefficient based on breaking gravity waves. Simple dashed lines show schematic extrapolations as discussed in the text. The line consisting of alternating short and long dashes shows the molecular diffusion coefficient. (*a*) results for winter; (*b*) results for summer.

from which we obtain

$$\left(1 + \frac{l^2}{k^2}\right)^{1/2} \sim 1.54$$

or

$$\frac{l}{k} \sim 1.17 \tag{26}$$

While (26) ought not be taken too seriously, the fact that l and k are about equal is not implausible. As a practical matter, it should be noted that a modest increase in l/k can significantly decrease both D_{eddy} and acceleration.

The guidelines for determining k, itself, are comparably uncertain. There does exist a lower bound of sorts on k. Namely, in the presence of rotation, vertical propagation occurs only when the doppler shifted frequency $|k(\bar{u} - c)|$ exceeds the Coriolis frequency, $f = 2\Omega \sin\theta$ (where Ω = earth's rotation rate and θ = latitude). Now, through the bulk of the mesosphere (near 40° latitude) $|u - c| > 25$ m/s, and propagation will be possible for

$$k \gtrsim \frac{2\Omega \sin 40°}{25 \text{ m/s}} \approx 3.74 \times 10^{-6} \text{ m}^{-1} \tag{27}$$

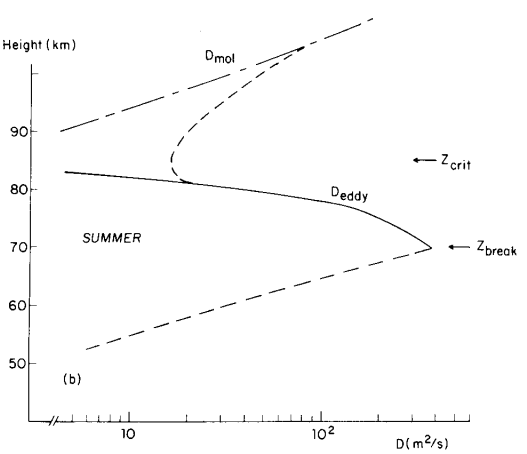

Fig. 5*b*

(40° is the approximate latitude for Figures 1 and 3). Finally, both surface topography and meteorological disturbances (both of which we have assumed are the basic sources of mesospheric gravity waves) tend to have red noise spectra. We will, therefore, take the lower bound for k given by (27) to also be the characteristic value of k. This value of k corresponds to a horizontal wavelength of 1680 km.

c. *Eddy Diffusion*

We evaluate (17) above z_{break} (appropriate to gravity waves) for the profiles of $\bar{u}$ and $\bar{T}$ shown in Figures 3 and 4. The results are shown in Figure 5. We have schematically continued D_{eddy} below z_{break} to indicate that nonbreaking gravity waves can still generate turbulence. We also show schematically an increase of D_{eddy} above the neighborhood of z_{crit}. The idea here is simply that while gravity waves may have a characteristic phase speed, c, they are not restricted to that phase speed. Weaker contributions at other phase speeds may break above that z_{break} appropriate to the bulk of the gravity wave energy. It is perhaps worth noting that the weaker gravity waves would break at a lower height if the bulk of the gravity wave spectrum were absent, since the weaker waves would not then be subject to damping by the turbulence generated by the stronger waves. Finally, one must recall that molecular diffusion increases as $1/\rho_0$ and reaches 0 (2×10^2 m^2/s) by about 110 km. Molecular processes, of course, tend to produce diffusive separation rather than turbulent mixing.

Turning to the explicitly calculated part of Figure 5, we see that for both summer and winter, D_{eddy} peaks near z_{break}. Here z_{break}, as determined from Figure 1, occurs near 50 km in winter and 70 km in summer. In contrast to most models for eddy diffusion, Figure 5 shows a decrease in D_{eddy} with height above the neighborhood of z_{break}. The more precipitous decrease in summer is simply associated with the more rapid approach of $\bar{u}$ to c in summer in the profiles shown in Figure 3. Whether such profiles are, in fact, applicable at any given time is open to question. In particular, during sudden warmings when an easterly flow regime sets on in the stratosphere, waves with $c = 0$ are effectively prevented from reaching the mesosphere and profiles for D_{eddy} should approach distributions similar to what is obtained for summer. This is what appears to be needed to produce enhanced D region ionization [*Koshelev*, 1976].

Interestingly, *Allen et al.* [1981] in a recent observation study of upper atmosphere composition, inferred a distribution of D_{eddy} very similar to the summer distribution in Figure 5. Their maximum value of D_{eddy} was about half of what is shown in Figure 5, but an increase in $(1 + l^2/k^2)^{1/2}$ of only 25% would eliminate this discrepancy.

Finally, we estimate D_{eddy} for the main propagating diurnal tidal mode. As already mentioned, the tide is expected to break at about 85 km. Since $c \cong -465$ m/s, $\bar{u}$ is too small to be of much significance. Thus (17) reduces to

$$D_{eddy} \approx \frac{kc^4}{N^3(1 + l^2/k^2)^{3/2}} \frac{1}{2H} \tag{28}$$

According to CIRA (1972), $\bar{T} \approx 200$°K at 85 km and $d\bar{T}/dz \approx 0$. With these values (28) yields

$$D_{eddy} \approx 1.83 \times 10^2 \text{ m}^2/\text{s}$$

The diminution of D_{eddy} with height due to the variation of $\bar{u}$ was not expected in this case. However, molecular viscosity

and conductivity rise rapidly in this region, and their role in damping the tide is similar to the role of D_{eddy}. Thus we must let D_{eddy} decrease with height so that the sum of molecular and eddy diffusion is given by the above value. This is shown in Figure 6. It should be repeated that although the roles of eddy and molecular diffusion in damping waves are essentially similar, the same cannot be said for their roles in transporting chemical constituents.

d. Wave-Induced Acceleration

As noted in section 2 and shown in Figure 1, $z_{break} \approx 50$ km in winter and $z_{break} \approx 70$ km in summer. Using the data in Figures 3 and 4 to evaluate (24) we obtain

$$-\frac{1}{\rho_0}\frac{d}{dz}\overline{\rho_0 uw} \approx 135 \text{ m/s/day}$$

for $z_{break} < z < z_{crit}$ in summer and

$$-\frac{1}{\rho_0}\frac{d}{dz}\overline{\rho_0 uw} \approx -102 \text{ m/s/day} \qquad (29)$$

for $z_{break} < z < z_{crit}$ in winter.

The values given by (29) seem large, and there is ample room for uncertainty. In particular, it was suggested in section 3*c* that it might be advisable to increase $(1 + l^2/k^2)^{1/2}$ 25% to reduce our estimates of D_{eddy} by a factor of 2. Such a change would also reduce the values in (29) by a factor of 2. That acceleration is constant in the layer $z_{break} < z < z_{crit}$ can, of course, only be approximately true. Total wave absorption in the neighborhood of the critical level, for example, implies the existence of a small neighborhood of the critical level where accelerations exceed the values given by (24).

Application of (24) to the diurnal tidal mode (using the same values as in section 3*c*) yields

$$-\frac{1}{\rho_0}\frac{d}{dz}\overline{\rho_0 uw} \approx -16.3 \text{ m/s/day} \qquad (30)$$

for $z_{break} < z \lesssim 110$ km. Recall $z_{break} \approx 85$ km while 110 km corresponds to a region within 30° latitude of the equator. However, as was noted by *Andrews and McIntyre* [1976], the detailed latitudinal distribution of the momentum deposition can be more complicated.

It was earlier remarked that the accelerations in (29) seemed 'large.' Clearly, such accelerations are not, as a rule, directly observed in the $\bar{u}$ field. However, it is not immediately clear whether the values in (29) are large compared to other contributors to the momentum budget. We might, for example, inquire what values of meridional velocity, $\bar{v}$, would allow Coriolis forces to balance the wave induced accelerations; that is,

$$2\Omega \sin\phi\, \bar{v} \sim 100 \text{ m/s/day}$$

or

$$\bar{v} \sim 0\left(\frac{100 \text{ m/s/day}}{2\Omega \sin\phi}\right)$$

$$\sim 0\left(\frac{8 \text{ m/s}}{\sin\phi}\right) \qquad (31)$$

Now according to CIRA (1972), such meridional winds are observed in the upper mesosphere (though one might question whether the observations really represent a zonal average). If this is so, then accelerations on the order of those given by (29) would be necessary to balance the 'observed' Coriolis torques.

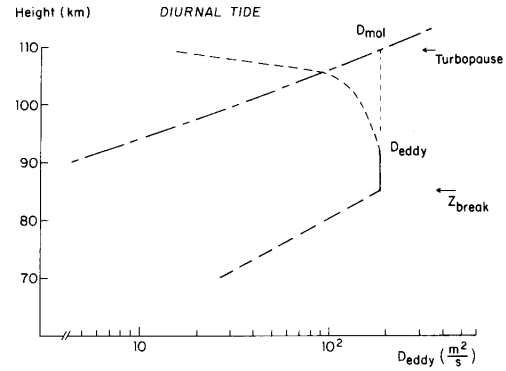

Fig. 6. Same as Figure 5, but for turbulence produced by the breaking of the diurnal tide.

Incidentally, the relatively small accelerations produced in the tropics could be balanced by the diffusion of momentum by the tidally induced eddy diffusion; this is not the case for the gravity wave-induced turbulence and acceleration in middle and high latitudes.

4. CONCLUDING REMARKS

For some years it has been accepted that tides and gravity waves propagating into the upper mesosphere from below are the major source of turbulence in the upper mesosphere. The purpose of the present paper has been to examine the implications of such a situation in some detail. The main propagating diurnal mode seems to be the primary contributor at tropical latitudes. Because of the high phase speed of this mode (−465 m/s), it is only slightly affected by the mean zonal flow of the atmosphere [*Lindzen,* 1971]. Wavebreaking appears to occur around 85 km, leading to a layer of enhanced eddy diffusion and wave induced acceleration (0(−16 m/s/day)) extending between 85 km and about 108 km above which height molecular transport dominates.

The situation at middle and high latitudes is more complicated. Gravity waves appear dominant at these latitudes, and if such waves originate in the troposphere (as seems likely) then their phase speeds will typically range from zero (appropriate to mountain waves, etc.) to typical tropospheric flow speeds. For such low phase speeds the effect of the mean zonal flow distribution will be crucial. The flow distribution will effectively determine which gravity waves (depending on phase speed) can reach the mesosphere and relatedly the amplitudes of mesospheric gravity waves and their breaking level. This effect, for example, implies that gravity wavebreaking will occur at greater altitude in summer than in winter (70 km versus 50 km). In addition, the turbulent diffusion and wave-induced accelerations no longer extend up to some level where molecular processes dominate. Instead, they are restricted to layers extending from the breaking level to some approximate critical level (where the mean flow, $\bar{u}$, equals or almost equals the wave phase speed). The lattr are likely to be developed by the wave-induced accelerations themselves. Between the critical levels and the thermosphere we expect a sharp minimum in eddy diffusion.

The wave-induced accelerations provide an explicit source for the 'friction' needed to reverse mesospheric shears and,

relatedly, to reverse the pole-to-pole temperature gradient at the mesopause. Models without such friction develop neither of these features [*Mahlman and Sinclair,* 1979]. The wave-induced acceleration acts to bring the mean flow toward the wave phase speed. In this respect the acceleration is similar to Rayleigh friction, provided the waves have zero phase speed. In contrast to Rayleigh friction the acceleration is not proportional to $(\bar{u} - c)$; indeed, it can increase as $(\bar{u} - c) \rightarrow 0$ (i.e., as a critical level is approached).

There are, in the present study, any number of shortcomings. For example, the existence of D_{eddy} below z_{break} requires that there be some momentum deposition below z_{break} in contrast to our restricting the deposition to $z \geq z_{\text{break}}$. Similarly, in a calculation where $A(\theta)$ is specified instead of z_{break} (viz. (10)), this will alter the value of z_{break}. It is not difficult to include such effects (at least approximately), but their inclusion seems unwarranted in the present paper, which is meant to be primarily illustrative. More problematic is the fact that our mathematical development considered only the vertical propagation of gravity waves (vis. (1)). A realistic application of the present concepts may require considering the propagation of gravity waves in a two-dimensional inhomogeneous medium. This, however, remains to be investigated. It is hoped that, for many purposes, a reasonable specification of $A(\phi)$, and the use of our present formulas, will suffice.

(Received 17 January 1997; accepted 11 June 1997)

A simulation program that provides insight into the vibrational properties of resonant mass gravitational radiation antennas is developed from scratch. The requirements that are set necessitate the use of an explicit finite element kernel. Since the computational complexity of this kernel requires significant computing power, it is tailored for execution on parallel computer systems. After validating the physical correctness of the program as well as the performance on distributed memory architectures, we present a number of ''sample'' simulation experiments to illustrate the simulation capabilities of the program. The development path of the code, consisting of problem definition, mathematical modeling, choosing an appropriate solution method, parallelization, physical validation, and performance validation, is argued to be typical for the design process of large-scale complex simulation codes. © *1997 American Institute of Physics.* [S0894-1866(97)01805-1]

INTRODUCTION

General background

Although the existence of gravitational radiation, predicted by Einstein's theory of general relativity,[1] is unquestioned, its detection is a long-standing problem in experimental physics. The aim of the GRAIL project[2] is to realize a spherical resonant mass detector with a sensitivity that is a few orders of magnitude higher than the present generation of detectors, thus offering the possibility of validating the existence of gravitational radiation that is emitted by astrophysical sources.[3] These sources include supernovae, stellar collapses to black hole states, and coalescence of binary neutron star systems.[4]

The quadrupole moment of a mass distribution $\rho(\mathbf{x})$ is given by

$$D_{ij}=\int_V dV\rho(\mathbf{x})\left(x_i x_j-\frac{1}{3}\,\delta_{ij}\mathbf{x}^2\right). \tag{1}$$

According to general relativity (GR), an oscillation of this quadrupole moment is the simplest mode of vibration that can generate gravitational waves. The counterstatement for absorption of gravitational waves is that in the simplest case it also takes place via the excitation of the quadrupole modes of vibration of a massive object. This principle is the main argument for constructing a gravitational radiation antenna, which essentially is a large resonant mass that is forced into oscillation by impinging gravitational radiation.

In GRAIL, the antenna will consist of a spherical resonant mass of a Cu alloy, possibly CuAl, with a mass of about 100,000 kg and a diameter of 3 m. It will be suspended in vacuum inside a large cryostat in such a way that the external vibrations at its resonant frequency ($\approx$700 Hz) are attenuated by at least a factor of 10^{16}. The sphere will be cooled to a temperature in the range of 10–20 mK in order to cancel out thermal noise. Transducers will be attached to the surface of the sphere to detect the vibrations induced by gravitational radiation. An analysis of the electric signals from these transducers must give information (such as source type and direction of incidence) about the gravitational radiation that interacts with the sphere. The gravitational waves have extremely weak interaction with matter; the typical deformations induced on a Cu sphere of 3 m will be of the order of 10^{-20} m, which explains why detection is such a difficult task and why it has not yet been realized. Several arguments can be given for using a spherically shaped antenna[5–8] instead of, for example, the cylinder or bar antennas in the pioneering days of gravitational radiation detection[9] and present-day experimental setups like the NAUTILUS detector at the Frascati National Laboratory in Rome.[10]

Since the estimated cost ($\approx$ 45 million Dutch guilders) of the project is quite high, a pilot study has been funded by NWO[11] to investigate the technological feasibility of GRAIL. In this project several critical aspects concerning the design of the antenna had to be addressed. The task of our simulation group was to construct detailed models of the antenna that provide insight into its vibrational properties. A schematic design of the GRAIL antenna concept is shown in Fig. 1.

The development and design of complex systems can be significantly enhanced by means of simulation. A recent example in which simulation was used in the analysis of the behavior of resonant mass antennas can be found in Ref. 8. In this work modal analysis was used to determine the frequency spectrum of a truncated icosahedral antenna. The accuracy of this simulation was fairly limited due to the low model resolution. The main result was that one can

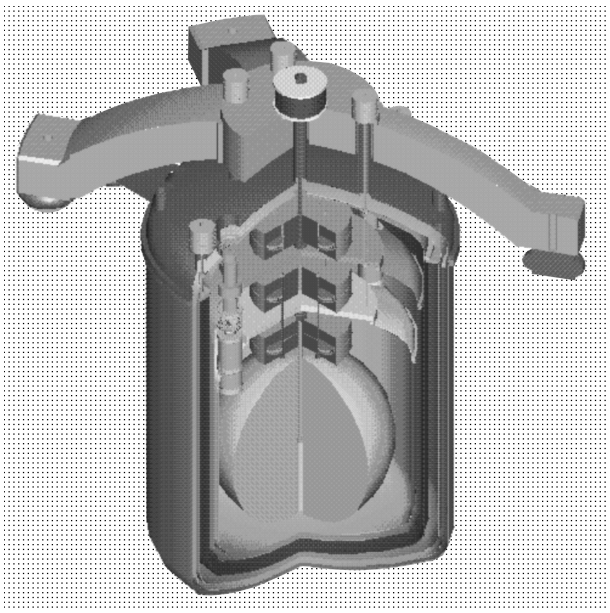

Figure 1. The GRAIL *antenna in a heat isolating vacuum chamber.*

conclude that the behavior of a truncated icosahedral antenna is very similar to that of a sphere.

In this article we will describe the development of a high-resolution simulation system for resonant mass gravitational radiation antennas that can be applied to a number of important design issues.

Design issues

The following questions need to be addressed by means of extensive simulation experiments.

(1) How does the suspension of the huge resonant mass affect the eigenmodes and eigenfrequency of the fundamental quadrupole modes of a sphere?
(2) How will material inhomogeneities affect these eigenmodes and eigenfrequencies?
(3) Given a perfect sphere, how will it deform under its own weight?
(4) Does the coupling between the suspension rod and the sphere induce additional modes that will cause interference with the modes we are looking for?
(5) What is the effect of mounting transducers on the antenna on the frequency spectrum of the system?
(6) How will seismic noise, entering the sphere through the framework in which it is suspended, influence the transducer signals?
(7) How will the fingerprint of typical gravitational wave sources be seen by the antenna?
(8) Can energy that has been deposited by cosmic rays or particles like muons induce system eigenmodes that are not distinguishable from those induced by gravitational waves?

We can identify two types of questions in this list. First, the design questions that need to be answered in order to tune the readout of the system, like the effects of the suspension hole, suspension rod, or material inhomogeneities on the frequency spectrum of the antenna. Second, we have those questions that pertain to the various sources of vibration: How can we discriminate whether the vibration that we observe is the result of a gravitational wave or of something else? Clearly a simulation that can help us in answering these questions can be of great value to the design and development phase of the GRAIL project. Eventually, when the system is operational, a (well-defined) simulation system can even be used to analyze the transducer output by means of reverse engineering of the transducer signal towards the original source. Incorporation of simulation in the experimentation cycle is sometimes referred to as ''living simulations'' or ''simulation in the loop.''

The remainder of this article is structured as follows. Section I begins with a description of two solution methods that can be used to answer a few basic questions but that are too restrictive for our overall goal. For this purpose we resort to development of a simulation that is based on the explicit finite-element (FE) method. The simulation accuracy required necessitates high-resolution FE models. The performance of the FE solver is therefore enhanced by exploiting the models' parallelism (Sec. II). Since the simulation is developed from scratch, we can circumvent several pitfalls that are known to hamper the migration of existing simulation codes to parallel computers.[12–14] In Sec. III the physical correctness of our simulation is validated by a comparison with an analytical solution as well as by experiments that were carried out with a small prototype antenna. It is further shown that we benefit greatly by exploiting computational concurrency. In Sec. IV we present a few typical simulation experiments that can be carried out with the simulation program. Some concluding remarks regarding the computational science approach taken in our study are given in Sec. V.

I. SIMULATION METHODS

A. Analytical solution

The equation of motion for elastic objects, also known as the Navier equation [Eq. (2)] describes the variation in time of the displacement field ($\mathbf{u}$) in homogeneous isotropic elastic objects. The material of such objects is parameterized by the two Lamé parameters (λ,μ) and the material density (ρ).

$$\mu\Delta\mathbf{u}+(\lambda+\mu)\nabla\nabla\cdot\mathbf{u}=\rho\ddot{\mathbf{u}}. \tag{2}$$

Two parameters that are frequently used to describe the elastic properties of a material are the Poisson ratio (ν) and Young's modulus (E). Both parameters can be expressed in terms of the Lamé parameters as follows:

$$\nu\equiv\frac{\lambda}{2(\lambda+\mu)}, \tag{3}$$

$$E\equiv\frac{\mu(3\lambda+2\mu)}{\lambda+\mu}. \tag{4}$$

The general solution of Eq. (2) consists of two different contributions that correspond to divergence-free ($\nabla\cdot\mathbf{u}=0$) and rotation-free ($\nabla\times\mathbf{u}=0$) waves that propagate through the material with unique velocities.

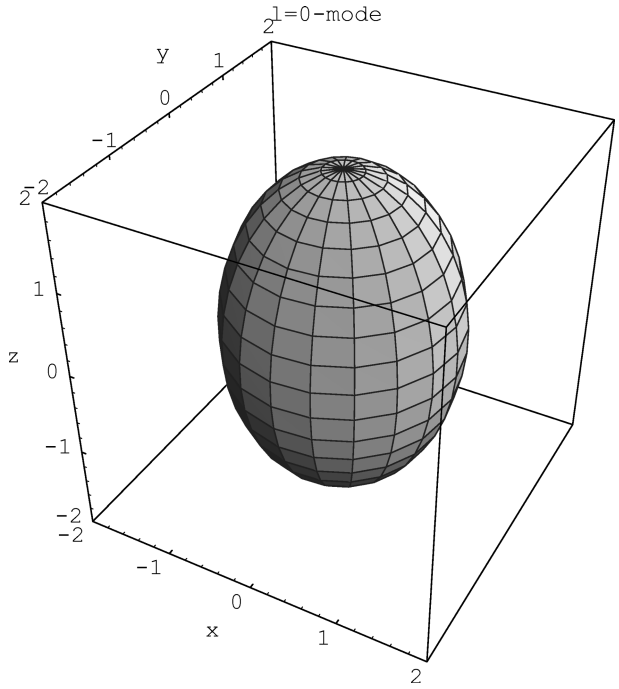

Figure 2. The prolate stage of the l=0 mode.

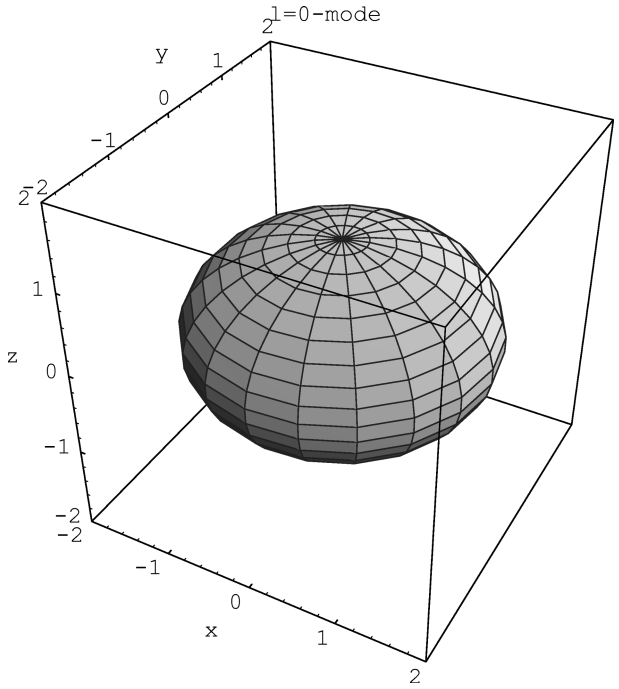

Figure 3. The oblate stage of the l=0 mode.

For both types of vibration a frequency equation can be derived for a freely vibrating (traction-free) elastic sphere and can be solved numerically.[15] The rotation-free vibrations are known as *spheroidal eigenmodes*. A general spheroidal eigenmode, Ψ^s, is given by Eq. (5), which is the superposition of all particular rotation-free solutions of Eq. (2) for a spherical object with traction-free boundary conditions; note that we use polar coordinates.

$$\Psi^s = \sum_{n=0}^{\infty} \sum_{m=-n}^{n} [a_n(r)\hat{e}_r + b_n(r)R\nabla]Y_{nm}(\theta,\phi), \quad (5)$$

with R the sphere radius and $\hat{e}_r$ the unit vector in the radial direction; $a_n(r)$ and $b_n(r)$ are dimensionless radial eigenfunctions determined by the boundary conditions, and Y_{nm} are spherical harmonics. For each value of n the frequency equation contains infinitely many solutions. A general quadrupole mode of the sphere can be described as the superposition of the five modes with $n=2$ $(m=-2...2)$. Since (according to GR) only these modes interact with gravitational radiation, they are the primary subject of our investigations. Figures 2 and 3 show the shape of one of the quadrupole modes (denoted as the $l=0$ mode[16]) differing by half a period. This eigenmode oscillates between a prolate and an oblate shape.

The applicability of this analytical model fails as soon as we perturb the sphere in any way. However, it provides us with a useful gauge for a simulation program. First, we take a look at an elegant numerical model that is less restrictive than the analytical model described above.

B. Numerical method

If we write down the Lagrangian [Eq. (6)] for a freely vibrating elastic object (following Ref. 17) (the summation convention is used where appropriate)

$$L = \int_V \left(\frac{1}{2}\rho\omega^2 u_i u_i - \frac{1}{2} c_{ijkl} u_{i,j} u_{k,l} \right) dV, \quad (6)$$

with u_i the component of the displacement field $\mathbf{u}$ that is parallel to the i axis, $u_{i,j}$ the derivative of u_i in the j direction, c_{ijkl} the elastic tensor (dependent on λ and μ), and ω the eigen- (angular) frequency, and apply the principle of least action, setting $\delta L = 0$, we get

$$\delta L = \int_V (\rho\omega^2 u_i + c_{ijkl} u_{k,lj})\,\delta u_i dV - \int_S (\nu_j c_{ijkl} u_{k,l})\,\delta u_i dS = 0, \quad (7)$$

where ν_j denotes the component along the j axis of the outward-pointing normal vector on the surface of the object. Equation (7) exactly expresses the elastic wave equation (2), with traction-free boundary conditions, of Sec. I A. If we expand the displacement vector in a set of basis functions according to

$$\mathbf{u} = \sum_{lmn} \mathbf{a}_{lmn} x^l y^m z^n, \quad (8)$$

and truncate the expansion to a certain polynomial order, Eq. (7) can be rewritten in terms of a generalized eigenvalue problem (9).

Table I. The analytical and "numerical" frequencies in Hz for a few spheroidal modes of a Cu sphere. The dashes denote that no frequencies in the same range were found for specific N. This is due to the fact that the polynomial expansion in question is not able to represent the corresponding eigenmode properly.

$$\omega^2 E\mathbf{a}=\Gamma\mathbf{a}. \tag{9}$$

The matrices E and Γ can be computed by integrating Eq. (7) properly. Solving for ω provides us with estimates of the eigenfrequencies of the system in question.[16,17]

1. Validation

Table I shows several eigenfrequencies found with the numerical method as well as the corresponding analytical values for a Cu sphere (material parameters: $\rho=8933$ kg/m^3, $E=129.810^9$ Pa, and $\nu=0.343$). N denotes the truncation order of the basis function expansion, and $R\times R$ is the matrix size of the corresponding eigenvalue problem. We have used a LAPACK[18] routine called DSYGV, which can be applied to symmetric generalized eigenvalue problems to solve the system.

2. Spheroidal perturbations

An ellipsoid is described by its three semi-axes d_x, d_y, and d_z:

$$\frac{x^2}{d_x^2}+\frac{y^2}{d_y^2}+\frac{z^2}{d_z^2}=1. \tag{10}$$

For a sphere these axes have equal length. When we make one semi-axis longer and keep the other two constant, the object is called a prolate spheroid. If we make one semi-axis shorter than the other two, we have an oblate spheroid. In Fig. 4 the dependence of the lowest quadrupole frequency on d_z is depicted [varied in the range (0.1, 5.0) m], while the other two axes are kept at 1.5 m for a Cu sphere. We can observe three lines that intersect at $d_z=1.5$. Since the spherical symmetry is broken in the z direction, the fivefold degeneracy is only partially removed. It splits into two doublets and one singlet. Additional perturbations in the x and y directions would break the symmetry completely, leaving us with five slightly different frequencies.

C. A finite-element model

The numerical method of Sec. I B also was applied to a sphere with a suspension hole. Again it can be observed that the five frequencies are split up (see Fig. 5). It leaves us with an uncomfortable feeling, however, since the sharp edges of the suspension hole possibly disrupt the numerical

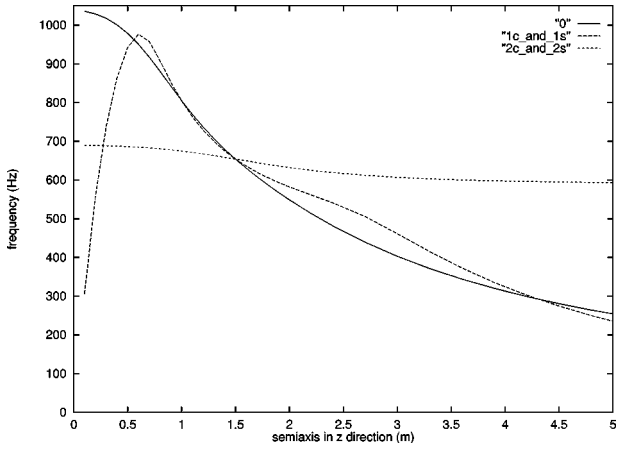

Figure 4. The fundamental quadrupole frequencies under variation of d_z. The spherical symmetry is broken in the $\hat{z}$ direction, resulting in a threefold splitting of the fivefold degenerate quadrupole frequency: two doublets and one singlet. The doublets are denoted by 1c_and_1s and 2c_and_2s and the singlet by 0.

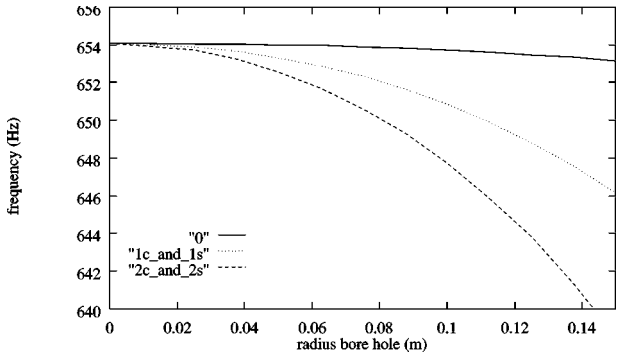

Figure 5. The fundamental quadrupole frequencies vs the radius of the suspension hole. The spherical symmetry is broken in the $\hat{z}$ direction, resulting in a threefold splitting of the fivefold degenerate quadrupole frequency: two doublets and one singlet. The doublets are denoted by 1c_and_1s and 2c_and_2s and the singlet by 0.

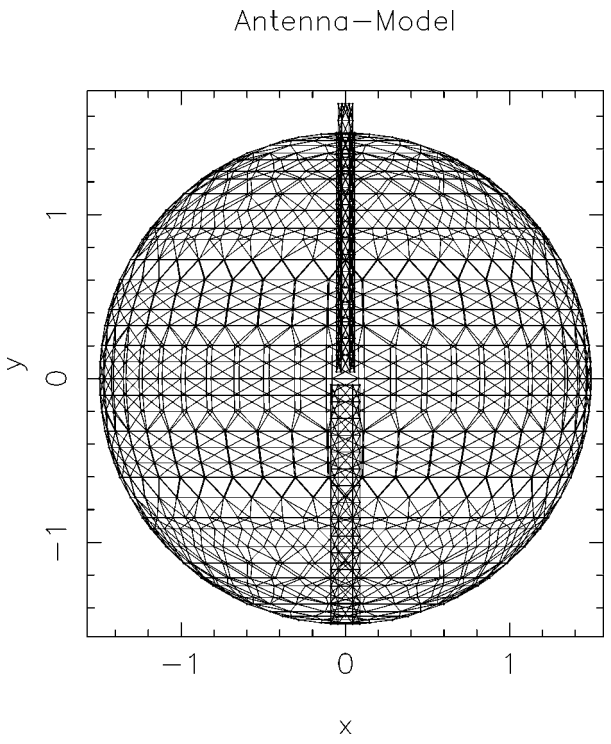

Figure 6. The hull of a finite-element antenna model with the suspension rod discretized into 39,684 tetrahedral elements.

process. Therefore, we do not know whether the frequency splitting is an artifact or is physically correct. Furthermore, we are stuck with a variety of questions that cannot be answered by the analytical and numerical approaches above. Next we will consider the finite-element method as a third alternative to answer our questions. We discretize our antenna model in first-order tetrahedral elements (each element has four nodal points). As an example, Fig. 6 shows the hull of such a finite-element model, consisting of 39,684 tetrahedral elements. One approach to the problem is by means of modal analysis, that is, by studying the following eigenvalue problem:

$$K\mathbf{d}=\omega^2 M\mathbf{d}, \tag{11}$$

with K the system's stiffness matrix, M the mass matrix, $\mathbf{d}$ an eigenmode, and ω an eigenfrequency of the system. Although it is theoretically possible to investigate a linear system such as ours on the basis of modal analysis, its practical realization is a different story. First of all, the model resolutions that we aim for are very high, necessitating solution of huge eigenvalue problems. These may be solvable using state-of-the-art numerical solvers. If we succeed in doing that, we have to cope with a storage problem, since for each nodal point a superposition of at least over 100 eigenmodes is necessary to characterize a general low-frequency solution of the system. In addition, it is difficult to model the effects that are due to coupling to external forces that are aperiodic, like seismic noise entering via the suspension or stochastic sources.

On the other hand we can choose for explicit time integration of the equation of motion (12).

$$M\mathbf{a}+C\mathbf{v}+K\mathbf{d}+\mathbf{F}=0. \tag{12}$$

The matrices M, C, and K are constructed by assembling the local mass, the viscosity, and the stiffness matrices of all individual finite elements in which the antenna model is divided; **a**, **v**, and **d** are vectors that describe, respectively, the acceleration, velocity, and displacement fields, and **F** is an external force vector. In order to integrate this system explicitly in time we adopt the following Newmark scheme:[19]

$$\begin{aligned}\mathbf{d}_{n+1}&=\mathbf{d}_n+\mathbf{v}_n\Delta t+\mathbf{a}_n\frac{(\Delta t)^2}{2},\\ \mathbf{a}_{n+1}&=M^{-1}K(\mathbf{d}_{n+1}),\\ \mathbf{v}_{n+1}&=\mathbf{v}_n+(\mathbf{a}_n+\mathbf{a}_{n+1})\frac{\Delta t}{2}\end{aligned} \tag{13}$$

with $\mathbf{a}_n$, $\mathbf{v}_n$, and $\mathbf{d}_n$ vectors that describe, respectively, the acceleration, the velocity, and the displacement fields in the FE system at time n. Viscous damping (C) and external forces (**F**) can easily be added to this algorithm.[19–21] The masses are ''lumped'' at the nodal points, resulting in a diagonal mass matrix. Therefore M^{-1} can be calculated quickly. For numerical stability Δt must be less than the Courant value, since the time integration scheme is conditionally stable. The choice of the algorithm is, on the one hand, motivated by the fact that it displays good numerical properties (low numerical dispersion and damping). This was found through a number of exploratory experiments on a one-dimensional finite-element model (data not shown). On the other hand, it is very well suited for exploiting computational concurrency, as we will see below. Although this explicit approach has the drawback that we have to solve our system in the time domain and afterwards perform a spectral analysis, it is much more flexible for our purposes, and is not hampered by the restrictions that apply to modal analysis. Furthermore, the simulation model can be extended such that it can incorporate nonlinear effects, such as *violin modes* in the suspension rod, that cannot be realized by modal analysis.

It was expected that the required simulation accuracy necessitates the use of a very-high-resolution FE model that is computationally and memory intensive. The simulation code was therefore designed and implemented for execution on distributed-memory computers.

II. PARALLELIZATION

In good tradition, we have chosen to base our parallelization method on the decomposition of the FE mesh. The consequences of the decomposition method for the time integration algorithm as well as the calculation of important system parameters (like energy) had to be considered in the design. In our discussion we will only consider the pure finite-element system. In the full-fledged simulation a variety of phenomena can be taken into account, such as transducer mounting, suspension rod, and sources of vibration. At this point it suffices to say that the parallelization method chosen does not have major consequences for the full-fledged simulation, and therefore may be left out of this discussion. We focus on two important aspects of the parallelization process: parallel time integration (the kernel) and parallel calculation of the energy.

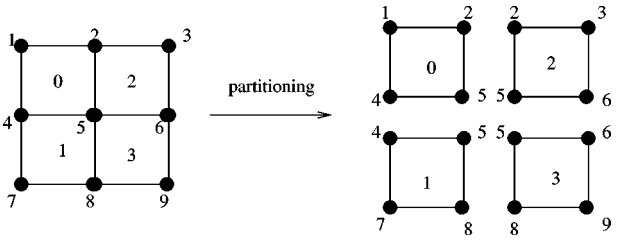

Figure 7. Partitioning of a quadrilateral mesh into four parts. The nodal points at the shared boundaries are replicated while elements are assigned to unique processes.

The code was implemented in C with PVM[22] message passing primitives according to the single-program, multiple-data paradigm.[23] The problem domain (the finite-element mesh consisting of N tetrahedral elements) is partitioned into P subdomains. Each subdomain is assigned to a single process and executes the same program applied to its local data. The process with identifier 0 is used to read in the whole mesh; it supplies the other $P-1$ processes with their locally essential data, and is used for input/output (I/O), a *primus inter pares* or *master* among the parallel processes.

A. Energy

In order to check energy conservation, we have to monitor the energy in the system. The total energy E_{tot} is given by

$$E_{\text{tot}} = \tfrac{1}{2}(\mathbf{v}^T M_{\mathbf{v}} + \mathbf{d}^T K \mathbf{d}), \tag{14}$$

with $\mathbf{v}$ the velocity vector in which the individual velocity vectors of all nodal points are concatenated, and $\mathbf{d}$ the displacement vector, also formed by concatenating the fields at all nodal points. How do we calculate this in parallel?

The FE mesh is decomposed along the surfaces of the tetrahedral elements that constitute the mesh. First, a dual graph of the mesh is constructed; this then can be partitioned using any graph-partitioning method.[24] Nodal points that lie on shared boundaries are replicated on each process with this boundary in its local domain, whereas elements belong to a unique process. This procedure is schematically depicted in Fig. 7 for a simple quadrilateral mesh.

The global mass and stiffness matrices are constructed by assembling the individual contributions from each element in a global matrix. If we denote the assembly of two-element stiffness matrices k_1 and k_2 by $k_1 \oplus k_2$, K is constructed (analogously for the mass matrix) as follows:

$$K = k_1 \oplus k_2 \oplus \ldots \oplus k_N, \tag{15}$$

with N the number of tetrahedral elements. If we monitor the energy values during a simulation run (it would be nice if this could be done completely separate), that is, for each subdomain (i), the energy content (E^i_{tot}) is calculated, and once in a while we assemble the subdomain energy contributions and accumulate them on process 0. This can be done as follows:

$$E^i_{\text{tot}} = \tfrac{1}{2}(\mathbf{v}^{\mathbf{i}T} M^i_r \mathbf{v}^{\mathbf{i}} + \mathbf{d}^{\mathbf{i}T} K_i \mathbf{d}^{\mathbf{i}}), \tag{16}$$

$\mathbf{v}^{\mathbf{i}}$ denotes the velocity vector for the nodes in subdomain i, $\mathbf{d}^{\mathbf{i}}$ is the displacement field, K_i is the stiffness matrix of subdomain i, which is simply the assembly of its local element stiffness matrices, and finally M^i_r is an adjusted version of the (diagonal) mass matrix of subdomain i. The ''normal'' mass matrix contains the mass for each nodal point at the appropriate entry. In this adjusted version the masses of the internal nodal points are untouched. However, for the shared nodal points this value is divided by its ''redundancy'' value, which denotes how many processes have a replica of it. For example, in Fig. 7 nodal point 5 has a redundancy value of 4. As a consequence, the corresponding entry in each local adjusted mass matrix, either being on process 0, 1, 2, or 3, has to be divided by 4. In this way we can assure that we are not counting any energy contributions twice.

B. Time evolution

If we have constructed the mass and stiffness matrices for each subdomain (or process) correctly, we can parallelize the Newmark scheme above as follows: Each process gets a unique process identifier (ID) equal to the subdomain identifier (i) above. Nodal points that are shared among two or more processes are considered to have one real owner (the owning process considers it as a node of type A), while the other processes only have the replica of this node (considering the node as type B). Assigning a node to a specific process is based on the process ID. The process with the lowest ID considers a shared nodal point as A type, while the other processes see it as B type. Consequently, process 0 can only have shared nodes of type A, while process $P-1$ (assuming we have P processes) can have only shared nodes of type B. The following construction parallelizes the Newmark scheme correctly:

$\mathbf{d}_{n+1} = \mathbf{d}_n + \mathbf{v}_n \Delta t + \mathbf{a}_n (\Delta t)^2/2$,
Send $\mathbf{d}_{n+1}$ from A nodes to B nodes,
Receive $\mathbf{d}_{n+1}$ for B nodes from A nodes,
$\mathbf{a}_{n+1} = M^{-1} K(\mathbf{d}_{n+1})$,
Send $\mathbf{a}_{n+1}$ from B nodes to A nodes,
Receive $\mathbf{a}_{n+1}$ for A nodes from B nodes,
Add contributions to $\mathbf{a}_{n+1}$ from B nodes,
$\mathbf{v}_{n+1} = \mathbf{v}_n + (\mathbf{a}_n + \mathbf{a}_{n+1})\Delta t/2$.

The A–B nodal point scheme was adopted from Lonsdale *et al.*[25]

III. VALIDATION

Here we show a selection of experimental results that were produced for validation of our parallel FE simulation. First, we investigate whether the model is physically correct. Next, we measure the performance benefits that we get from exploiting parallelism for different mesh resolutions. Meshes are decomposed by two different graph-partitioning methods: recursive spectral bisection (RSB) and a generalized version of orthogonal recursive bisection (ORB),[24] which we call *generalized* ORB (GORB). GORB operates in such a way that consecutive partitionings are not necessarily orthogonal and that partitioning cardinalities are not necessarily a power of 2 (as is the case in ORB). Figure 8 shows partitioning in the case of GORB in four parts, where the consecutive partitionings are not performed orthogonally but at an angle of 80°. GORB recursively bi-

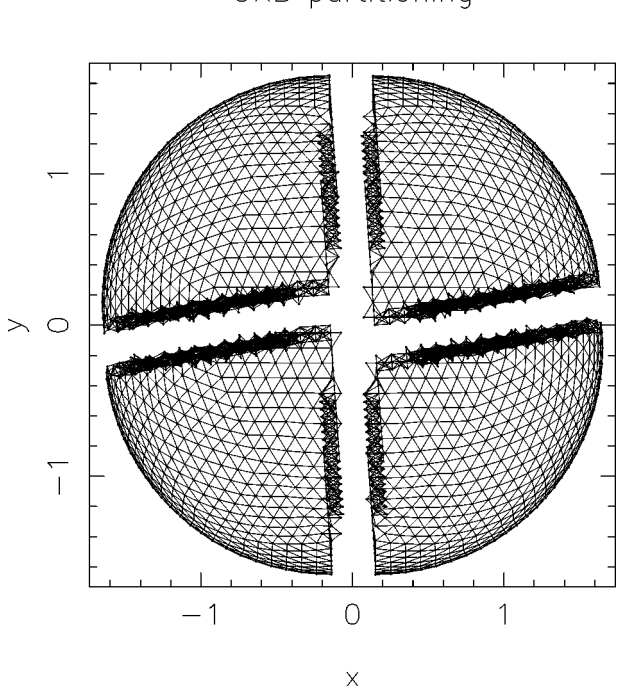

Figure 8. The hulls of the four partitions obtained for a sphere consisting of 79,556 tetrahedral elements obtained using the GORB *partitioning method. Each of the four hulls has about 3140 triangular faces. The first bisection is along the* $\hat{x}$ *direction. Next, the bisection surface is rotated 80° and the two subdomains are both bisected individually along this second direction.*

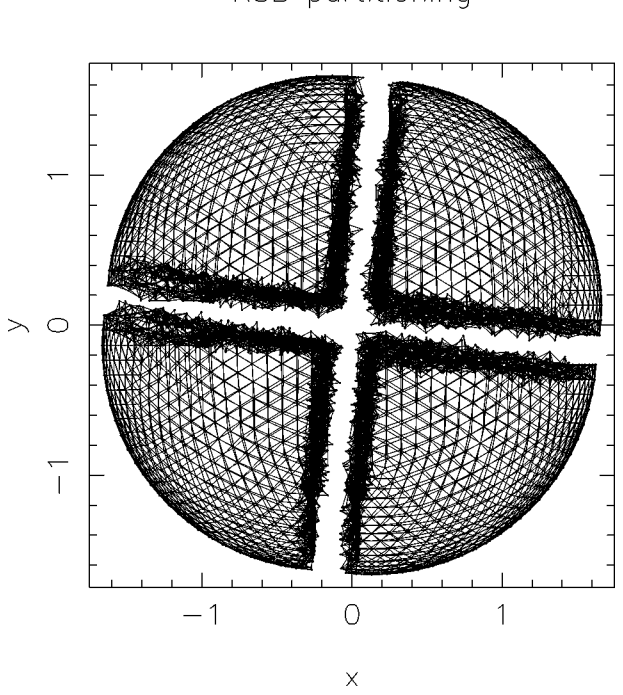

Figure 9. The hulls of the four partitions obtained for the same sphere as in Fig. 8, but now using the RSB *partitioning method. Although the edges in this partitioning appear more ragged than those obtained using* ORB, *they have only about 3010 faces.* RSB *optimizes the connectivity within partitions and minimizes the communication between them.*

sects the geometrical domain in equal partitions (work load balancing), in alternating directions, not paying any attention to the mesh connectivity (communication). RSB applies a more complex, and consequently computationally more expensive, method to partition the mesh. In contrast with (G)ORB it also takes into account the mesh connectivity. It recursively bisects a finite-element mesh into equal numbers of elements (work load balancing), while (approximately) minimizing the number of edges between the resulting subdomains (communication load balancing). Figures 8 and 9, respectively, show the partitioning in the cases of GORB and RSB into four parts, with both bisections applied to a FE sphere of 79,556 elements. The difference in partitioning quality between GORB and RSB will have to be determined by explicitly measuring the kernel execution times because it cannot be found by simple visual inspection.

The performance measurements are carried out on two target platforms both installed at the IC^{3}A in Amsterdam;[26] a Parsytec PowerXplorer [32 PowerPCs 601, with each 32 Mbytes of random access memory (RAM)] and a Parsytec CC (40 PowerPCs 604, each having 96 Mbytes of RAM). Our target material in the experiments below is the alloy CuAl (90–10) (with $\rho = 7534.0$ kg/m^3, $E = 154.0 \times 10^9$ Pa, and $\nu = 0.3265$), and only considers spheres with radii of 1.5 m. All results with respect to the physical experiments given below are independent of the number of processors used, which indicates the correctness of our parallel implementation.

A. Physical correctness

Let us consider simulations that are initiated with a pure quadrupole mode, that is, each nodal point in the system gets an initial velocity $\mathbf{v}^T = \dot{h}(x, -y, 0)$, with $\dot{h}$ the time derivative of h, a scale-free parameter denoting the deformation of space. Since the FE models are always slightly asymmetric, the fivefold degeneracy will be removed. Table II enumerates the average frequencies that are found around the analytical eigenfrequency f_0 ($f_0 = 780.25$ Hz)

Table II. The average frequency $\langle f \rangle$ and the approximated error $\sigma(f)$ in % for the quadrupole principal mode for various model resolutions.

n	$\langle f \rangle$	$\sigma(f)$ %
84	7.91e+02	8.72e−01
124	7.92e+02	1.70e+00
698	8.01e+02	4.87e−01
1086	7.97e+02	4.44e−01
2724	7.90e+02	3.23e−01
2851	7.96e+02	3.62e−01

9412	7.85e+02	3.01e−01
51501	7.82e+02	2.85e−01
79556	7.82e+02	1.56e−01

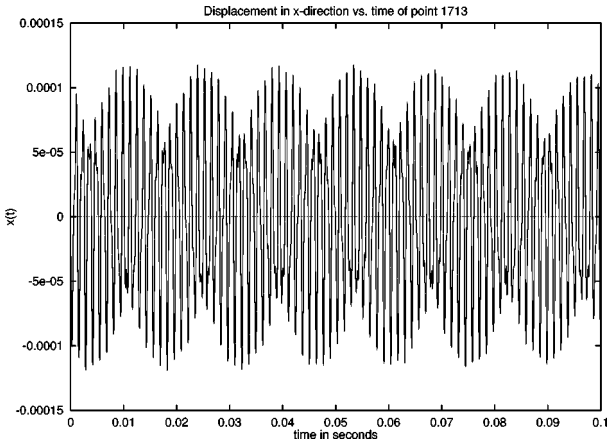

Figure 10. The time trajectory in the $\hat{x}$ direction of an arbitrary nodal point at the surface of a FE model of 79,556 elements initiated with a pure quadrupole velocity field.

and the deviation in % of the average value for 10 different FE models that consist of n tetrahedral elements. These results indicate that the dominating frequency for the FE models approaches the analytical frequency value for increasing model resolution (up to 0.16% from the analytical value for the highest resolution model).

Figure 10 shows the $\hat{x}$ displacement of an arbitrary nodal point at the sphere surface in the same simulation for the highest-resolution model. At first glance, it seems that the nodal point oscillates with a frequency of about 780 Hz, with a signal of $\approx$70 Hz superimposed. However, Fourier analysis (data not shown) has pointed out that this signal mainly results from superposition of the three oscillations that are most pronounced, that is, those oscillating at 781.8, 1493, and 1499 Hz, respectively. Possible beats that result from superposition of the principal quadrupole modes (around 780 Hz) are not visible in this picture.

We can also observe the system energy during simulation. It can be derived that the analytical energy (E_{quad}) for a sphere vibrating in a pure quadrupole mode can be expressed in terms of the radius (R) and the material density (ρ) as follows:

$$E_{\text{quad}} = \tfrac{4}{15}\,\pi\rho R^5 \dot{h}^2. \tag{17}$$

For the CuAl sphere with a radius of 1.5 m it follows that $E_{\text{quad}} = 47{,}929.2$ Nm. Within the finite-element simulations, it was found that the energy approaches this value very well for increasing model resolution (data not shown). For instance, the total energy for the highest-resolution model of 79,556 elements is approximately equal to 47,924.7, which approaches the analytical value up to 0.01%.

Within the GRAIL project, a prototype spherical antenna of the same CuAl alloy as that above, but with a radius of 0.075 m was fabricated. The following experiment was carried out. The prototype is excited by a radial impulse. Next, the time series of radial vibrations are recorded at several (arbitrarily chosen) places on the antenna surface. From these time series we have derived the power spectrum of the antenna vibrations by alternately applying a fast Fourier transform (FFT) and a nonlinear least-squares fitting procedure on the signal residue. Simultaneously, a simulation experiment was performed in which the same procedure was carried out. That is, a radial displacement is induced on an arbitrary surface point of a detailed finite-element model consisting of 191,310 tetrahedral elements. The model is realistic in the sense that it incorporates the suspension rod and the suspension hole. For several points at the model surface we record the time series, analogous to the real experiment, followed by the same procedure to produce a power spectrum. Table III lists a part of the frequency spectrum that is obtained for a radial impulse on the prototype antenna, accompanied by the frequencies found from the finite element simulation. The third column in Table III corresponds to the ratio of model frequency to experimental frequency. We can observe that the frequency spectrum found in the simulation model is quite close to experimental values. The residue of the experimental signal and the simulated signal turns out to be less than 0.1%.

Table III. Matches between frequencies computed using the explicit finite element code and experimental values for a 15 cm sphere that is excited by a purely radial excitation. In both sets of data, mode excitations may have been below the detection threshold, explaining frequencies occurring in a single set only. The analytical frequencies that are found for a pure sphere with the same material specifications are (within the same frequency range) 14830 (2,1), 15,708 (2,2), 21,243 (1,2), 22,915 (3,1), 23,407 (3,2), 30,025 (4,2) Hz, with, for instance, 14,830 (2,1) denoting a mode vibrating with 14,830 Hz, $n=2$ of toroidal type (1), and 15,708 (2,2) a mode vibrating with 15708 Hz, $n=2$ of spheroidal type (2).

B. Parallel performance

Next we consider the parallel performance of the simulation kernel. We apply GORB (partitioning cardinalities of 2, 4, 6, 8, 9, 12, 16, 18, 24, 27, and 32) and RSB (partitioning cardinalities of 4, 8, 16, and 32) to four different meshes consisting of 6114, 9412, 51,501, and 79,556 elements, respectively. Table IV displays the single-kernel execution times (one time step in the Newmark scheme) that were obtained for simulations on the PowerXplorer for a varying number of processors. Table V shows similar results obtained on the Parsytec CC. The execution times are the best case, that is, energy and external force calculations (modeling gravitational radiation sources) are left out.

In both Tables IV and V we can observe that the difference in execution speed between GORB and RSB is not significant. In fact GORB is often slightly better than RSB for partitioning cardinalities that are powers of 2. This can be ascribed to the fact that both partitioning methods create compact three-dimensional subdomains that do not contain any disconnected parts, and this leads to an average surface–volume ratio (or, equivalently, communication–calculation ratio) of these subdomains that is approximately the same.

The working memory of the CC processors is much larger than that of the PowerXplorer. Therefore on the CC all problems can be executed on a single processor, in contrast to the PowerXplorer, where single-processor performance cannot be determined for high-resolution problems. The CC communication network and CPU are significantly faster than those of the PowerXplorer, which accounts for the fact that the kernel execution time for each problem is shorter on the CC.

For the PowerXplorer the kernel execution times are not significantly decreased for more than 16 partitions, whereas in case of the CC increasing partitioning cardinality consequently leads to faster execution times, at least for high-resolution models. Since we have considered the best performance, we can expect that the absolute performance of the simulation code in a more realistic simulation (taking other phenomena into account) will be degraded compared to the best case and, consequently, result in a relatively better ''scalability'' of the code, since the amount of work per subdomain increases whereas the communication pattern and size remain unchanged.

IV. "SAMPLE" SIMULATION EXPERIMENTS

Since the main theme of this article is the concept of a complex parallel simulation program, we will not present detailed quantitative results with respect to the feasibility of

Table V. The kernel execution times in seconds on the CC for four different mesh sizes and two different decomposition methods (GORB denoted by suffix G and RSB denoted by suffix R) versus the partitioning cardinality.

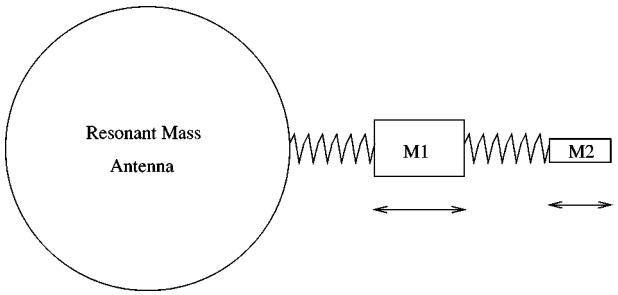

Figure 11. The spherical antenna with one transducer system mounted.

building a gravitational wave detector. Nevertheless, we will illustrate the capabilities of the FE simulation program using a few ''sample'' experiments.

All simulations are carried out with full-fledged antenna models of high resolution (approximately 130,000 elements) on the two high-performance distributed-memory platforms discussed in Sec. III B. The antenna material resembles CuAl (90–10). Six resonant mass transducers are mounted on the antenna in somewhat of an arrangement that places the transducers at the pentagons on the lower half of a truncated icosahedron; this was also done in the TIGA project.[27] Each transducer consists of two masses. The first mass of $M_1 = 100$ kg is attached to the antenna by a spring that is described by the diagonal stiffness matrix $K_1 = \mathrm{diag}(2.27\times10^9, 2.27\times10^{10}, 2.27\times10^{10})$ N/m. The second mass of $M_2 = 0.385$ kg is attached to the first mass by a spring with stiffness matrix $K_2 = \mathrm{diag}(8.70\times10^6, 8.70\times10^7, 8.70\times10^7)$ N/m.

Figure 11 schematically depicts a transducer that is attached to the antenna. The principal resonance frequency f_r of the transducer system is equal to $f_r = 780$ Hz, which coincides with the principal quadrupole frequency of the ideal detector (see Sec. III A). The two masses are chosen such that the amplitude of vibration detected at the antenna's surface will be amplified by two orders of magnitude. The addition of the multimode resonant transducers results in a significant splitting of the resonant frequencies of the system (data not shown). Although the transducer models that we have implemented are rather simplistic (point masses coupled with ideal springs), they have already given quite satisfactory results in several applications (see, for example, Sec. IV B).

A. Gravity

Earth's gravity will induce internal strain in the antenna. The sphere that is suspended is expected to deform due to this strain. We would like to quantify the amount of deformation that results due to the presence of gravity. In order to do this we perform the following simulation. At time zero we ''switch on'' gravity ($g = 9.8$ m/s^2), and let the antenna fall down. The suspension rod is fixed at the top to prevent the sphere from dramatically accelerating towards the Earth's surface. The velocities in the sphere are quenched by a small damping factor in order to get rid of the kinetic energy in the system. When the system has come to rest, we take a look at the displacement and strain distribution within the sphere. Figure 12 displays a contour

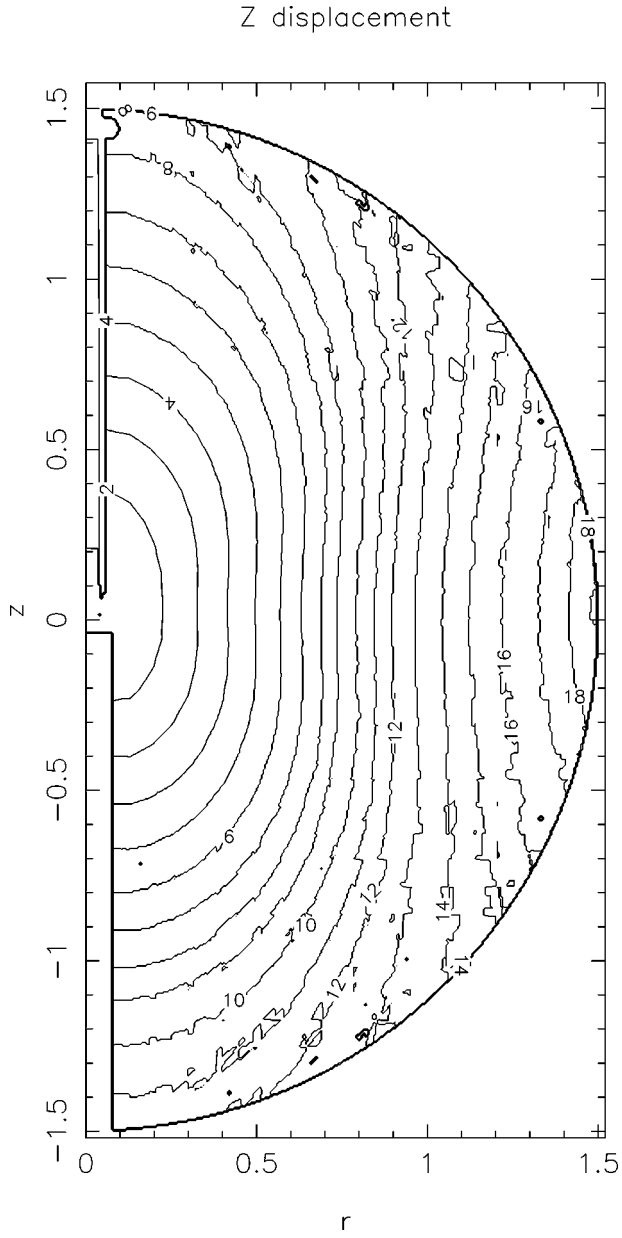

Figure 12. Contour plot of the displacement in the $\hat{z}$ direction of the suspended CuAl *sphere due to gravity ($g = 9.8$ m/s^2). The displacement values of the various contours correspond to (1) −0.35, (2) −1.96, (3) −2.18; further contours do not differ significantly from the value of contour (3); all values are in 10^{-3}* m. *The minus signs indicate displacements towards the Earth's surface.*

plot of the displacement field in the $\hat{z}$ direction within the antenna, after this deformation process. Figure 13 zooms in on the suspension region, again showing a contour plot of the displacement in the $\hat{z}$ direction. Overall, the sphere moves about 2 mm downwards, which results from the fact that the suspension rod is elongated by this amount in the $\hat{z}$ direction. The displacement values within the sphere vary from about 2×10^{-3} to 3×10^{-4} m when we traverse the sphere from the outside towards the suspension rod. Another interesting view is provided by the vertical strain

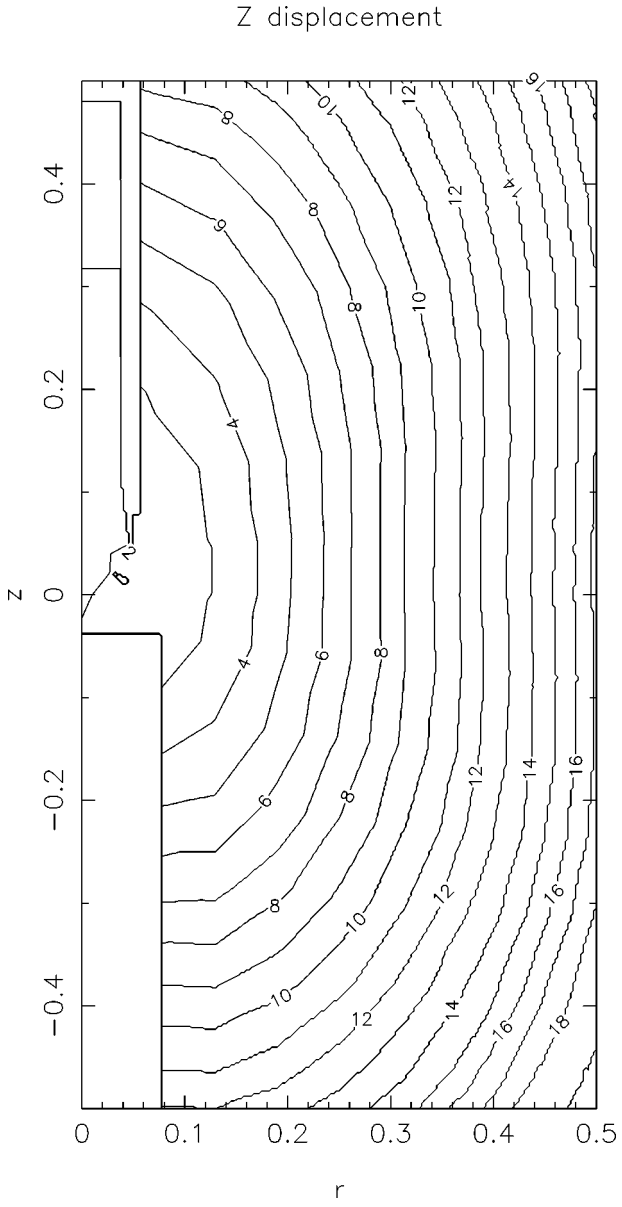

Figure 13. The same contour plot as that displayed in Fig. 12, but zoomed in on the suspension region. The displacement values of the various contours correspond to (1) −1.60, (2) −1.82, (3) −2.16, (4) −2.18; further contours do not differ significantly from the value of contour (4); all values are in 10^{-3} m. The minus signs indicate displacements towards the Earth's surface.

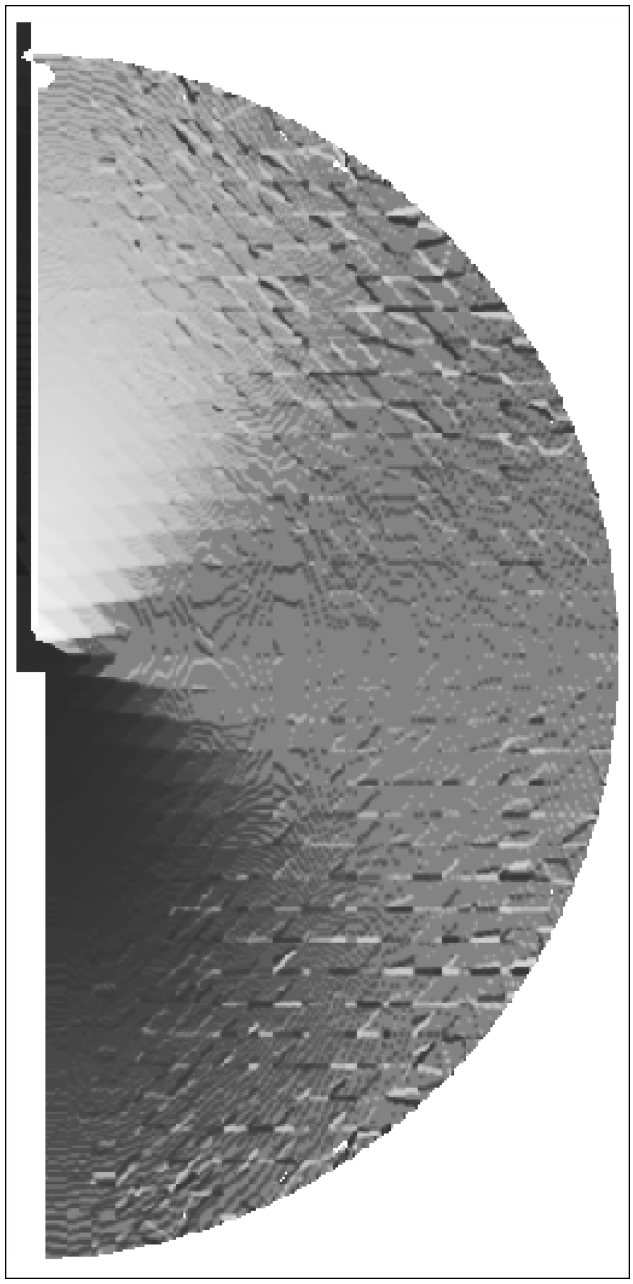

Figure 14. The vertical strain $(\partial u_z/\partial z)$ within the antenna. High strain values (dark areas) are found in the suspension rod, that is carrying the entire sphere, and near the contact region of the sphere and the rod. The strain in the sphere itself is much lower (light colored areas).

$(\partial u_z/\partial z)$ within the antenna, which is shown in Fig. 14. As expected, the suspension rod is subjected to the highest strain, as is the region where the sphere and rod make contact.

A shortcoming of our simulation program is that it relies on a linear finite element solver. As a consequence, we are not able to model nonlinear effects, such as so called *violin modes* in the suspension rod, or show how the internal strain of the sphere affects the eigenmodes. Incorporating these into our simulation program is a future challenge.

B. Seismic noise

The suspension system of the antenna must attenuate vibrations at the principal resonance frequency to a factor of 320 dB.[28] If we let seismic noise enter the system via the suspension, how does it appear at the transducer readout? The following experiment is carried out. The suspension points (connections to the outside world) of the suspension rod are driven by forced oscillation in the $\hat{z}$ direction. That is, the z coordinate of the displacement field $u_z(t)$ of each suspension point oscillates as follows:

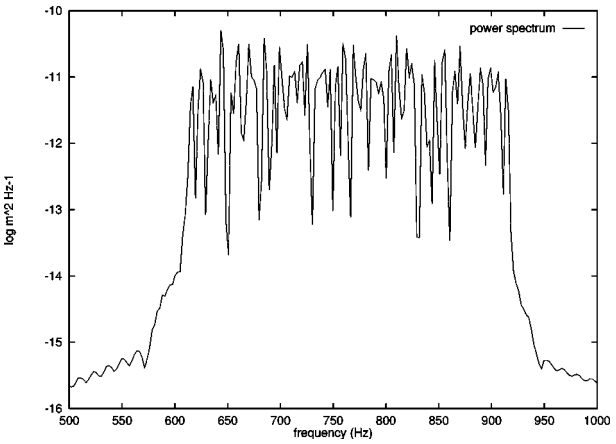

Figure 15. Narrow-banded seismic noise around the principal quadrupole frequency.

$$u_z(t)=\sum_{n=1}^{N}\left[A_n\cos(2\pi f_n t)+B_n\sin(2\pi f_n t)\right]. \quad (18)$$

The amplitudes A_n and B_n and the frequency spectrum f_n model the seismic noise. In the following experiment the narrow-banded noise spectrum depicted in Fig. 15 was used. The $\hat{z}$ displacement versus time, which is driving the suspension points according to this spectrum, is displayed in Fig. 16.

Figures 17 (inner mass) and 18 (outer mass) show the radial displacement of the two transducer masses starting at $t=0$ in one of the six transducers. The maximum amplitude in the noise spectrum (Fig. 15) has the same order of magnitude as the maximum amplitude of the outer mass. Consequently, it is of paramount importance that all seismic vibrations in the target frequency range are attenuated below the expected amplitude of vibrations that are induced by gravitational radiation in order to assure that we have a decent signal-to-noise ratio.

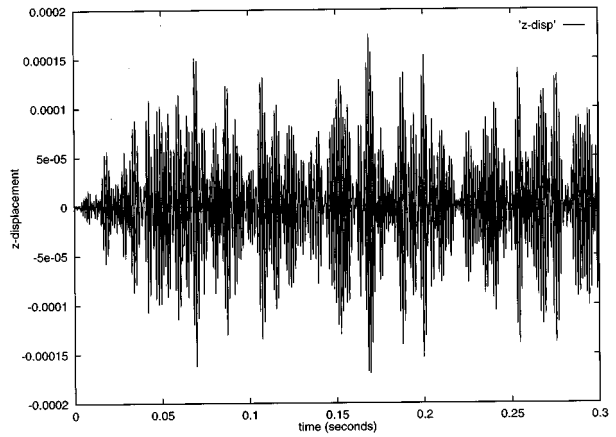

Figure 16. The $\hat{z}$ displacement for the suspension point driven by the noise spectrum of Fig. 15.

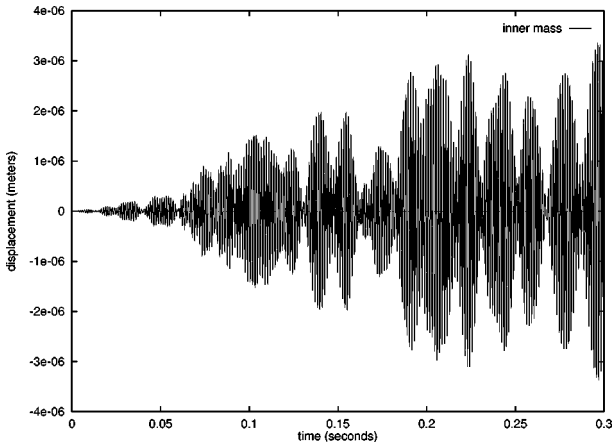

Figure 17. Time trajectory of the inner transducer mass on one transducer. The system is forced into oscillation by the seismic noise spectrum of Fig. 15.

C. Chirps

A so-called gravitational radiation ''chirp'' will be emitted (expected theoretically) just before coalescence of a binary neutron-star system.[29] The effects of this phenomenon on the detector can be modeled by applying a time-varying ''chirp force'' $\mathbf{f}(t)$ on the antenna, which acts along a pure quadrupole field, according to

$$\mathbf{f}^T(t)\propto\ddot{h}(x,-y,0), \quad (19)$$

with $\ddot{h}$ the second-order time derivative of the deformation of space, derived in a Newtonian approximation.

Let us consider a chirp that enters the antenna at time $t=-0.04$ s. Figure 19 models its time varying amplitude $\ddot{h}$. The normalization of the chirp signal has an order of magnitude that is representative for an event in the Virgo cluster. Since the antenna responds purely linearly, the shape of the response signal resulting from interaction with any other identically shaped incoming signal will be exactly the same.

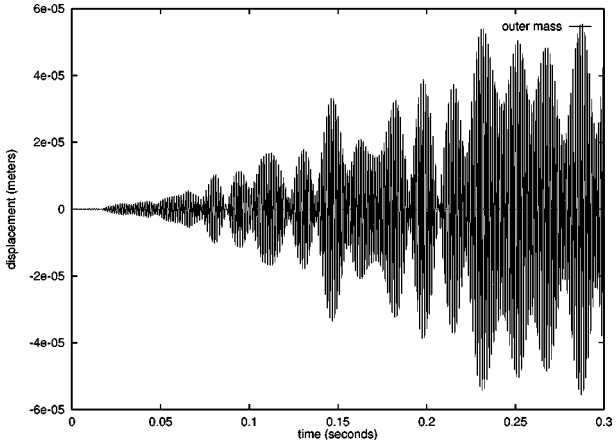

Figure 18. Time trajectory of the outer transducer mass on one transducer. The system is forced into oscillation by the seismic noise spectrum of Fig. 15.

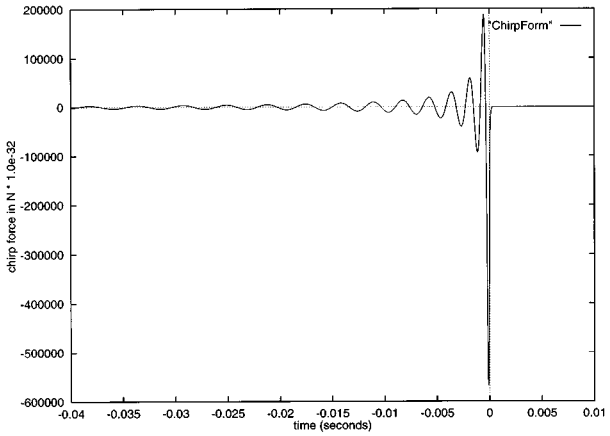

Figure 19. The time dependent amplitude $\ddot{h}$ of a chirp initiating at time $t=-0.04$ s. The chirp ends at $t=0$.

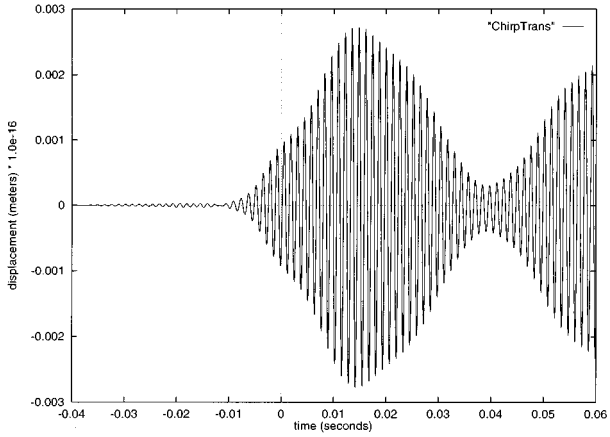

Figure 21. The $\hat{x}$ displacement of one of the outer transducer masses. The transducer already ''notices'' the chirp's presence before $t=0$.

Figure 20 shows the evolution of the energy in the antenna from the moment that the chirp enters until it has passed. The energy of the chirp gets deposited in the antenna. After the chirp has passed, the energy stabilizes (at $t=0$ s).

The response to this chirp can again be measured. Figure 21 shows the time trajectory in the $\ddot{x}$ direction of one of the outer transducer masses. We observe the tiny ($\approx 10^{-19}$ m) displacements of the transducer masses.

V. CONCLUSIONS

In this article we have sketched the complete path along which a complex high-performance simulation was developed. We were able to identify the problem definition, modeling choices, the code design for parallel systems, validation, and experimentation. In order to realize such a system, it is mandatory that we have knowledge of a variety of disciplines, like computer science, numerical mathematics, and (computational) physics. It is our feeling that the whole process that is described above is typical for the development of new simulation systems that utilize high-performance methodology and therefore can serve as an example of *computational science*, which inherently is an interdisciplinary research field. Mixing the best of several worlds allowed us to realize a full-fledged simulation system that meets our purposes.

In the future we will focus on embedding the simulation program within the experimentation cycle of GRAIL, referred to as ''simulation in the loop'' in the Introduction.

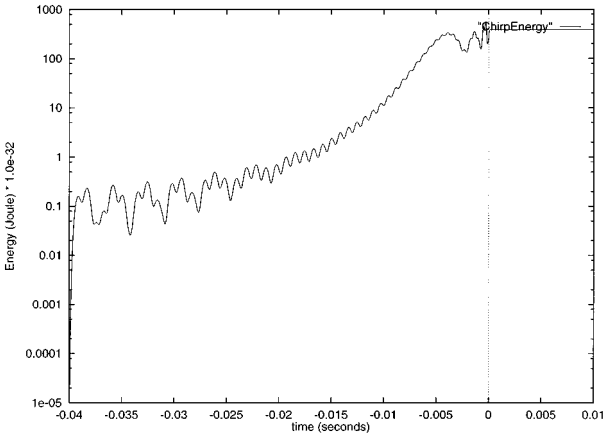

Figure 20. The time evolution of the total energy deposited by the chirp of Fig. 19. After $t=0$ the energy stabilizes. Note that we have used a log scale on the energy axis.

Detection of Gravitational Waves with High Frequency Square Waves from Crystal Oscillator

Dhananjay P. Mehendale
Sir Parashurambhau College, Tilak Road, Pune 411030, India

Abstract

We propose novel technique for detecting gravitational waves using setup like LIGO and a robust square wave generator as source of waves generating stable square waves with high frequency using an appropriate crystal oscillator. This change in source will prove very effective for the process of detecting gravitational waves because even if with extremely small change in phase of two interfering waves reaching the beam splitter there will be detectable change in the amplitude due to the suddenly rising sharp edge of these almost but not exactly destructively interfering waves upon the passing of gravitational waves. This idea of achieving detectable amplitude of a portion of signal reaching the detector will make it possible to record extremely small phase difference generated due to passing of some gravitational waves through apparatus in the two interfering square wave beams. The change suggested in the gravitational wave detection experiment using high frequency well regulated square wave source will produce the following effects. When no gravitational waves will reach the apparatus the square waves from crystal oscillator will move towards beam splitter and will split into two square waves heading towards reflectors kept orthogonally to each other at equal distance from beam splitter at the ends of two interferometer arms and these waves will reflect back to interfere destructively so that no signal will reach the detector. But when some gravitational waves will be reaching the apparatus and further suppose there is squeezing along arm A and stretching along arm B of the interferometer as an effect these gravitational waves will be producing the (very small) phase difference in the interfering square waves reaching back to beam splitter. Now, however small may be this phase difference its undetectably small amount still will remain detectable because of sharp rise and fall of amplitude at edges of square wave because of its typical shape and so some detectable part of these interfering waves will pass towards detector to offer a conclusive proof for the existence of gravitational waves!

1. **Introduction:** Experimental detection of gravitational waves is a big challenge of this time and enormous efforts are on world over by people working in highly sophisticated gravitational wave detection laboratories. Gravitational wave laboratories will be leading laboratories in the coming future to offer new important insights in our study of large scale phenomena. Detection and study of gravitational waves of different types and of different intensity and frequency will make revolutionary contributions to our knowledge about galactic dynamics. It will add greatly to our knowledge about astrophysical sources and about processes driven by strong gravitational fields. Objects of fundamental importance, such as astrophysical black holes, merge and radiate with luminosity larger than the entire electromagnetic universe, and these events will become clearly detectable only through a tool for detection of gravitational waves that are mainly associated with detectable amplitude with such unimaginably huge events [1]. When observed with gravitational waves these intrinsically interesting astronomical sources such as massive black holes and their merger, extremely compact stellar binaries and their collisions, supernovae events etc will surely yield many new surprises. Thus, the discovery potential associated with detection of gravitational waves is immense.

   Gravitational radiation was detected indirectly in 1974 by J. Taylor and R. Hulse, who observed its effects on the orbital period of a binary system containing two neutron stars, one of them a pulsar (PSR 1913 + 16). Efforts to detect gravitational waves directly have been severely challenged by the extreme weakness of the waves impinging on the Earth. However, as the 21st century begins, observations of the gravitational waves from astrophysical sources such as black holes, neutron stars, and stellar collapse are expected to open a new window on the universe [2].

   There are two major gravitational wave detection concepts: acoustic and interferometric detection [3]. The acoustic method deals with a resonance response of massive elastic bodies on gravitational wave excitations. Historically the acoustic method was proposed first by J. Weber [4] where he suggested to use long and narrow elastic cylinders as Gravitational Wave Antennas. Although a significant progress has been achieved in fabrication and increasing sensitivity of such type of detectors [4, 5, 6] the interpretation of obtained data is still far to claim undoubtedly the detection of gravitational waves. On the other hand a considerable attention has been shifted recently to more promising interferometric detection methods. The interferometric gravitational wave detector like Laser Interferometer Gravitational Wave Observatory (LIGO) and VIRGO [7, 8] represents a Michelson interferometer with a laser beam split between two perpendicular arms of interferometer. The principles of operation of such type of detectors are reviewed in Refs [9, 10, 11, 12, 13]. The action of gravitational waves on an interferometer can be presented as relative deformation of both interferometer arms. A gravitational wave with dimensionless amplitude h induces the opposite length changes $\frac{\delta l}{l} = \frac{1}{2} h \cos(\Omega t)$ in each arm of the Michelson interferometer, where l stands for the length of each of the arm, Ω for the gravitational wave frequency. These

length changes produce opposite phase shifts between two light beams in interferometer arms, when interference occurs at the beam splitter of Michelson interferometer. The resulting phase shift of a single beam of light spending time τ in the interferometer can be written as [13]

$$\delta\phi = h\frac{\omega}{\Omega}\sin\left(\frac{\Omega\tau}{2}\right), \qquad (1)$$

where, ω is the light frequency. This phase shift results an intensity signal change of the light from interferometer beam splitter hitting the photo detector.

The main problem of the acoustic and interferometric methods that they both deal with gravitational waves with extremely small amplitudes of the order $h \sim 10^{-21}$ [14] reached the Earth from deep space. One can see from equation (1) that for gravitational wave frequencies in the 1 kHz range, $\Omega \sim 10^3$ Hz, and for the light in visual frequency range, $\omega \sim 10^{14}$ Hz, one has the maximum phase shift of the order $\delta\phi \sim 10^{-10}$ for interferometer arms length of the order 150 kilometers. Such extraordinarily weak effect requires exceedingly high detector sensitivity for both acoustic as well as interferometric detectors.

2. **The Novel Technique:** As seen above one requires extraordinarily high sensitivity of detectors to conclusively capture signal called gravitational wave and this may be one of the important reasons that we have not yet succeeded in this task even though many gravitational waves would have passed through our apparatus installed at different locations.

In this paper we suggest a new idea of using as source a square wave generator generating stable high frequency square waves from a crystal oscillator. This change in the source will cause passing of detectable value of the part of interfering square waves due to the typical steep rise and fall in the amplitude of waves at the locations of completion of distance equal to wavelength. Due to this typical shape of waves the undetectably small phase difference created in the interfering waves reaching the beam splitter due to passing of gravitational waves in the beams reflected back from two perfect reflectors, fixed at ends of two orthogonal interferometer arms, due to which these beams come back to interfere almost destructively at beam splitter will produce detectable portion of amplitude reaching the detector. We take high energy well regulated square wave generator as new source and perform usual experiment. Now, suppose when the beams of square waves were running through two mutually orthogonal arms and were coming back to beam splitter there was squeezing in the arm, A say, of the interferometer and reciprocally suppose there was stretching in the interferometer arm, B say, of the interferometer. As an effect of this specially chosen source generating square waves the phase difference, however small it may be, will produce detectable overlap in the interfering square waves because of their typical shape having a sharp rise, equal to full amplitude of the waves. It will cause reaching of sufficient amplitude towards detector which essentially will lead to reaching of detectable amplitude at the detector. This will give us a confirmation that though the phase difference is

extremely small still our new choice of the shape of the waves makes it detectable to our instrument and thus will give a confirmation that beams are in fact not interfering destructively as they are sending in effect sizable amplitude towards detector.

The main idea in brief behind the suggestion in this paper is to capture the undetectably small phase difference that should result due to passing of gravitational waves by making it sizable by choosing the square shape for the waves from the source. Thus, we are suggesting a way out to achieve sizable value of the amplitude of waves reaching the detector by choosing typical square shape for the signal from the source to make the undetectably small phase difference detectable.

Generation and Detection of Low-Frequency Squeezing for Gravitational-Wave Detection

Michael Steve Stefszky

A thesis submitted for the degree of
doctor of philosophy of
The Australian National University

April 2012

Declaration

This thesis is an account of research undertaken between March 2008 and April 2012 at The Department of Physics, Faculty of Science, The Australian National University, Canberra, Australia.

Except where acknowledged in the customary manner, the material presented in this thesis is, to the best of my knowledge, original and has not been submitted in whole or part for a degree in any university.

Michael S. Stefszky
April, 2012

Acknowledgements

The last four years of my life have been amazing and I would like to thank (hopefully) everyone who has contributed and supported me over this time.

These years have been made fruitful and enjoyable by the support of an outstanding supervisory panel. For this, I would like to first give my sincerest thanks to Professor Ping Koy Lam, Doctor Ben Buchler and Doctor Thomas Symul from the Quantum Optics Group (now CQC2T), and Professor David McClelland and Doctor Daniel Shaddock from the Centre for Gravitational Physics.

The foremost thanks has to go to Ping Koy Lam, whom I have studied with for many years now. Much appreciation is given for my acceptance into the quantum optics group many years ago, first for my honours year and then for my PhD. The foresight and sense of direction that Ping Koy has showed over the years, both in individual experiments and for the entire group, has been, and continues to be, invaluable. I am very grateful for the opportunities I have had to travel both locally and overseas for conferences and collaborations. Ping Koy's outstanding abilities as a group leader have been made apparent to me many times and his enthusiasm for his work is very addictive.

My decision to work on the H1 LIGO squeezer project later into my PhD I can now look back and say was most certainly the correct one. For this opportunity I have firstly to thank David. Working on this project meant many things. It meant the support of a second research group, the Centre for Gravitational Physics, the opportunity to collaborate with many institutions and people on a truly international project, and the learning advantages from working in a new group with its own areas of expertise. Working on this project allowed me to work at MIT for nearly 6 months and at LIGO for nearly 3. The experience gained from these travels makes up a large portion of what I consider to be the most valuable training from my studies and for this opportunity I need to thank David. Additionally, David always found time in a busy schedule to help with experimental problems and provide direction when needed.

Sincerest thanks then goes to Ben and Daniel. Together with Ping Koy and David, I cannot imagine a better group of people to have available when a problem arose. Although by no means the limit of their knowledge, Daniel's expertise in electronics and locking loops, combined with Ben's expertise in just about anything related to optics, particularly non-linear optics, meant that solutions to any problem were quickly found. The willingness to help combined with the knowledge and good humour of both Daniel and Ben was both invaluable and greatly appreciated.

Onto my two lab mates, Sheon Chua and Conor Mow-Lowry. If it were not so much fun to work in the lab as it was, then I am sure things would not have progressed as far as they did. The environment in the lab was a relaxed one, where input from each person was valued, and I really appreciate the synergy we had going. Conor's knowledge ensured that progress was smooth and constantly provided alternative solutions to problems that arose. Sheon's problem solving techniques were different to mine and so together we attacked problems from many different angles.

From the ANU still, I need to thank the electronics and mechanical workshops, Shane

Grieves, Neil Hinchey, James Dickson, Paul McNamara, Paul Tant and Neil Devlin. The work these people do is of the highest quality and without their help, I might still be milling steel and soldering circuits. Also to everyone from both the quantum optics group and all of the graviteers, as well as everyone else from the physics department. How enjoyable a particular job is depends on both the work one is doing and the people involved. The people in the physics department have have certainly made the last few years enjoyable. A quick mention to Nicolai Grosse for his aid, wisdom and friendship during my honours year. A big thanks also goes out to Phil Threlfall, Richard Barry, and especially Conor Mow-Lowry and Timothy Lam, who along with Ping Koy, David, Daniel and Ben, drafted various sections of this thesis.

To all the people in the United States, thank you. To Nergis Mavalvala, Daniel Sigg, Lisa Barsotti, Sheila Dwyer and the rest of the LIGO team, thank you very much for the opportunity to visit a new country and work in new places on exciting experiments. Thank you to Nergis and Daniel for allowing me to work at MIT and at LIGO, and thank you to Lisa for her excellent organisational skills in organising both human resources and experiments. Thanks to Sheila for making my stay in Boston as enjoyable as possible and to Dick Gustafson for introducing me to Cognac and ice-cream in Hanford.

Onto the friends and help that I have received from people at the Max Planck Institute for Gravitational Physics. Firstly, thank you to Roman Schnabel, Henning Vahlbruch and Alexander Khalaidovski and Moritz Mehmet. Thank you for the many discussions that were had on detector design, balanced homodyne detection and squeezed light production. Your willingness to share information and aid us in our experiment was invaluable. Thank you to all the people at Hannover who made my short stay there incredibly fun. So much fun that I hope to return to Hannover some time in the near future. Thank you to Moritz for showing me around your home country and institute. I hope I can return the favour soon.

Then there are my friends outside of work. My housemates and friends for many years, Neil, Mitch, Sam, and Jason as well as my friends whom I see the most often; Conor, Andrew, Kieran, Neil and Phil to name but a few. Thank you for providing distractions when I needed it, and sometimes when I did not, and for making my home environment a fun place to be. Thank you for trying to keep me fit with the many mountain bike rides we went on. The ability to unwind and relax after writing for hours on end is not an easy task sometimes but you guys made it easier.

Onto my family. Thank you to Mum, Dad, Michael and Angelina for your never ending support. Thank you to Warren, Tanya, Michael, and Anthony for keeping things real. Finally, the most heartfelt thank you to Jenessa, whose understanding and support has been nothing short of amazing.

Abstract

Gravitational-wave astronomy promises a radically new method of investigating the universe, one that does not detect elementary particles, but rather ripples in space-time itself. One might expect that with this radically new method, our understanding of the universe will make an equally giant leap. One of the most promising methods for the eventual detection of gravitational-waves is that of interferometric gravitational-wave detection.

The sensitivity of these devices is nothing short of amazing, and their sensitivity continues to improve. The next generation of detectors are expected reach a point where increasing the laser power, previously used to increase the sensitivity, is no longer expected to provide any benefit. One of the most promising options for further increasing the sensitivity, through reduction of the quantum noise, is via the application of "squeezed states of light". Squeezed states of light are light fields for which the noise of some observable has been reduced below the quantum noise limit. These states have been shown for many years to offer increased sensitivity in interferometers and recently in interferometric gravitational-wave detectors. One of the most challenging tasks to make suitable squeezed light sources for these detectors is to produce low-frequency squeezing, corresponding to the detection band of these interferometers.

This thesis details the doubly resonant travelling wave bow-tie squeezer as a source of squeezing for interferometric gravitational-wave detection. This squeezer achieves record results of squeezing in the gravitational-wave detection band. For the first time, 10 dB of shot noise suppression at 10 Hz is directly observed and above 200 Hz, 11.6 dB is observed. The work presented in this thesis provides evidence that further substantiates previous progress indicating that squeezed states of light are now ready for full-time integration into interferometric gravitational-wave detectors. The new cavity design, described in detail throughout this thesis, is shown to outperform previous designs and provide benefits when integrating squeezing into these detectors, in particular, isolation to backscattered light from the interferometer.

The noise sources that typically lead to degradation in squeezing measurements are investigated and discussed. Additionally, a modification to the standard locking technique used to control these vacuum squeezed states, *coherent locking*, is presented and discussed. The modified technique reduces the required number of locking loops and provides a larger beat note from which to derive an error signal for one of the remaining loops.

A squeezer using these design philosophies is then constructed and used to inject squeezing into the LIGO gravitational-wave detector. Injection of the squeezed state provides enhancement of the sensitivity of the detector at frequencies around 200 Hz and above. The sensitivity seen was equivalent to approximately 2 dB of shot noise reduction. The enhancement is limited by the loss within the interferometer. Injection of the squeezed state did not show any degradation in the sensitivity of the device below 200 Hz, indicating for the first time that noise couplings between the interferometer and the squeezer could be sufficiently suppressed at these frequencies even for the most sensitive detectors.

Summary of symbols and acronyms

Symbol	Definition
h_s	Interferometer strain
l	Interferometer arm length
$(\Delta Z)_{rp}$	Interferometer error due to radiation pressure
$(\Delta Z)_{pc}$	Interferometer error due to photon counting or shot noise
S_{Th}	Root power spectral density due to thermal fluctuations on the test mass
M	Mass of interferometer test mass
I	Laser field intensity
i	Photocurrent
k	Optical mode
E	Energy
ω	Optical angular frequency or angular detection frequency
$h\,(\hbar)$	Planck's constant & (reduced Planck's constant)
c	Speed of light in vacuum
b	Bounce number
τ_s	Storage time
τ_m	Measurement time
P	Optical power
$\vec{k}$	Wavevector
Δk	Wavevector mismatch
L_C	Coherence Length
$w(z)$	Beam radius at position z
$w(0)$	Beam waist
z_R	Rayleigh Range
q	Complex beam parameter
M	ABCD Matrix
d	Physical distance
d_{eff}	Crystal Non-linear susceptibility strength
$\hat{n}$	Photon number operator
ϕ	State phase angle
$\hat{D}(\alpha)$	Displacement operator
$\hat{S}(\rho)$	Squeezing operator
r	Squeezing parameter
MM	Mode matching
η_{vis}	Efficiency of spatial overlap from visibility measure

Symbol	Definition
$\hat{a}, (\hat{a}^\dagger)$	Annihilation & (creation) operators of intra-cavity mode
$\hat{A}, (\hat{A}^\dagger)$	Annihilation & (creation) operators of travelling wave
$\check{A}$	Frequency domain annihilation operator of travelling wave
$a_3^{crit}, (A_3^{crit})$	Intra-cavity & (external) field threshold amplitude
P_3^{crit}	External field threshold power
$\delta\hat{a}, (\delta\hat{a})$	First order fluctuating term of annihilation & (creation) operators
$\hat{X}^+, (\hat{X}^-)$	Amplitude & (phase) quadrature operators
$\delta\hat{X}^+, (\delta\hat{X}^-)$	First order fluctuation term of amplitude & (phase) quadrature operators
$\hat{X}^\theta$	General quadrature operator
$\Delta\hat{G}$	Standard deviation of observable $\hat{G}$
$V(\hat{G}) \equiv \Delta^2(\hat{G})$	Variance of the observable $\hat{G}$
α	Classical coherent amplitude
η	Beamsplitter power transmissivity or propagation efficiency
η_{esc}	Escape Efficiency
τ	Cavity round-trip time
δ	Frequency offset
L	Cavity optical path length
κ	Cavity decay rate
$R, (T)$	Power Reflectivity & (Transmittance)
Δ	Cavity detuning
g	Intra-cavity non-linear coupling strength
G	Combined non-linear coupling strength and intra-cavity pump amplitude
λ	Optical field wavelength
n	Refractive index
$\mathcal{V}$	Visibility
$\chi^{(2)}$	Second order non-linear susceptibility
$\mathcal{F}$	Finesse
Δ_ν	Cavity linewidth
$1, 2, 3$	Defines parameters for signal, idler and pump fields, respectively

Acronym	Definition
aLIGO	advanced LIGO
ANU	The Australian National University
AR	Anti-Reflection
AURIGA	Ultracryogenic Antenna for Astronomical Gravitational Investigation
CLL	Coherent Locking Loop
CMRR	Common-Mode Rejection Ratio
CSF	Coherent Sideband Field
DOPA	Degenerate Optical Parametric Amplifier
EOM	Electro-Optic Modulator
EPR	Einstein-Podolsky-Rosen
ETX500	Epitaxx 500 photodiode
FFT	Fast Fourier Transform
FSR	Free Spectral Range
FWHM	Full-Width-at-Half-Maximum
GEO600	British-German Cooperation for Gravity Wave Experiment
GRIIRA	Green Induced Infra-Red Absorption
GSF	Generated Sideband Field
GW	Gravitational-Wave
GWINC	Gravitational-Wave Interferometer Noise Calculator
H1	4km arm length interferometer at enhanced LIGO Hanford site
H2	2km arm length interferometer at enhanced LIGO Hanford site
HD	Homodyne
HR	High Reflectivity
KAGRA	Kamioka Gravitational Wave Detector
KNB	Potassium Niobate
KTP	Potassium Titanyl Phosphate
LIGO	Laser Interferometer Gravitational-wave Observatory
LN	Lithium Niobate
LSC	LIGO Scientific Collaboration
MC	Modecleaner Cavity
MgO:LN	Magnesium Oxide doped Lithium Niobate
MIT	Massachusettes Institute of Technology
MZ	Mach-Zender
NDOPA	Non-Degenerate Parametric Amplifier
Nd:YAG	Neodymium doped Yttrium Aluminium Garnet
NGO	New Gravitational-wave Observatory
OPA	Degenerate Optical Parametric Amplifier
OPO	Optical Parametric Oscillator
PDH	Pound-Drever-Hall Locking Technique
PPKTP	Periodically Poled Potassium Titanyl Phosphate
PZT	Lead Zirconate-Titanate piezo/electric ceramic
RBW	Resolution BandWidth
RMS	Root Mean Square
RoC	Radius of Curvature
RP	Radiation Pressure
SHG	Second Harmonic Generation
SN	Shot Noise
TEM	Transverse Electro-Magnetic
VIRGO	Italian-French Laser Interferometer Collaboration

Chapter 1

Introduction

Our understanding of the universe around us, from subatomic particles to the vast cosmos, shapes the way we live our lives. As precision measurements improve and we unravel more about how the world works, we are constantly transforming society in ways that are nearly impossible to predict. A perfect example is that of light amplification by stimulated emission of radiation, or the laser [1]. In a mere fifty years, the laser has become a building block of modern society. From entertainment, to beauty treatments, to surgery and probing of the fundamental laws of our universe, the usefulness of lasers has shaped the way our modern world works [2]. Our understanding of things on the opposite side of the size-scale have arguably had just as large an impact. Many years ago, astronomy led to the realisation that the earth is indeed round and not the centre of the universe, contrary to prior beliefs. This type of knowledge impacts significantly on theological ideas and in turn, on society itself.

Arguably, the advent of the telescope was the catalyst for the evolution of astronomy as a modern science. Early in the 17^{th} century, Galileo was the first to utilise their potential in observing details of the surface of the moon and the motions of the planets and the stars. Whilst telescopes evolved, becoming larger and providing more precise images, all early telescopes were restricted by the same fundamental limitation. Detections were made with the user's eye, and thus the information gathered was limited to the visible spectrum of light. Visible light, however, is a very small portion of the electromagnetic spectrum. Astronomy progressed, and the advantages obtained by widening the detection band were revealed. In the 1800's infra-red radiation was discovered by Herschel and was later used to study properties of the moon [3]. The detection band has continued to increase over time, such that we now routinely observe many orders of wavelengths of electromagnetic radiation, from gamma rays to radio waves [4, 5]. However, these forms of astronomy are all founded upon a common principle, the detection of electromagnetic waves. As such they all share similar advantages, and of course, similar disadvantages. Their detection can be hampered by various complications; they are prone to absorption, and follow the local space-time trajectory. One example of particular importance is that this means that direct detections of black holes cannot be made using electromagnetic observations. For many of the most violent, massive and arguably interesting phenomenon, another measurement method is required to complement the often limited information that electromagnetic waves can provide.

This is the role that gravitational-wave detection is hoped to fulfil in the near future. This thesis presents work that aims to improve the sensitivity of current interferometric gravitational-wave detectors via the integration of squeezed optical states. With the enhanced sensitivity that squeezed states are to offer, along with other improvements to current detector designs, we are nearing the era of gravitational-wave astronomy.

1.1 Thesis Structure

The thesis is structured as follows;

- Chapter 2 - Background

  The exciting realm of ground based gravitational-wave astronomy is introduced. Noise sources in current and next generation detectors are detailed and in particular the role of quantum noise sources is highlighted. Methods for reducing quantum noise are discussed and optical squeezing is introduced as an exciting new method of reducing the quantum noise in future detector designs.

- Chapter 3 - Quantum States of Light

  The mathematical description of the states of light used in this work is presented in this chapter. The ball-on-stick representation and the sideband representation for visualising the states of light are detailed. Using these representations, the properties of squeezed states, vacuum states, and coherent states are all introduced.

- Chapter 4 - Generation of Squeezed States

  In this chapter the generation of squeezed states is introduced. The various methods available are first discussed before detailing the production of squeezing from the second order non-linearity. Second harmonic generation, non-degenerate optical parametric amplification and optical parametric oscillation are introduced as modes of operation for the second order non-linearity.

- Chapter 5 - Optical Cavities

  The properties of optical cavities are introduced in this chapter. The cavity equations of motion are first introduced and then used to derive the classical and quantum response of an empty cavity. The finesse, free spectral range, linewidth and circulating power are defined. The cavity equations of motion are then investigated for an optical cavity containing a non-linear medium. From this work, the escape efficiency, non-linear gain, and expected squeezing from such a cavity are investigated.

- Chapter 6 - The Doubly Resonant Bow-Tie Optical Parametric Oscillator

  The methods and philosophies for designing a travelling wave cavity cavity are detailed in this chapter. The available non-linear mediums, techniques for overcoming intra-cavity dispersion and the choices involved when deciding all remaining parameters are discussed. The effect that variation of the cavity parameters has is illustrated.

- Chapter 7 - The ANU Squeezer

  The details of the ANU squeezer are given in this chapter. All of the chosen cavity parameters are stated before the methods for accurately measuring threshold and intra-cavity loss are introduced. A layout of the optical and electronic components is given. The coherent locking scheme used to control the angle of the squeezed state is investigated and a modified coherent locking scheme is introduced as a means for simplifying and improving the original scheme. This work was jointly undertaken with Sheon Chua and Conor Mow-Lowry at the ANU under the supervision of David McClelland, Ping Koy Lam, Ben Buchler and Daniel Shaddock, with much appreciated input from Kirk McKenzie and which utilised a cavity design originally devised

by Nicolai Grosse. Improvements to the squeezer were also made by Sheila Dwyer, who was involved for a number of months on the project. The later measurements of the squeezing produced by this squeezer were taken using a homodyne detector supplied by Roman Schnabel and Henning Vahlbruch.

- Chapter 8 - Detection of Squeezed States

  This chapter details an investigation into understanding the low-frequency performance of the homodyne detector setup used to measure the squeezed states. Many noise sources are investigated and methods for detecting and overcoming these noise sources are presented. The homodyne detector supplied by Roman Schnabel and Henning Vahlbruch plays a large role in this work. A short history of the squeezing produced by the ANU squeezer illustrates the various improvements made in order to improve the squeezing over a timespan of nearly 3 years. The work on detecting low-frequency noise sources as presented in this chapter was primarily undertaken with Conor Mow-Lowry, with some input from Sheon Chua, and the modified coherent locking scheme was devised by Conor-Mow Lowry and Kirk McKenzie. The modified coherent locking scheme was implemented by Sheon Chua.

- Chapter 9 - The LIGO Injection

  In this chapter the details of the LIGO squeezed light source are introduced. The cavity properties, including threshold and intra-cavity loss are given. The squeezing produced by the LIGO cavity is presented and the results are discussed. The integration of the squeezer into LIGO is briefly discussed but greater detail pertaining to the integration of the squeezer will be presented in the PhD theses of Sheon Chua and Sheila Dwyer as well as future papers. The squeezer was constructed and tested by myself, Sheon Chua, Conor Mow-Lowry, Alexander Khalaidovski and Sheila Dwyer at MIT. The LIGO squeezed light injection project was a large collaborative project, with too many people involved to mention them all, but particular mention is made to Nergis Mavalvala, Daniel Sigg, Keita Kawabe, Sheila Dwyer and Lisa Barsotti, who I worked most closely with during my time on this project. A number of months were personally spent aiding in the integration of the squeezer with the LIGO detector.

- Chapter 10 - Conclusions and Further Work

  The conclusions from the work presented in this thesis are summarised. The future work on integration of squeezed light into interferometric gravitational-wave detectors that needs to be undertaken, in light of the work presented in this thesis, is then discussed.

Chapter 2

Background

In this chapter, gravitational-waves are introduced. The properties of gravitational waves are briefly discussed and two methods for their detection, resonant bar detectors and interferometric detectors, are detailed. The noise sources in interferometric detectors are then listed and squeezed light is introduced as a solution to reducing the quantum noise in interferometric detectors.

2.1 Gravitational-Waves

Since the advent of general relativity it is now common to consider the three space dimensions and one time dimension as part of a single manifold, known as space-time. It was postulated by Albert Einstein early in the 20^{th} century that accelerating masses should release energy in the form of gravitational-waves, or ripples in space-time [6, 7]. These gravitational-waves oscillate perpendicular to the direction of propagation and act to shrink space in one direction, whilst simultaneously expanding in the perpendicular direction, as shown in Figure 2.1. The magnitude of these oscillations is incredibly small. An extensive review of the various sources and the characteristics of these waves is given in [8, 9]. By the time these waves propagate from their original sources and reach the Earth, we might expect the largest gravitational-wave sources to have a strain amplitude, h_s, on the order of 10^{-20} [10], where strain is defined as the change in length, Δl, over the length, l, in question

$$h_s \equiv \frac{\Delta l}{l}. \tag{2.1}$$

Many searches have been made [11, 12, 13], but direct detection of gravitational-waves has yet to be achieved. However, strong evidence for their existence has been identified. The binary pulsar system PSR 1913+16 was observed for many decades by Russell Hulse and Joseph Taylor [14]. The point of closest approach between these two pulsars, the periastron, was seen to decrease over the measurement time of 30 years. The decrease seen agreed with the change in periastron predicted by Einstein's theory of general relativity with startling accuracy. The challenge now is to directly detect these waves and retrieve from them the information that they carry about the systems from which they originated, thus opening to door into gravitational-wave astronomy.

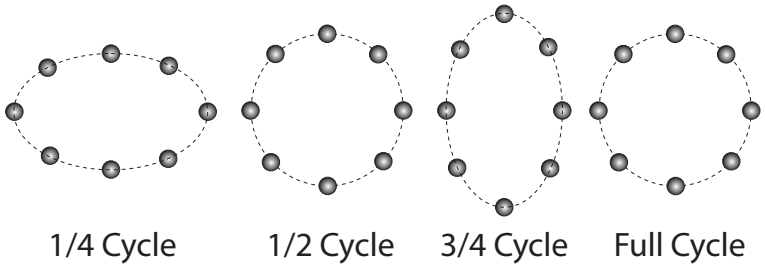

Figure 2.1: The effect of a gravitational-wave passing through a ring of free falling test masses. As the wave passes (into the paper), space-time is stretched along one axis and compressed in the orthogonal axis. This action oscillates at the frequency of the passing gravitational-wave.

2.2 Detecting Gravitational-Waves

The incredibly small amplitude of gravitational-waves makes their detection an overwhelmingly challenging task. When Albert Einstein first postulated their existence early in the 20^{th} century, there was conjecture, even from Einstein himself, as to whether these waves were mathematical artefacts or whether they would theoretically able to be detected [15]. However, it was not long before people were devising various methods that should, in theory, be capable of detecting the largest gravitational-waves here on Earth [16, 17].

2.2.1 Resonant Bar Detectors

Figure 2.2: AURIGA, cryogenically cooled resonant bar detector [18].

The first attempts at observing gravitational-waves were made by Joseph Weber in the 1960's [16]. Weber's design was that of a resonant bar. Resonant bars work on the principle that a gravitational-wave passing through it, with sufficient magnitude and the correct frequency, will excite a resonance mode within the bar. The resonance frequency of Weber's bar was tuned to a frequency of around 1660 Hz with a strain sensitivity of approximately $10^{-17}\frac{1}{\sqrt{Hz}}$ [19, 20]. The chance of detecting events with this detector was incredibly small, due to its very narrow bandwidth, of 10s of millihertz [19] and limited

sensitivity. Even now, the sensitivity of resonant bar detectors is limited to strains of approximately $10^{-21}\frac{1}{\sqrt{Hz}}$, which is believed to be enough to detect only the strongest, and as such the rarest, of sources. Bandwidths of a few hertz are typical in current resonant bar detectors and up to a few kilohertz is attainable in resonant sphere systems, with resonance frequencies typically in the kilohertz region or above [21].

2.2.2 Interferometric Detectors

An alternative method of detecting these waves, proposed by Thorne, Drever and Weiss [22], began construction in 1992 [23], after many years of research into design choices and various noise sources [24, 25, 26]. This new class of detector would use a laser interferometer design to increase both sensitivity and bandwidth over resonant bar designs. The geometry was to resemble that of a typical Michelson interferometer with arm lengths of 4 km. The effect of a passing gravitational-wave on a Michelson interferometer is shown in Figure 2.3. This interferometer is incredibly sensitive to path length differences in the two arms and it is this property that would be used to detect gravitational-waves. The two end mirrors are suspended such that they act as free falling test masses. A gravitational-wave passing through the plane of the detector acts to increase the length of one arm by displacing one of the test masses, whilst decreasing the length in the other. An overview of interferometric gravitational-wave detector design is given in [27].

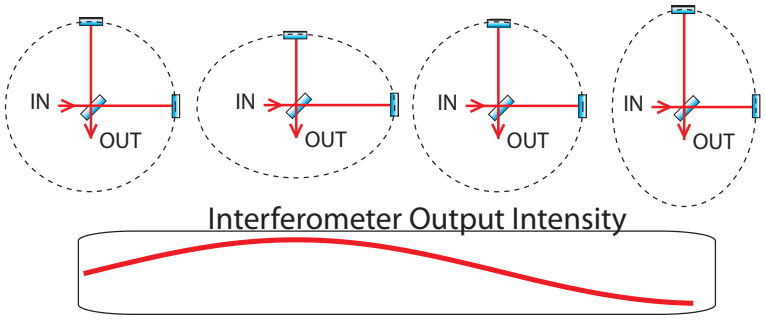

Figure 2.3: The effect of a passing gravitational-wave on a Michelson interferometer operating in the middle of an interference fringe. A gravitational-wave passing through the interferometer causes the length of the two arms to oscillate. This changes the relative phases of the laser fields from the two interferometer arms, 1 and 2, resulting in modulation of the intensity of the output field.

The detector shown in Figure 2.4, the Laser Interferometer Gravitational-wave Observatory (LIGO), is more sensitive and has a much larger bandwidth than current resonant bar detectors. LIGO's full detection band is from 10 Hz to 10 kHz, which is also known as the *audio detection band*. However, the the sensitivity of LIGO varies over this band. The device is currently undergoing upgrades but during its last science run, the device had a strain sensitivity of approximately $10^{-23}\frac{1}{\sqrt{Hz}}$ at around 100 Hz and greater than 10^{-22} from around 60 Hz up to approximately 1 kHz [28]. The device in this state was known as enhanced LIGO, further improvements are currently under way, with the next generation to be known as aLIGO [29]. Looking for gravitational wave sources at frequencies higher than these is not useful due to the fact that there is a limit as to how fast the massive bodies producing these waves can move. In LIGO's full detection band, the

most promising source of gravitational-waves are the inspiral of massive bodies, such as black holes and neutron stars, as well as the burst signature from supernovae, gravitational radiation background and pulsars [10, 8]. A comprehensive overview of the properties of these sources and how their magnitudes relate to the various detectors is given by Schutz in [30] and the expected detection rates are presented in [31].

A network of detectors is necessary for both triangulation and increasing the confidence of events [10]. The device in Figure 2.4 is one of two 4 km interferometers situated in the United States. There is also a 3 km detector in Italy known as VIRGO [32] and another one in Germany with an arm length of 600 m known as GEO600 [33]. Together, these make up the current network (although not all are currently in operation) of interferometric gravitational-wave detectors.

Figure 2.4: The Laser Inteferometric Gravitational-wave Observatory (LIGO) in Livingston, Louisiana.

2.3 aLIGO Noise Sources

Interferometric gravitational-wave detectors are sensitive to noise sources that either directly change the position of one of the test masses or noise sources that mimic such a change. The aLIGO noise budget, as illustrated in Figure 2.5, shows that the expected major contributing noise factors below approximately 100 Hz are; thermal noise, seismic noise and quantum noise. At these frequencies, the quantum noise is dominated by radiation pressure noise. Above 100 Hz, the dominant quantum noise source is shot noise, resulting from photon counting error at the detector readout.

2.3.1 Low-frequency Noise Sources

Radiation Pressure Noise

It is expected in the next generation of interferometric gravitational-wave detectors that seismic and thermal noise will be so small in the region from around 10 Hz to 100 Hz that quantum noise will become the dominating source in this frequency regime. This is shown in Figure 2.5. The quantum noise source in this frequency band is known as *radiation pressure noise*. Photons reflecting off the end mirrors, or test masses, will impart

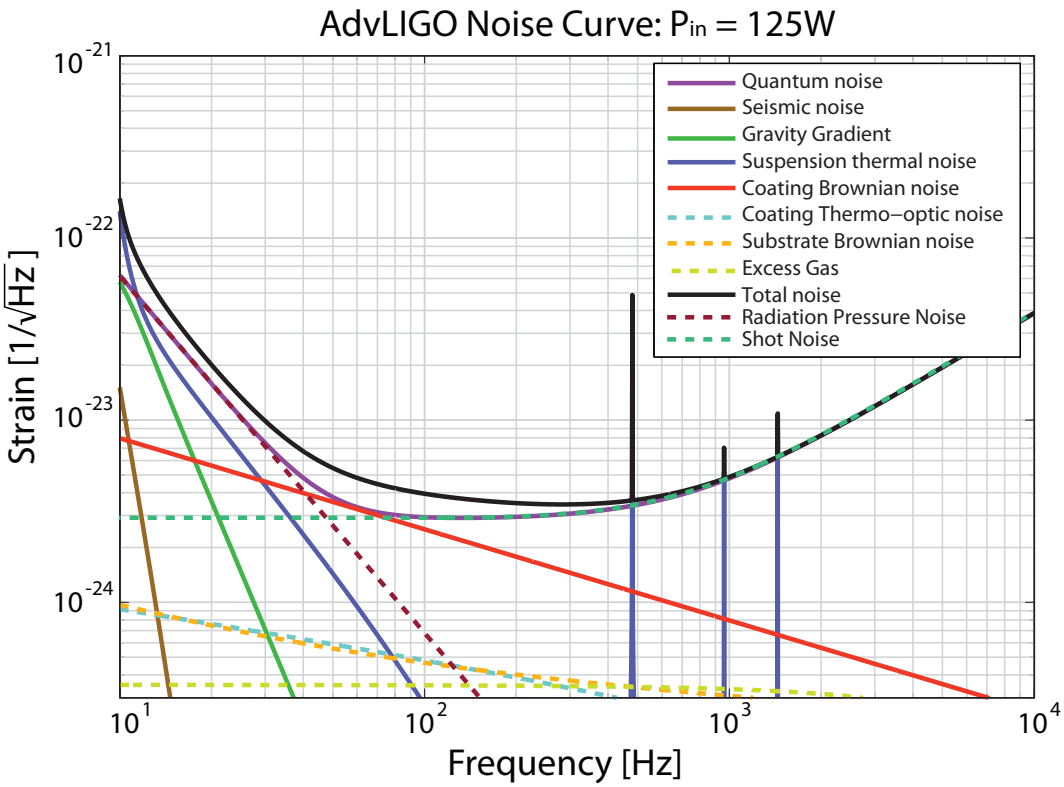

Figure 2.5: The expected aLIGO sensitivity. Plot produced using GWINC, developed by the LSC community.

a momentum kick to the mirror, conserving momentum in the collision. The momentum imparted is proportional to the number of photons, and hence proportional to the intensity of the incident field. If the intensity of the field were constant, then the constant stream of photons hitting the mirror would impart momentum that would simply alter the free resting position of the mirror. However, as the intensity of the field fluctuates, the position of the mirror will also fluctuate. If the intensity noise were classical, then the radiation pressure force felt by each test mass would be identical and this effect could be optically subtracted at the beamsplitter. However, due to the quantum mechanical nature of light, uncorrelated vacuum noise will be incident on each test mass. One can regard these fluctuations as vacuum fluctuations entering the empty input port of the interferometer beamsplitter [25], the same port where the interferometer output typically exits as in Figure 2.3. This uncorrelated noise cannot be subtracted and will be detected, masking the gravitational-wave signal. The radiation pressure error is written [34]

$$(\Delta Z)_{rp} \simeq \frac{b\hbar 2\pi f \tau_m}{mc} \left(\frac{P\tau_m}{\hbar 2\pi f}\right)^{\frac{1}{2}} e^r, \tag{2.2}$$

where $(\Delta Z)_{rp}$ is the radiation pressure error, or uncertainty due to radiation pressure, b is the number of bounces at each end mirror, τ_m is the measurement time, P is the optical

power, f is the frequency of the laser light and $\hbar$ and c are the reduced Planck constant and speed of light respectively. The squeezing factor, r, introduced in detail in § 3.5.3, is a measure of the magnitude and angle of a squeezed state injected into the second input port of the beamsplitter of the interferometer. By convention, a positive squeezing factor implies the use of a phase squeezed state. Therefore, radiation pressure error is reduced through injection of an amplitude squeezed state, with a negative r value, into the second input port of the interferometer.

Radiation pressure noise is reduced by either decreasing the number of photons hitting the mirror, decreasing the velocity imparted to the mirror by each photon, or by directly reducing the uncorrelated noise. The number of photons can be reduced by decreasing the circulating power by varying the parameters P, τ_m and b, the velocity imparted to the mirror by individual photons is reduced by increasing the mirror mass, m, or reducing the energy of the photons, f. The uncorrelated quantum noise can be reduced via the introduction of an amplitude squeezed state. The effect of radiation pressure on a test mass is shown in Figure 2.6. In Figure 2.6, the case where no laser field is incident,

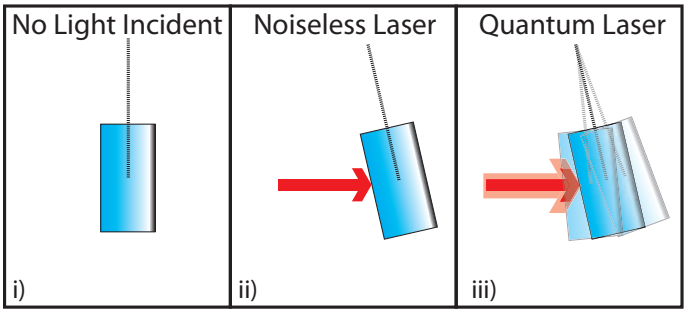

Figure 2.6: The effect of radiation pressure on a test mass for three cases: i) with no light incident; ii) with a theoretical incident laser that has no classical or quantum noise; and iii) with a laser that has quantum noise.

i), shows the test mass hanging freely. In the case of the completely noiseless laser, ii), which cannot physically exist, the photons impart momentum to the mirror resulting in a constant force. In the final case, there is a quantum noise limited laser source, a so called coherent state, incident on the test mass. The incident laser field no longer has a constant intensity, but rather fluctuates, a direct consequence of Heisenberg's uncertainty principle. The varying intensity imparts a varying force and the position of the mirror fluctuates. The forces imparted to the test masses in the two arms are uncorrelated due to the vacuum noise entering the second input port of the interferometer, resulting in a noise source which cannot be subtracted.

Thermal Noise

Thermal noise causes mechanical expansion and contraction that changes the length of the interferometer arms relative to one another. There are a few main sources of thermal noise; the suspension wires or fibres that hold the test masses in place [35], the internal motion of the test masses [36] and the thermal motion of the coatings on the optics [37, 38]. Using the fluctuation-dissipation theorem [39], the root power spectral density of thermally

induced fluctuations on the test mass as read by the interferometer is written [37]

$$S_{Th} = \frac{k_B T}{\pi^2 \Omega^2} \mathrm{Re}\{\mathbb{Y}(\Omega)\}, \tag{2.3}$$

where k_B is Boltzmann's constant, T is the temperature of the test mass, Ω is the frequency of the fluctuations and $\mathrm{Re}\{\mathbb{Y}(\Omega)\}$ is the mechanical admittance of the test mass to a cyclic pressure distribution that has the same form as the intensity profile of the interferometer beam. This term can be calculated with knowledge of the mechanical loss angle of the test mass response to the applied cyclic Gaussian pressure distribution [36].

One method of overcoming this noise source is to cool the masses. A new detector, to be built in Japan, known as KAGRA (previously called LCGT) [40, 41], is planning to use precisely this technique in order to minimise their thermal noise contribution, cooling their test masses and fibre suspensions to tens of Kelvins [42]. The other method for reducing thermal noise is to increase the quality factor and reduce the intrinsic loss of the materials involved. In aLIGO, the thermal noise in the test masses is decreased through the use of high quality factor fused silica test masses, the replacement of steel wires with silica fibres, and the use of advanced coatings [43, 28, 37].

Seismic Noise

Below frequencies of tens of hertz, seismic noise limits the performance of ground based detectors [44]. The magnitude of seismic noise increases rapidly at lower frequencies. Seismic noise causes motion in the test masses, resulting in interferometer noise.

Significantly improved seismic isolation systems have been produced for aLIGO that will reduce the coupling of seismic noise to test mass motion [45], but ultimately seismic noise will limit the very low-frequency performance of ground based gravitational-wave detection, below 10's of hertz. One method of reducing seismic noise is to build a detector underground, where seismic noise is reduced [46]. KAGRA is planned to be built underground for this purpose and is expected to have a sensitivity of 10^{-23} or greater down to 50 or 60 Hz depending upon the operating conditions [40]. Seismic noise can be bypasses altogether operating a gravitational-wave detector in space. This is the goal of what was originally called the Laser Interferometer Space Antenna (LISA) but is now known as the New Gravitational-Wave Observatory (NGO) [47, 48]. The operational band of this detector is expected to be from approximately 0.1 mHz up to around 1 Hz.

2.3.2 High Frequency Sensitivity

Shot Noise

In the high frequency region of the spectrum, frequencies above 100 Hz, the noise is almost entirely quantum in origin [49], as shown in Figure 2.5. All of the classical and technical noise sources drop off as the frequency increases. The photons arrive at the photodetector with a Poissonian distribution in the mean number of photons per unit time. The Fourier transform of this distribution is white noise across the entire spectrum. The optical response of the arm cavities shapes this noise source into that seen in Figure 2.5. The photon counting error, or error due to shot noise, of a Michelson interferometer is given by [25],

$$(\Delta Z)_{pc} \simeq \frac{c}{4b\pi f} \left(\frac{\hbar 2\pi f}{P\tau_m} \right)^{\frac{1}{2}} e^{-r}, \tag{2.4}$$

where $(\Delta Z)_{pc}$ is the photon-counting error, or uncertainty due to shot noise, b is the number of bounces at each end mirror, τ_m is the measurement time, P is the optical power, f is the frequency of the laser light, r is the squeezing factor, and $\hbar$ and c are the reduced Planck constant and speed of light respectively. As with Equation 2.2, a positive squeezing factor, which in this case will result in a negative exponent, implies the use of a phase squeezed state.

The strain sensitivity can be improved by increasing the values of b, f, l, P, or r. However, for each of these variables, increasing their values will eventually reach a practical limit. Perhaps the simplest method of reducing the photon counting error is to increase the optical power, P. However, increased power will eventually lead to thermal heating issues [50] and, as shown in § 2.6, increases the radiation pressure noise. Likewise, increasing the laser frequency requires investigation into new low loss materials and coatings and the development of high-power laser sources at these frequencies.

Equation 2.2 shows that most of the processes that reduce the shot noise increase the radiation pressure noise. This can be understood with a very simple principle. Error due to shot noise is reduced with increased power, whereas error due to radiation pressure noise increases with higher powers. Of note is that the same squeezing used to decrease the photon counting noise, a positive squeezing factor, will act to increase the radiation pressure noise. This is because squeezing in the phase quadrature results in anti-squeezing in the amplitude quadrature, conserving Heisenberg's uncertainty principle. The anti-squeezing increases the noise in the amplitude quadrature, resulting in an increase in the radiation pressure noise. Dependent upon the frequency band of interest and the dominating noise sources at these frequencies, phase squeezing, amplitude squeezing, or some squeezing angle between the two might be optimal. This is not made clear in the presented equations for the error due to radiation pressure noise and shot noise. It is shown in Figure 2.5 that radiation pressure noise dominates at low frequencies, and shot noise dominates at high frequencies. Progress has been made on producing frequency dependent squeezed states, which are squeezed in the amplitude quadrature at low frequencies, and squeezed in the phase quadrature at high frequencies [51]. In this way, squeezing can reduce the error due to both radiation pressure noise and shot noise in an interferometer simultaneously.

Increasing Laser Power

Equation 2.4 shows that the effect of shot noise can be reduced by increasing the laser power. The shot noise scales as the square root of the power of the optical field, whereas the signal scales as the power, therefore, an increase of the laser power by a factor of 4 will increase the signal to noise ratio of a shot noise limited system by 3 dB. However, increasing the laser power comes at a cost. Increased laser power results in larger radiation pressure noise and increased thermal effects. First, thermal lensing [43], and eventually parametric instabilities [52], will arise in the interferometer as the laser power is increased. These unwanted effects will reduce the efficiency and perhaps even more importantly, the stability of the detector.

The next generation of detectors will have the ability to operate at circulating powers of up to 0.5 MW. The original LIGO design had circulating powers of approximately 10 kW. The laser power in the initial LIGO setup was already large enough to require compensation for thermal effects [53]. With increased laser power, aLIGO is expected to require more sophisticated thermal compensation systems to ensure stable, reliable

operation [54, 50, 43]. Eventually a limit will be reached where the laser power cannot be increased, whilst maintaining reliable interferometer operation. It will then be necessary to decrease the shot noise of the device through other means.

2.4 Quantum Enhancement

In order to improve the sensitivity of ground based gravitational-wave detectors for and beyond the next generation, methods will need to be introduced that are capable of reducing the quantum noise in the interferometer without increasing the operational power. Many such methods have been proposed, such as variational readout, quantum non-demolition measurements and the use of squeezing [49]. Perhaps the simplest method is through the use of squeezed states due to the fact that it is fully compatible with current detector designs (See Chapter 8. Some of the other quantum enhancement techniques require complete redesigns of current interferometers.

2.5 Optical Squeezing

Optical squeezing is a means of reducing the quantum noise in a laser field, under certain conditions, below the standard limit. The usefulness of these states has been proven in various applications such as spatial displacement measurements [55] and atomic spectroscopy measurements [56]. In 1981 Caves showed that the introduction of squeezing to a Michelson interferometer was theoretically capable of improving the sensitivity of the system [25]. However, squeezed states had not yet been produced, let alone ones that were suitable for such an application. The first squeezed state, exhibiting a mere 7 % reduction in the shot noise at a measurement frequency of 422 MHz, was observed in 1985 by Slusher *et al.* using a four wave mixing process [57]. For many years thereafter, a multitude of systems were used to produce varying levels of squeezing [58]. A goal was set by some members of the squeezing community to produce squeezed states with 10 dB of quantum noise reduction down to frequencies as low as 10 Hz [59, 49, 60]. Squeezing with these properties would provide a substantial sensitivity enhancement to interferometric detectors and would display squeezing across the entire detection band of ground based detectors, marking a time when squeezing had matured to a point where the production of squeezed states was a solved problem. This thesis presents the first measurements that have achieved this 10 dB at 10 Hz goal for squeezed light production.

2.5.1 Low-frequency Squeezing

Early squeezed states could not be used for interferometric gravitational-wave detection due to the fact that they degraded at frequencies below a few MHz [61]. Recall that Figure 2.5 shows that ground based detectors require squeezing in the audio-band, from tens of hertz up to ten kilohertz. The majority of experiments aimed at producing low-frequency squeezing have utilised the second order non-linearity in crystalline materials placed in optical cavities to generate these states. Attempts were made in one of these systems to recover the squeezing at low-frequencies by building two identical squeezers and subtracting excess noise, and while it did improve the low-frequency performance, this technique still only resulted in squeezing down to approximately 200 kHz [62].

The breakthrough was made when McKenzie *et al.* determined that the presence of a bright seed field, traditionally used to control the phase of the squeezed state, was coupling

noise into the state [63]. It was determined that removing the bright seed, resulting in what is known as a vacuum squeezed state, should allow for the production of squeezed states in the audio-band. However, new control techniques would need to be introduced to control the phase of these squeezed states, which lack a coherent amplitude to use as a phase reference. Using a technique called "quantum noise locking", McKenzie *et al.* observed squeezing down to frequencies of a few hundred hertz [63]. Below these frequencies it was believed that beam pointing [64] and dust [65] were reducing the measured squeezing.

Progress was made regarding the control of these states. A new locking technique, later called "coherent locking", was developed in order to more stably control the vacuum squeezed states [66, 67]. However, degradation in the squeezing was still seen at frequencies below a couple of hundred hertz. In 2007 Vahlbruch *et al.* managed to measure large levels of squeezing, up to 6.5 dB, down to frequencies as low as tens of Hertz. The improvement was attributed to the reduction of parasitic interference (see § 8.3.4. A squeezing source had now been produced that was able to deliver a reasonable magnitude of squeezing that covered the complete frequency range of large scale interferometers. The demonstration of more squeezing, particularly at lower frequencies, was still desirable and additionally, the integration of squeezing into the detectors was a challenge that still needed to be addressed.

2.5.2 Squeezing Enhancement of Interferometers

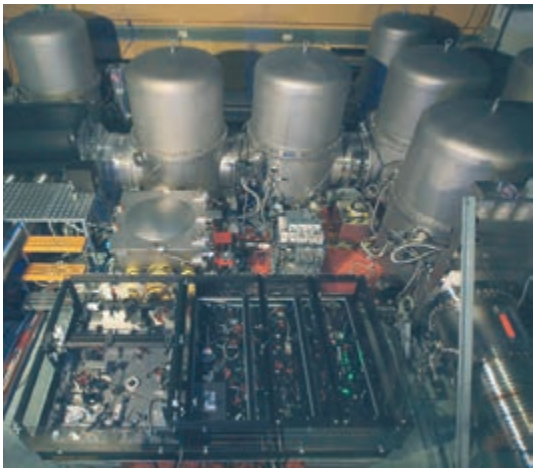

Figure 2.7: The squeezing experiment on the GEO interferometer. The squeezing is produced on the table at the bottom of the picture and injected into the interferometer located inside the vacuum chambers [68].

In the absence of low-frequency squeezing, the first experiments showcasing the improvement in sensitivity offered by squeezed states was demonstrated at higher frequencies. In 1987 Xiao *et al.* showed sensitivity improvement in a squeezing enhanced interferometer at a frequency of 1.6 MHz [69]. In 2002, McKenzie *et al.* showed a sensitivity improvement in a power-recycled squeezing enhanced Michelson interferometer at 5.5 MHz. In 2008 Goda *et al.* [70] showed a 3 dB improvement in a prototype gravitational-wave detector down to frequencies of tens of kilohertz. Only very recently has broadband improvement been demonstrated in a large scale interferometer, GEO600 [68], the experimental setup

of which is shown in Figure 2.7. Reduction in the shot noise of up to 3 dB was achieved across the entire shot noise limited region, from frequencies of a couple of hundred of hertz up to ten kilohertz. A duty cycle of 99 % was achieved and the squeezing did not degrade the performance of the detector at frequencies below hundreds of hertz. The squeezing table is modular in design, meaning it can be switched off and the interferometer is able to function as normal. This landmark achievement showed that squeezing is viable in large scale interferometers to improve the high frequency sensitivity of the device. However, a more sensitive device was needed to demonstrate the effect of squeezing on the lower frequency region.

2.5.3 Squeezing in LIGO H1

The work presented in this thesis was part of an international collaboration, involving the ANU, Caltech, the Max Planck Institute for Gravitational Physics and MIT, to inject squeezing into the LIGO detector situated in Hanford, Washington State, in the United States of America. Enhanced LIGO had just finished its sixth science run and the squeezed light injection occurred as upgrades towards aLIGO were beginning [71, 29]. The enhanced LIGO Hanford detector had two interferometers within its beam tubes, H1 and H2. H2 was a shorter detector with arm lengths of 2 km and H1 had arm lengths of 4 km, which, along with the LIGO Louisiana site, had the longest arm lengths of any current detector. These two LIGO detectors were the most sensitive interferometers ever made. In particular, their low-frequency sensitivity surpassed the performance of any other interferometer [72]. Figure 2.8 shows a picture of the squeezing table at the LIGO Hanford site.

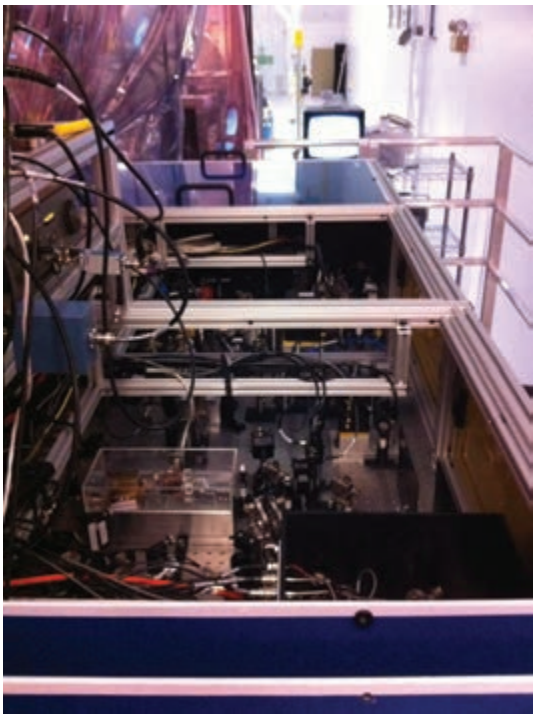

Figure 2.8: The squeezing experiment at the LIGO site.

It was previously noted that squeezing has already been shown to be viable in the GEO600 interferometric gravitational-wave detector [68]. The differentiating factors be-

tween this experiment and the LIGO injection are that the squeezer itself was to be a very different design (discussed in Chapter 6), and that the improved sensitivity of the LIGO H1 interferometer at lower frequencies would allow for the investigation of noise couplings at these frequencies. With the injection of squeezed light, it was also expected that the sensitivity of the device would exceed that previously seen by any gravitational wave detector.

Chapter 3

Quantum States of Light

This chapter introduces the formal description of the quantised electromagnetic field. This will form the basis for an investigation into squeezed states and their application in gravitational-wave detectors. First, the quadrature operators of the light field and their uncertainty relation are introduced. From here the necessary properties of these states of light and various methods of visualising these states are detailed. The effect of loss on squeezed states is investigated and the standard method for detecting these states of light, balanced homodyne detection, is analysed.

3.1 The Quantum Mechanical Electromagnetic Field

A quantum mechanical picture of light begins with quantization of the electromagnetic field. The details of this procedure are not described here but can be found in [73]. The result is that we can describe an optical mode, k, in terms of the annihilation and creation operators, $\hat{a}_k$ and $\hat{a}_k^\dagger$ respectively, in much the same way that one can describe a quantum harmonic oscillator [74]. As with the quantum harmonic oscillator, vacuum energy is present for every optical mode k, which is this case is given by $E = \frac{1}{2}\hbar\omega_k$. A classical description of the electromagnetic field does not include a description of these vacuum modes, and as such they are a defining feature of the quantum mechanical description. These vacuum fluctuations are the lowest energy state of the field and can be regarded as the instantaneous creation of particle and anti-particle pairs. In order to measure quantum mechanical states of light, including the vacuum state, it is first necessary to develop a framework for describing them.

3.1.1 Quadratures

Electric fields are often written in complex form, given by $E = Ce^{i\omega t}$, where C is the amplitude of the wave, ω is the angular frequency and E is the electric field [75]. In this form, equations are often compact and easy to manipulate. However, in some situations, this is not the most useful representation. The quadrature representation of the electromagnetic field is an alternative method of describing the electromagnetic field. The operators arising form this description are Hermitian, and therefore observable in the lab, providing a method by which quantum mechanical theories can be tested.

3.1.2 Quadrature Operators

The annihilation and creation operators, $\hat{a}$ and $\hat{a}^\dagger$ respectively, can be used to describe the electromagnetic field but they are not Hermitian, and are therefore not observable. In

order to relate measurements in the lab to the theory it is necessary to introduce Hermitian operators. This is the role that the amplitude, $\hat{X}^+$, and phase, $\hat{X}^-$, quadrature operators fulfil, they can be written [76]

$$\hat{X}^+ = \hat{a} + \hat{a}^\dagger \tag{3.1}$$

$$\hat{X}^- = i(\hat{a}^\dagger - \hat{a}). \tag{3.2}$$

By definition, the amplitude quadrature operator is chosen to have an angle that aligns with the coherent amplitude of the state. Under certain circumstances this can complicate issues because the chosen reference frame may rotate. We can also write a more general form of these operators

$$\hat{X}^\theta = \hat{a}e^{-i\theta} + \hat{a}^\dagger e^{i\theta}, \tag{3.3}$$

where θ is the angle of the field relative to a second field. The amplitude and phase quadrature operators are particular cases of the general quadrature operator. For $\theta = 0$ Equation 3.3 results in the amplitude quadrature operator and for $\theta = \frac{\pi}{2}$ it returns the phase quadrature operator. Provided that they are orthogonal to one another, which is to say that there is a $\frac{\pi}{2}$ difference between the angles, θ, of the operators, any pair of quadrature operators can be used to describe the various states of light.

3.2 The Heisenberg Uncertainty Principle

The uncertainty relation between the phase and amplitude quadrature operators can now be determined. Heisenberg's uncertainty principle for a pair of non-commuting observables is given by

$$\Delta(\hat{G})\Delta(\hat{H}) \geq \frac{1}{2i}\langle[\hat{G}, \hat{H}]\rangle, \tag{3.4}$$

where $\Delta(\hat{G})$ and $\Delta(\hat{H})$ are the standard deviation in the observables $\hat{G}$ and $\hat{H}$ and $\langle[\hat{G}, \hat{H}]\rangle$ is the expectation value of the commutation relation of the Hermitian operators $\hat{G}$ and $\hat{H}$. The commutation relation between the two operators, $\hat{G}$ and $\hat{H}$, is defined by

$$[\hat{G}, \hat{H}] = \hat{G}\hat{H} - \hat{H}\hat{G}. \tag{3.5}$$

Using the boson commutation relations, $[a, a^\dagger] = 1$ and $[a, a] = [a^\dagger, a^\dagger] = 0$ [73], we can now calculate the uncertainty relation for the any pair of orthogonal quadrature operators,

$$\Delta(\hat{X}^\theta)\Delta(\hat{X}^{\theta+\frac{\pi}{2}}) \geq 1. \tag{3.6}$$

Equation 3.6 is integral to the work presented in this thesis. In fact, it is direct manipulation of this equality that describes much of the work presented.

3.2.1 State Variance

It is typically the variance of the observable in question which is measured in the lab and not the standard deviation, as will be discussed in § 3.7.2. We define the variance, Δ^2, of an arbitrary operator $\hat{G}$ as,

$$\begin{aligned} V(\hat{G}) &= \Delta^2(\hat{G}) \\ &= (\Delta(\hat{G}))^2 \\ &= \langle\hat{G}^2\rangle - \langle\hat{G}\rangle^2. \end{aligned} \tag{3.7}$$

Notice that this also defines a relationship between the variances of the operators as set by the Heisenberg uncertainty relationship,

$$\Delta^2(\hat{X}^+)\Delta^2(\hat{X}^-) \geq 1. \tag{3.8}$$

3.2.2 Minimum Uncertainty States

A minimum uncertainty state is defined as any state where Equation 3.8 is a strict equality. A minimum uncertainty state can thus be written

$$\Delta^2(\hat{X}^+)\Delta^2(\hat{X}^-) = 1. \tag{3.9}$$

A minimum uncertainty state is one in which no classical noise is present. It is not uncommon to produce these states under certain conditions. For example, solid-state lasers are often in this minimum uncertainty state at frequencies where the low-frequency technical noise has rolled off. This typically occurs above a few megahertz. For example, a typical Nd:YAG system might be in a minimum uncertainty state at 20 MHz or lower [77]. Another way of saying this is that above these frequencies, the performance of many lasers is governed by Heisenberg's uncertainty principle.

3.2.3 Squeezing Purity

Imperfect processes, such as loss, will result in an output state that is not a minimum uncertainty state. We can define the squeezing purity, henceforth simply known as the purity, of a state, P as a means of quantifying this loss (the effect of loss is shown in §3.6. This value is not to be confused with the traditional quantum state purity [78], which is not used in this thesis. The purity is written as

$$\Delta^2(\hat{X}^+)\Delta^2(\hat{X}^-) = P. \tag{3.10}$$

A pure state will have a purity of $P = 1$, as does the vacuum. The value P, as described here, increases as loss is introduced but will eventually begin to decrease as the state approaches the vacuum state with very large losses [76]. This value is particularly important for squeezed states, as it is a measure of the efficiencies of the processes used to produce and measure the state. Excess noise in particular systems reduces Einstein-Podolsky-Rosen (EPR) entanglement [79] and as such is a limitation to many entanglement experiments [80, 81].

3.2.4 The Number Operator

The number operator, $\hat{n}$, is defined by

$$\hat{n} = \hat{a}^\dagger \hat{a}. \tag{3.11}$$

When operated upon a mode, $\langle\hat{\alpha}|\hat{n}|\hat{\alpha}\rangle$, returns the average number of particles in the mode. This operator is particularly useful when describing number, or Fock states. A Fock state is a state of light where the number of photons in the state is well known. It is particularly relevant to states with very small numbers of photons, such as the single photon state. The number operator can be used when determining the power in a state because the power is proportional to the number of photons.

3.3 Linearisation

Linearisation of the creation and annihilation operators can be used, under appropriate circumstances, to simplify calculations. The first order linearisation of the annihilation operator is written

$$\hat{a}(t) = \alpha + \delta\hat{a}(t), \tag{3.12}$$

where α is the complex classical coherent amplitude and $\delta\hat{a}(t)$ is the first order fluctuating term. The same process can be repeated for the creation operator. Linearisation requires that the average of the fluctuations in the field is zero and that the coherent amplitude of the state of light is much larger than the first order fluctuation term. These requirements are written

$$\langle \delta\hat{a}(t) \rangle = 0 \tag{3.13}$$

$$| \delta\hat{a}(t) | \ll | \alpha | . \tag{3.14}$$

It is also useful to linearise the number operator

$$\begin{aligned} \hat{n} &= \hat{a}^\dagger \hat{a} \\ &= (\alpha^* + \delta\hat{a}^\dagger)(\alpha + \delta\hat{a}) \\ &= \alpha^2 + \alpha(\delta\hat{a} + \delta\hat{a}^\dagger) + \delta\hat{a}^\dagger\delta\hat{a} \\ &\approx \alpha^2 + \alpha(\delta\hat{X}^+) \end{aligned} \tag{3.15}$$

where the second order fluctuation term has been removed.

3.4 Representing the States of Light

In this section the *ball-on-stick* and *sideband* representations of the states of light are introduced. These tools provide an intuitive way of visualising the various states of light.

3.4.1 Ball-on-Stick Representation

The ball-on-stick figure is the phase space diagram of the states of light. At a glance, the coherent amplitude, α, the standard deviation of the quadratures on the axes, $\Delta(\hat{X}^\theta)$ and $\Delta(\hat{X}^{\theta+\pi/2})$, and the phase of the state, ϕ, can be identified. Figure 3.1 shows the ball-on-stick representation for a coherent state, the details of which will be introduced in § 3.5.2. The ball-on-stick representation can be regarded as an ensemble of measurements of the amplitude and phase of the state. Each measurement of the state is plotted against the two quadratures and eventually, as many measurements are made, leads to the ball-on-stick diagram. The noise in the state will produce the ball and the stick is drawn from the origin to the average of these measurements. The length of the stick then defines the coherent amplitude and the angle of the stick, the phase of the state.

3.4.2 Sideband Representation

The sideband represenation is complementary to the ball-on-stick representation. Any modulation on some carrier field at some frequency, Δ, can be represented as sidebands around the carrier field at a frequency separation of Δ from the carrier. In this representation we move into the reference frame of the carrier. This means that when the sideband

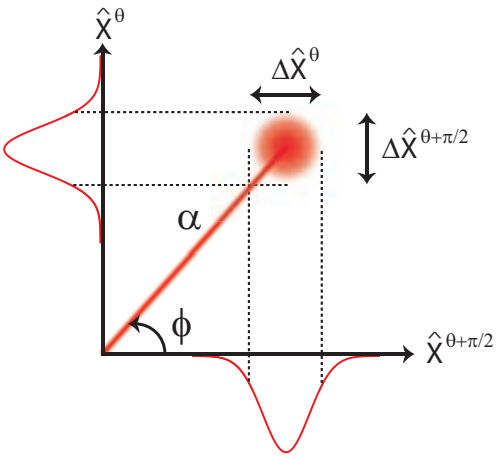

Figure 3.1: The ball-on-stick representation of a coherent state with coherent amplitude, α, and phase, ϕ. The projection of the uncertainty ball onto the two axes indicates the standard deviations, $\Delta(\hat{X}^{\theta,\theta+\pi/2})$ of the two quadrature operators.

representation of a state is drawn, this figure is of a snapshot in time. If one were to draw the representation at some later time, the figure will have evolved. Sidebands above the carrier frequency rotate in one direction and sideband fields below the carrier rotate in the opposite direction. These sidebands add together to modulate the carrier field and as such it is the relative alignment of the sidebands at frequencies Δ and $-\Delta$ that determine the dynamics of the carrier at the frequency Δ. Figure 3.2 shows the sideband representation for a coherent state.

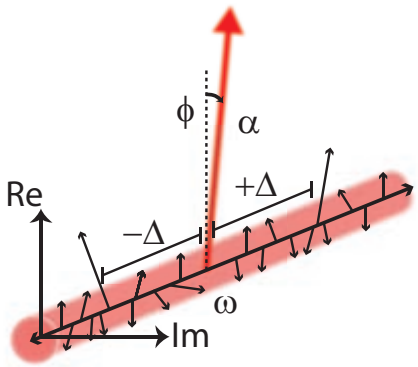

Figure 3.2: The sideband representation of a coherent state with coherent amplitude, α, and phase, ϕ. Quantum noise in the state is represented by a cylinder of quantum sidebands spanning the entire spectrum. The sideband pair at $\pm\Delta$, which are above the quantum noise level, define the motion of the carrier at the frequency Δ.

The quantum sidebands around the carrier frequency are equal in magnitude at all frequencies and beat with the carrier field. This causes the length and phase of the carrier field to fluctuate. If one were to take a slice of the sideband representation at a single

frequency, the ball-on-stick diagram could be constructed from this information.

3.5 Introducing the States of Light

Now that the framework for describing and visualising various states of light has been constructed, we can introduce the relevant states of light; the coherent state, the vacuum state, the squeezed state and the squeezed vacuum state.

3.5.1 Vacuum State

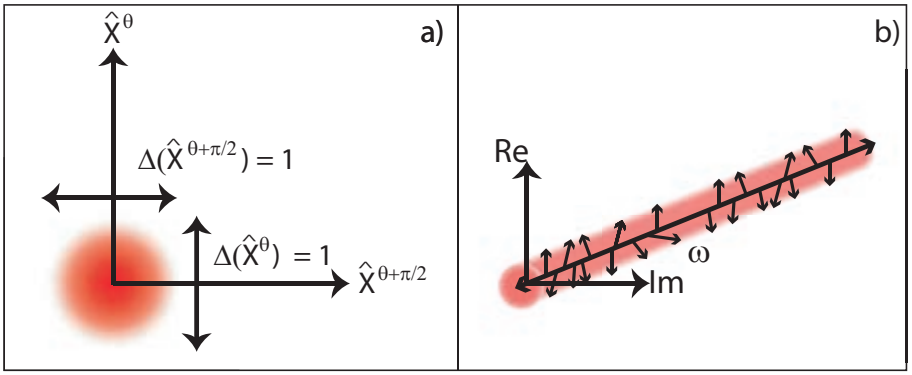

Figure 3.3: The ball-on-stick a) and sideband b) representations of the vacuum state of light.

The vacuum state has no coherent amplitude, determined by operating on this state with the number operator,

$$\langle 0 \mid \hat{n} \mid 0 \rangle = 0. \tag{3.16}$$

Even though there is no coherent amplitude, the vacuum state is not free from fluctuations. It is a minimum uncertainty state with equal noise in all quadratures,

$$\Delta(\hat{X}^{+}) = \Delta(\hat{X}^{-}) = 1. \tag{3.17}$$

These fluctuations are a consequence of the non-zero ground state energy of the quantum harmonic oscillator. It is commonly referred to as zero-point energy or vacuum fluctuations and can also be regarded as virtual particles. These fluctuations occur in every possible optical mode and this has important ramifications when considering optical loss, on squeezed states in particular.

3.5.2 Coherent State

The coherent state, $|\alpha\rangle$, can be produced through application of the displacement operator, $\hat{D}$, on the vacuum state

$$\hat{D}(\alpha)|0\rangle = |\alpha\rangle, \tag{3.18}$$

where the displacement operator is defined by

$$\hat{D}(\alpha) = e^{(\alpha\hat{a}^\dagger - \alpha^*\hat{a})}. \tag{3.19}$$

The representations of the coherent state are shown in Figure 3.4.

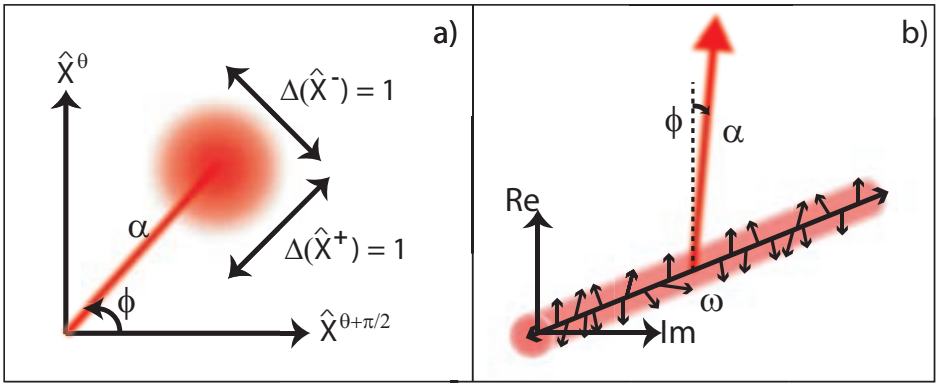

Figure 3.4: The ball-on-stick a) and sideband b) representations of a coherent state of light with phase θ and coherent amplitude α.

The coherent state is a minimum uncertainty state, and has the same noise properties as the vacuum state,

$$\Delta(\hat{X}^+) = \Delta(\hat{X}^-) = 1. \tag{3.20}$$

The coherent state is also defined as having a coherent amplitude that is greater than zero. An ideal laser source would produce a coherent state at all measurement frequencies. However, technical limitations in the low-frequency regime tend to add additional classical noise to the state. As mentioned in § 3.9, the lasers used in this work tend to be shot noise limited above a couple of megahertz. This is analogous to saying that these lasers produce coherent states above these frequencies.

3.5.3 Squeezed State

Squeezed states can be generated through the use of the squeeze operator, $\hat{S}(\rho)$, and the displacement operator,

$$\hat{D}(\alpha)\hat{S}(\rho)|0\rangle = |\alpha, \rho\rangle. \tag{3.21}$$

The squeezing operator is defined by

$$\hat{S}(\rho) = e^{\frac{1}{2}(\rho^*\hat{a}\hat{a} - \rho\hat{a}^\dagger\hat{a}^\dagger)} \tag{3.22}$$

$$\rho = re^{i\varphi}, \tag{3.23}$$

where $r \geq 0$ is known as the squeezing parameter and ψ is the angle of the squeezing.

The squeezing operator reduces the noise in some quadrature by a factor or e^{-r} and

increases it by a factor of e^r in the conjugate observable. The noise in the conjugate quadrature is necessarily increased such that the Heisenberg uncertainty relation between the two observables is not violated. A squeezed state of light is shown in Figure 3.5.

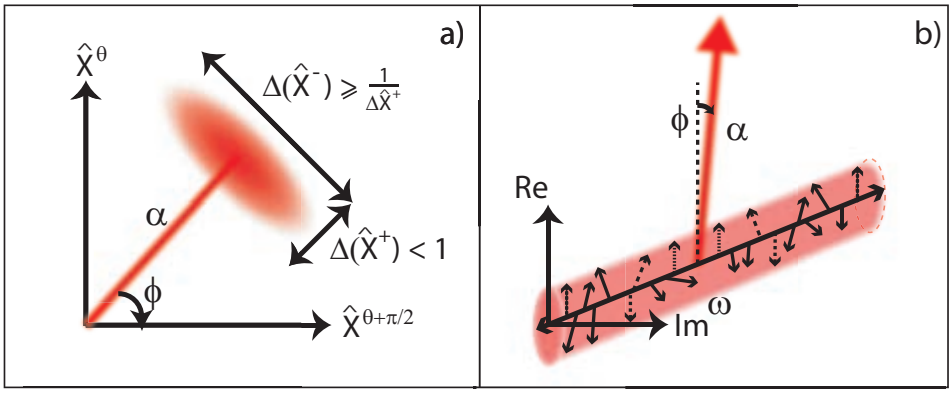

Figure 3.5: The ball-on-stick a) and sideband b) representations of a squeezed state of light with phase θ and coherent amplitude α. Correlated sideband pairs are represented by matching dashed and/or dotted lines in b)

Note that squeezed states need not be minimum uncertainty states. In fact, any real state will have some loss from any number of sources, such as scattering or absorption. This loss will reduce the purity of these states, as discussed in § 3.6.

For an amplitude squeezed state, application of the number operator will yield

$$\langle \alpha, \rho \mid \hat{a}^{\dagger}\hat{a} \mid \alpha, \rho \rangle = \sinh^2(r) + |\alpha|^2. \tag{3.24}$$

The variance of the quadrature is found to be

$$\Delta^2(\hat{X}^{+}) = e^{-2r} \tag{3.25}$$

$$\Delta^2(\hat{X}^{-}) = e^{2r}. \tag{3.26}$$

Inspection of the squeezing operator, Equation 3.22, shows that this operator acts to create or destroy photons in pairs. In fact it is these pairs of photons that are the source of squeezing.

Squeezed Vacuum States

Squeezed vacuum states are simply squeezed states with no coherent amplitude. However, Equation 3.24 shows that the squeezing operation produces photons. The photons produced are correlated photon pairs. The angle of the squeezing is determined by how these photon pairs align in the sideband representation. Whilst squeezed vacuum states have no coherent amplitude, they are still sensitive to loss because the removal of these correlated sidebands leaves more noisy vacuum fluctuations in its place. The various representations of the squeezed vacuum state are shown in Figure 3.6.

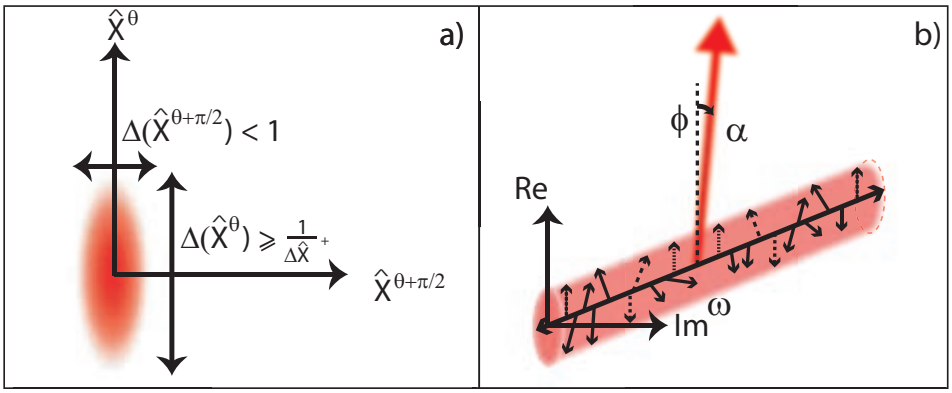

Figure 3.6: The ball-on-stick a) and sideband b) representations of a squeezed vacuum state of light. Correlated sideband pairs are represented by matching dashed and/or dotted lines.

3.6 Squeezed State Loss

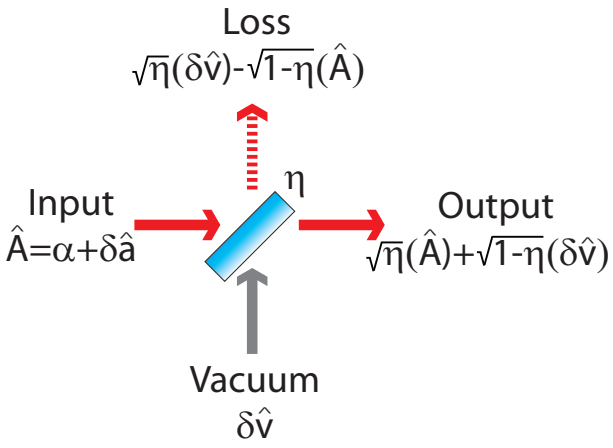

Figure 3.7: Modelling loss on an optical state. The power transmissivity of the beamsplitter, η, can be regarded as the efficiency of propagation of the field.

Optical loss can occur from many different processes such as absorption, scattering and transmission. Due to the presence of vacuum fields, the effect of loss on quantum states can have a large impact. To understand loss, we model the process as a beamsplitter with a power transmissivity of η, as shown in Figure 3.7. In this way, η can also be considered as a measure of the efficiency of some process. An η value of 1 corresponds to no state loss and the noise properties of the output of the process is equal to the input. The beamsplitter can be regarded as having two input ports and two output ports. One of the input ports has a bright field, $\mathrm{A} = \alpha + \delta a$, and the second input port is the vacuum field, $\delta\hat{v}$. The output field is then the field that has passed through the beamsplitter and has been attenuated by a factor of $\sqrt{\eta}$. The remaining field, labelled loss, is considered to be

removed from the system and is unmeasurable, thus representing loss. The output field, $\hat{A}_{out}$ is written

$$\hat{A}_{out} = \sqrt{\eta}\hat{A} + \sqrt{1-\eta}\delta\hat{v} \tag{3.27}$$

If η is not unity then we couple noise from the vacuum field, δv, into the output via beamsplitter power transmissitivity, η. In many situations this vacuum field is of little consequence because the noise of the vacuum field is either identical to, or much less than, the noise on the original input field. However, if the input field is squeezed then, by definition, the noise on the vacuum field is greater. The squeezing measurable at the output will now be less than the amount of squeezing that was measurable at the input due to the added noise from the vacuum field. This effect is extremely important as the loss of a system will set a hard upper bound on the improvement that squeezing can offer.

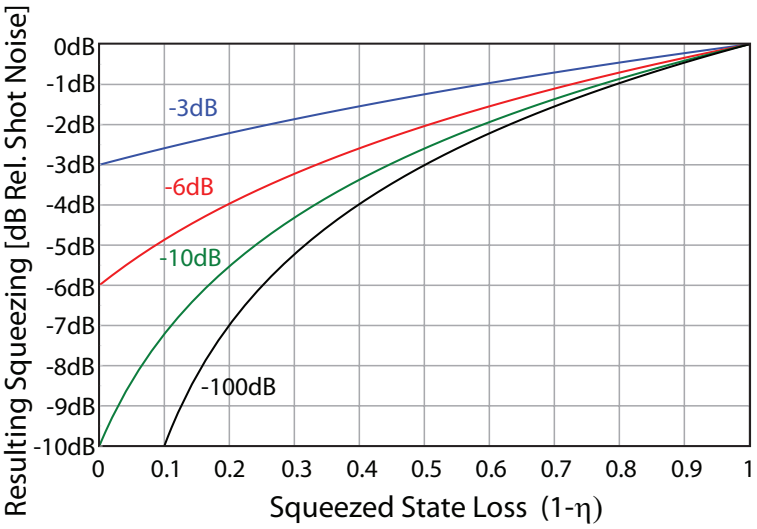

Figure 3.8: The effect of loss on various initial squeezed states.

It is important to have an intuition of the effect of loss on squeezed states. Figure 3.8 shows the resulting squeezing from four different initial squeezed states after having undergone various losses, $(1-\eta)$. The four initial squeezed states have 3, 6, 10, and 100 dB suppression of the quantum noise when compared to a field with equal intensity. Along the y-axis it can be seen that, as expected, a value of $\eta = 1$, or no loss, results in squeezing equal to that of the initial state. It can also be seen that with total loss of the initial squeezed state, $\eta = 1$, all traces converge to 0 dB, or the vacuum shot noise set by Heisenberg's uncertainty principle. The 100 dB state, although currently impossible to produce, illustrates the point that even with infinite squeezing, for a given loss there is a maximum amount of squeezing that can still be measured. With a 50% loss, we can only ever hope to measure 3 dB of squeezing, even if our original input state is infinitely squeezed. At higher losses, the dependence on the initial amount of squeezing also tends to be less important. With a 70% loss, a 6 dB initial state will result in a squeezing level of just over 1.1 dB, whereas a 100 dB initial state will result in approximately 1.5 dB.

Another way of looking at this is to consider what happens to a pure squeezed state after undergoing various levels of loss. The ball-on-stick representation of this situation

is illustrated in Figure 3.9. The resulting states after a pure, 10 dB squeezed state has undergone power losses of 25, 50, 75 and 100 percent are shown. Figure 3.9 shows that loss results in degradation of the squeezing, and also gives a feeling for the rate at which the squeezing and anti-squeezing degrades.

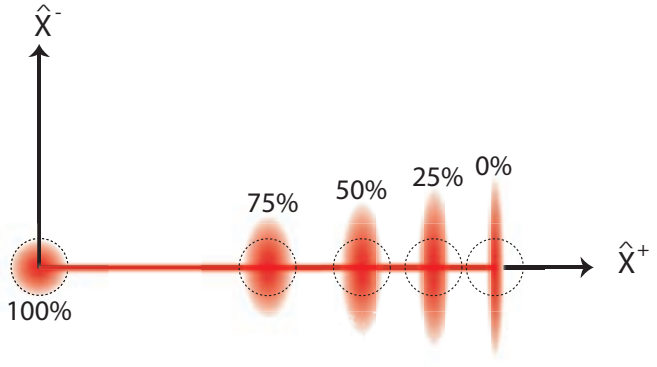

Figure 3.9: The effect of power losses of 25, 50, 75 and 100 percent on an initial pure 10 dB squeezed state are shown.

3.7 State Measurement

States of light are typically measured using a photodetector, consisting of a photodiode and a trans-impedance gain stage, and the resulting signal is then observed on either a spectrum analyser or an oscilloscope. The photodetector is shown in Figure 3.10.

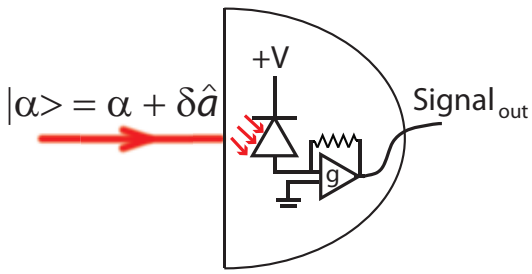

Figure 3.10: Detection of a an optical state, $|\alpha\rangle$, with a photodetector. This simple photodetector consists of a photodiode and a trans-impedance gain stage.

Ideally, the photodiode provides a one-to-one conversion of photons into electrons. Due to this, the photocurrent, i, immediately after the photodiode follows the intensity of the input field. The gain stage then converts this current signal into a voltage signal, with an amplification factor of g Ohms, resulting in

$$\begin{aligned} \text{Signal}_{out} &= g\text{i} \\ &= g(\alpha + \delta a)(\alpha^* + \delta a^\dagger) \\ &\approx g(\alpha^2 + \alpha(\delta \hat{X}^+(t))). \end{aligned} \tag{3.28}$$

3.7.1 Oscilloscope Measurements

Oscilloscopes are a means of measuring voltages in the time domain. Equation 3.28 is a voltage signal and hence oscilloscopes directly measure this value. The signal consists of a DC term proportional to the intensity, α^2, and a scaled fluctuation term, $\alpha(\delta\hat{X}^+)$.

3.7.2 Spectrum Analysers

In contrast to the oscilloscope, a spectrum analyser provides measurements in the frequency domain. It measures the variance of the input voltage signal for the frequency band in question. This variance in the voltage is proportional to the intensity spectrum of the incident laser field. For the output of our photodetector, given by Equation 3.28, we find

$$\begin{aligned} V(\text{Signal}_{\text{out}}) &\approx g(\alpha^2 + \alpha(\delta\hat{X}^+(t)) \\ &= g^2\alpha^2 V(X^+(t)), \end{aligned} \tag{3.29}$$

which is found making use of the identity,

$$V(aX + b) = a^2 V(X). \tag{3.30}$$

We can then transform this into the frequency domain to determine the signal measured with the spectrum analyser.

$$V(\text{Signal}_{\text{out}}(\omega)) = g^2\alpha^2 V(\check{X}^+(\omega)), \tag{3.31}$$

where the caron, or inverted hat, is used to signify operators in the frequency domain. The final step is to then determine the variance of the amplitude quadrature operator in the frequency domain. Using linearisation we can write

$$\begin{aligned} V(\check{X}^+(\omega)) &\equiv \Delta^2(\check{X}^+) \\ &= \langle(\check{X}^+)^2\rangle - \langle\check{X}^+\rangle^2 \\ &= \langle(\check{a} + \check{a}^\dagger)^2\rangle - \langle\check{a} + \check{a}^\dagger\rangle^2 \\ &= \langle(\alpha + \delta\check{a} + \alpha^* + \delta\check{a}^\dagger)^2\langle - \langle\alpha + \delta\check{a} + \alpha^* + \delta\check{a}^\dagger\rangle^2 \\ &= \langle(\delta\check{a} + \delta\check{a}^\dagger)^2\rangle \\ &= \langle(\delta\check{X}^+)^2\rangle. \end{aligned} \tag{3.32}$$

The variance for the phase quadrature operator is found in much the same way

$$\begin{aligned} V(\check{X}^-(\omega)) &\equiv \Delta^2(\check{X}^-) \\ &= \langle(\check{X}^-)^2\rangle - \langle\check{X}^-\rangle^2 \\ &= \langle(i(\delta\check{a}^\dagger - \delta\check{a}))^2\rangle \\ &= \langle(\delta\check{X}^-)^2\rangle. \end{aligned} \tag{3.33}$$

3.8 Balanced Homodyne Detection

Loss is one limitation to the measurement of many of these quantum states of light but the measurement itself is also a complicated issue. Measuring the quantum noise in these

states requires that all classical noise terms, such as laser intensity noise and electronic noise, are reduced to a level well below the noise level of interest (This is discussed in detail in § 8.3.1). In the case of squeezed light, where the noise in some quadrature may have been reduced by even more than one order of magnitude below the shot noise limit, achieving the required suppression of classical noise is non-trivial. A measurement system that allows for the detection of any general quadrature, including the amplitude and phase quadratures, is also necessary in order to fully characterise the measured states. All of these conditions can be met using the balanced homodyne detector [82], illustrated in Figure 3.11.

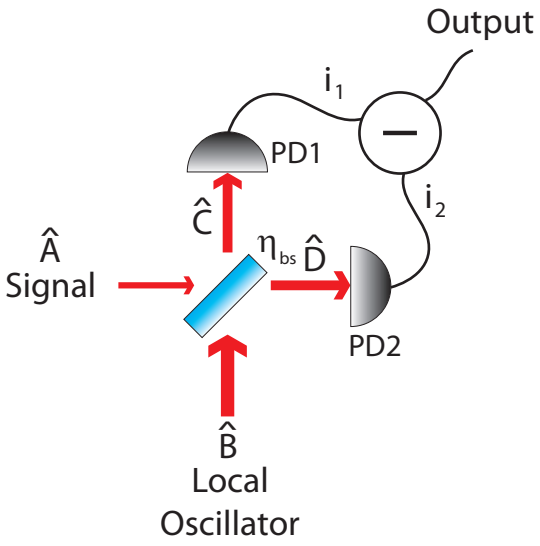

Figure 3.11: The idealised balanced homodyne detector. The signal and the local oscillator (LO) fields are both incident on the beamsplitter, of power transmissivity $\eta_{bs} = 0.5$, and the two output fields are detected on separate photodetectors, PD1 and PD2.

In the balanced homodyne detector the weak *signal field*, whose noise properties one wishes to measure, and a bright *local oscillator* (LO) field, used to amplify and probe the signal field, interfere on a beamsplitter with a power transmissivity of $\eta_{\rm bs}$, which is ideally 50 %. Using linearisation (§ 3.3) the signal field is labelled as $\hat{A} = \alpha_a + \delta\hat{a}$ and the local oscillator field as $\hat{B} = \alpha_b + \delta\hat{b}$, where the subscripts a and b on the coherent amplitudes, α, are used to distinguish between amplitudes of the signal and local oscillator fields respectively.

The fields incident on the two photo-detectors, $\hat{C}$ and $\hat{D}$, are written

$$\hat{C} = \sqrt{1-\eta_{bs}}\hat{A} + \sqrt{\eta_{bs}}\hat{B} \tag{3.34}$$
$$\hat{D} = \sqrt{\eta_{bs}}\hat{A} - \sqrt{1-\eta_{bs}}\hat{B}. \tag{3.35}$$

Here we will ensure that the coherent amplitude terms of the fields are real by separating the relative phase between the two fields into a phase term, $\hat{B}$, where $\hat{B} = \hat{B}e^{i\theta}$. We can now write

$$\hat{C} = \sqrt{1-\eta_{bs}}\hat{A} + \sqrt{\eta_{bs}}\hat{B}e^{i\theta} \tag{3.36}$$
$$\hat{D} = \sqrt{\eta_{bs}}\hat{A} - \sqrt{1-\eta_{bs}}\hat{B}e^{i\theta}. \tag{3.37}$$

Assuming that the photodetectors are perfect, every photon hitting the detectors will result in an electron at the output of the detector. The photocurrent produced by PD1 is equal to $\hat{C}^\dagger\hat{C}$ and the photocurrent from PD2 is equal to $\hat{D}^\dagger\hat{D}$. The two photocurrents, i_1 and i_2 can then be written,

$$\begin{aligned}\mathrm{i}_1 &= \hat{C}^\dagger\hat{C} \\ &= (1-\eta_{bs})\hat{A}^\dagger\hat{A} + \eta_{bs}\hat{B}^\dagger\hat{B} + \sqrt{\eta_{bs}(1-\eta_{bs})}(\hat{A}^\dagger\hat{B}e^{i\theta} + \hat{B}^\dagger\hat{A}e^{-i\theta}) \qquad (3.38)\\ \mathrm{i}_2 &= \hat{D}^\dagger\hat{D} \\ &= \eta_{bs}\hat{A}^\dagger\hat{A} + (1-\eta_{bs})\hat{B}^\dagger\hat{B} - \sqrt{\eta_{bs}(1-\eta_{bs})}(\hat{A}^\dagger\hat{B}e^{i\theta} + \hat{B}^\dagger\hat{A}e^{-i\theta}). \qquad (3.39)\end{aligned}$$

As shown in Figure 3.11, the output of the homodyne detector is then the resulting signal when these two photocurrents are subtracted. The result is

$$\mathrm{i}_1 - \mathrm{i}_2 = (1-2\eta_{bs})\hat{A}^\dagger\hat{A} + (2\eta_{bs}-1)\hat{B}^\dagger\hat{B} + 2\sqrt{\eta_{bs}(1-\eta_{bs})}(\hat{A}^\dagger\hat{B}e^{i\theta} + \hat{B}^\dagger\hat{A}e^{-i\theta}). \quad (3.40)$$

Utilising the linearisation technique described in § 3.3 allows for simplification of some of the terms in Equation 3.40. We begin by recalling that the problem was constructed such that the coherent fields are real, and we choose to drop terms of second order. Using these simplifications we can write

$$\begin{aligned}\hat{A}^\dagger\hat{A} &\approx (\alpha_a^* + \delta\hat{a}^\dagger)(\alpha_a + \delta\hat{a}) \\ &\approx \alpha_a^2 + \alpha_b\delta X_A^+ \qquad (3.41)\\ \hat{B}^\dagger\hat{B} &\approx (\alpha_b^* + \delta\hat{b}^\dagger)(\alpha_b + \delta\hat{b}) \\ &\approx \alpha_b^2 + \alpha_b\delta X_B^+. \qquad (3.42)\end{aligned}$$

where $\delta X_A^+ = \delta\hat{a} + \delta\hat{a}^\dagger$ is the amplitude quadrature operator for the field $\hat{A}$, and $\delta X_B^+ = \delta\hat{b} + \delta\hat{b}^\dagger$ is the amplitude quadrature operator for the field $\hat{B}$. Making use of Equations 3.41 and 3.42 we can now simplify Equation 3.40, resulting in

$$\begin{aligned}\mathrm{i}_1 - \mathrm{i}_2 \approx\ & (1-2\eta_{bs})(\alpha_a^2 + \alpha_a\delta X_A^+) + (2\eta_{bs}-1)(\alpha_b^2 + \alpha_b\delta X_B^+) + \\ & 2\sqrt{\eta_{bs}(1-\eta_{bs})}[(\alpha_a^* + \delta\hat{a}^\dagger)(\alpha_b + \delta\hat{b})e^{i\theta} + (\alpha_b^* + \delta\hat{b}^\dagger)(\alpha_a + \delta\hat{a})e^{-i\theta}].\end{aligned} \quad (3.43)$$

This can be rewritten (using various trigonometric identities on the exponential terms) as

$$\begin{aligned}\mathrm{i}_1 - \mathrm{i}_2 \approx\ & (1-2\eta_{bs})(\alpha_a^2 + \alpha_a\delta X_A^+) + (2\eta_{bs}-1)(\alpha_b^2 + \alpha_b\delta X_B^+) + 2\sqrt{\eta_{bs}(1-\eta_{bs})} \times \\ & \left[2\alpha_a\alpha_b\mathrm{Cos}\theta + \alpha_a\left(\delta\hat{X}_B^+\mathrm{Cos}\theta - \delta\hat{X}_B^-\mathrm{Sin}\theta\right) + \alpha_b\left(\delta\hat{X}_A^+\mathrm{Cos}\theta + \delta\hat{X}_A^-\mathrm{Sin}\theta\right)\right].\end{aligned} \quad (3.44)$$

It is typically required that the local oscillator field strength, α_b, is much brighter than the signal field in order to suppress the noise from the local oscillator. For most of the work presented in this thesis the signal field is a vacuum squeezed state, with no coherent amplitude, and hence this condition is easily met. This condition allows us to remove all

terms that do not contain the coherent amplitude of the LO field, α_b, resulting in

$$\begin{aligned} \mathrm{i}_1 - \mathrm{i}_2 &\approx (2\eta_{bs} - 1)(\alpha_b^2 + \alpha_b \delta X_B^+) + \\ &\quad 2\sqrt{\eta_{bs}(1-\eta_{bs})}\left[2\alpha_a\alpha_b \mathrm{Cos}\theta + \alpha_b\left(\delta\hat{X}_A^+ \mathrm{Cos}\theta + \delta\hat{X}_A^- \mathrm{Sin}\theta\right)\right]. \end{aligned} \tag{3.45}$$

If we now assume that our beamsplitter ratio is exactly 50 % we completely subtract the contributions from the local oscillator field and Equation 3.45 simplifies to

$$\mathrm{i}_1 - \mathrm{i}_2 \approx 2\alpha_a\alpha_b \mathrm{Cos}\theta + \alpha_b\left(\delta\hat{X}_A^+ \mathrm{Cos}\theta + \delta\hat{X}_A^- \mathrm{Sin}\theta\right). \tag{3.46}$$

It is worth taking a moment and considering the ramifications of this equation. The first term, $2\alpha_a\alpha_b \mathrm{Cos}\theta$, is a DC term that describes the interference between the two fields as the phase of the local oscillator, θ, is varied. If the two fields are in exactly the same spatial mode then this term will completely vanish, given an appropriate value for θ. In practice, however, the two fields are never perfectly matched in shape and size and hence this term will not completely vanish. The overlap between the two fields can be quantified using the *visibility* of the balanced homodyne detector, which will be introduced in § 3.8.1.

The remaining terms are the quantum noise terms. The quantum noise terms have been "amplified" by the coherent amplitude term of the LO field, which we see occurs without adding any noise from the LO field in the case of perfect subtraction. This gain factor allows us to measure vanishingly small quantum noise terms on the signal field. It is also evident that as the phase of the LO field is varied, the noise seen at the output is some mixture of amplitude and phase quadratures. The balanced homodyne detector, by varying the phase of the LO, works as a measuring device for any general quadrature operator that we wish to measure, allowing us to fully characterise the noise characteristics of any state.

3.8.1 Balanced Homodyne Detector Fringe Visibility

The visibility of the homodyne detection system is a measure of the overlap between the signal and local oscillator fields. In order to achieve complete destructive or constructive interference the waist size and waist position of the two fields must be exactly the same. If this is not the case then the wavefronts will not match and the same phase relationship will not be kept over the entire beam. The visibility is a way of quantifying the spatial mode mismatch between the signal and LO fields and is given by

$$\mathcal{V} = \frac{I_{Max} - I_{Min}}{I_{Max} + I_{Min}}. \tag{3.47}$$

I_{Max} is the maximum intensity seen as the phase is varied, which corresponds to constructive interference, and I_{Min} is the minimum intensity measured, corresponding to destructive interference. The values are determined by ensuring that the power of the local oscillator and signal fields are first equal. The phase of the local oscillator is then swept whilst examining the output DC term on an oscilloscope.

It can be shown that the fringe visibility is equivalent to optical loss on the signal field [83]. If the equivalent loss due to an imperfect fringe visibility is given by η_{vis}, it can be defined as

$$\eta_{vis} = \mathcal{V}^2. \tag{3.48}$$

It is perhaps not surprising that an inefficient spatial overlap between these two fields is equivalent to a loss on the signal field. Equation 3.46 shows that the noise terms from the signal field are amplified by the coherent amplitude of the LO field. If some part of the signal field does not overlap then it will not receive this gain and will be unmeasurable, thus acting as a loss source.

Chapter 4

Generation of Squeezed States

This chapter begins by discussing the various methods for producing squeezed states and from there looks at a brief history of squeezing results from cavity systems utilising the second order non-linearity from various materials. The second order process is then described in detail. First, the photon interaction in second harmonic generation is detailed, followed by the optical parametric amplifier and optical parametric oscillator systems. From there, some of the technical issues present in these systems are discussed such as phase matching and intra-cavity dispersion.

4.1 Methods of Squeezed State Production

The first observation of squeezed states was achieved by Slusher *et al.* using a four wave mixing process involving Na atoms in a gas cell [57]. Since then, optical squeezing has been produced in many systems, such as vapour cells [84] and fibres [85]. For many years there was no system that clearly outperformed the others [58], however, one of the stronger performers over the years has been the below threshold optical parametric oscillator (OPO) [58]. Additionally, the parameters of the optical cavity can be tuned for the specific application, providing flexibility. As opposed to three wave mixing processes such as those present in fibre or vapour squeezing, the strength of the second order non-linear interaction, $\chi^{(2)}$, utilised in the OPO is very strong. These properties result in the OPO being a versatile, reliable source of squeezing and currently holds the record for squeezing magnitude, of 12.7 dB [86], and low-frequency performance, 10 dB at 10 Hz [87]. These low-frequency results are presented in Chapter 8. However, squeezing results generated with four-wave mixing experiments are also progressing [88, 89].

4.1.1 History of Optical Parametric Oscillator and Amplifier Performance

A short list of relevant landmark squeezing results from optical cavity systems and some of the details of the systems used to produce these results are shown in Table 8.14.

Table 8.14 shows that the highest level of squeezing measured to date is 12.7 dB at a measurement frequency of 5 MHz [86]. This was achieved in a singly resonant monolithic Periodically Poled Potassium Titanyl Phosphate (PPKTP) cavity. The largest magnitude of squeezing at the lowest frequency is 10 dB at 10 Hz and was achieved in 2012 in a doubly resonant bow-tie cavity also using PPKTP. This work is presented in § 8.4.5. The same work, presented in this thesis showed squeezing of 11.6 dB down to 200 Hz. Two of the most influential results were the first to observe squeezing at audio frequencies, and the first to achieve a suppression of the shot noise by an order of magnitude. The first

Year	Group	Mag.	Freq.	Cavity	λ [nm]	Material

Table 4.1: A brief list of relevant squeezing results, pioneering squeezing in terms of magnitude, frequency, cavity design and/or wavelength. The magnitude of the squeezing given (Mag.) is the directly observed squeezing level, with no corrections for imperfect detection efficiencies. The λ column indicates the wavelengths resonant in the squeezer, where finesses greater than 5 are considered resonant. The materials used by the various groups are labelled; Magnesium Oxide doped Lithium Niobate (MgO:LN), Potassium Niobate (KNB), Potassium Titanyl Phosphate (KTP) and Periodically Poled Potassium Titanyl Phosphate (PPKTP).

audio frequency squeezing was achieved in 2004 by McKenzie *et al.* in a singly resonant hemilithic cavity using MgO:LN [63]. The first directly observed 10 dB of squeezing below the shot noise level was achieved by Vahlbruch *et al.* in 2007 using a singly resonant monolithic MgO:LN cavity [98].

4.2 The Second Order Non-linearity

The OPO utilises the relatively strong second order non-linear interaction, $\chi^{(2)}$, in order to produce squeezing. We can write the induced polarisation, $\vec{P}$, in a non-linear dielectric medium due to an external electromagnetic wave, $\vec{E}$, as

$$\vec{P} = \varepsilon_0(\chi\vec{E} + \chi^{(2)}\vec{E}^2 + \chi^{(3)}\vec{E}^3 + \dots), \tag{4.1}$$

where the $\chi^{(x)}$ terms are the various orders of the non-linear susceptibility and ε_0 is the electric permittivity of free space. The third order susceptibility, $\chi^{(3)}$, is typically orders of magnitude lower than the second order term. It is responsible for four-wave processes such as the Kerr effect, third harmonic generation and self phase modulation [103]. The second order interaction can be used to drive processes such as second harmonic generation (SHG), optical parametric amplification (OPA) and optical parametric oscillation (OPO).

4.3 Second Harmonic Generation

The simplest of these processes is second harmonic generation, or SHG, and as such is a good introduction to the other non-linear processes. Here, only the photon interactions, and as such the energy conservation requirements, are investigated. Consideration of momentum conservation is left until § 4.5. SHG is an up-conversion process, meaning that photons at a lower frequency, ω, combine to produce photons at a higher frequency, in this case at 2ω. It was first experimentally achieved in 1961 by Franken *et al.* [104]. We can write

$$\omega_{sh} = \omega + \omega, \tag{4.2}$$

where ω_{sh} is the frequency of the second harmonic field and ω is the angular frequency of the fundamental field. This process is shown in Figure 4.1. These systems are often placed inside a resonator such that the fundamental field undergoes many passes through the material, substantially improving the conversion efficiency.

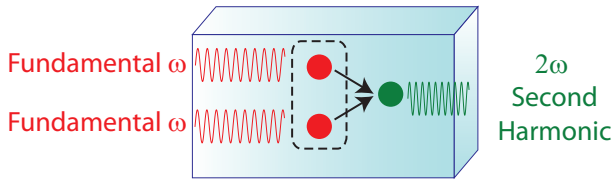

Figure 4.1: The SHG system. Two photons at frequency ω combine to produce one photon at frequency 2ω.

4.4 Downconversion Processes

Downconversion processes are ones in which pump photons are converted into lower energy photons. Although the basic setup is similar, we can identify three different downconversion modes of operation for our system, depending upon how the process is seeded. These are the degenerate optical parametric amplifier, the non-degenerate optical parametric amplifier, and the optical parametric oscillator. These various modes of operation are integral in squeezed state production from a second order system.

4.4.1 The Degenerate Optical Parametric Amplifier

It is often easier to first consider the more intuitive case of the DOPA before moving onto describing the processes in the OPO. The difference between the two, as shall soon be made clearer, is the presence of a bright seed field. The OPA is capable of producing exotic quantum states of light but in this instance we will only investigate the classical behaviour. The quantum behaviour will follow in the treatment of the OPO.

Figure 4.2 depicts the DOPA and the processes involved. The presence of the seed field, also known as the signal field, can be thought of as a catalyst for the reaction of the pump photon downconversion. In the DOPA these two frequencies are equal. We write

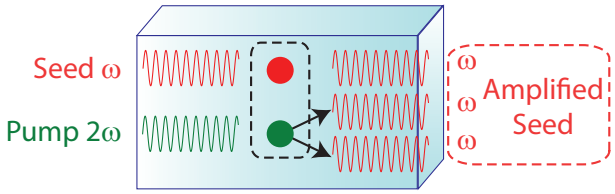

Figure 4.2: The degenerate optical parametric amplifier (DOPA). The system is driven with a pump field at frequency 2ω and a seed field at frequency ω. Inside the non-linear medium, the presence of a seed photon causes the pump photon to split into two photons of frequency ω, thus amplifying the seed field.

for the energy, E, of the process,

$$E \propto \omega_{pump} = \omega + \omega. \tag{4.3}$$

An idealised picture of the process is shown. In reality, only a portion of the pump photons will undergo the downconversion process. The remaining light will exit the system and is known as the residual pump. In many applications, the portion of the pump that is converted is very small due to the relative magnitude between the seed and pump fields, and an approximation is made that the power of the pump field is constant. Conservation of momentum must also be achieved and this is done through a technique known as phase matching, introduced in § 4.5.

Explicitly writing the origin of the two incident fields at angular frequencies of ω and 2ω as ω_{pump} and ω_{seed} respectively, the combined field present on the non-linear dielectric, $\vec{E}_{inc}(t)$, can thus be written

$$\vec{E}_{inc}(t) = \vec{E}_{seed}e^{-i\omega_{seed}t} + \vec{E}_{pump}e^{-i\omega_{pump}t} + \vec{E}^*_{seed}e^{i\omega_{seed}t} + \vec{E}^*_{pump}e^{i\omega_{pump}t}. \tag{4.4}$$

If we look at only the second order term from Equation 4.1 then we can investigate the second order processes involved. Dropping the vector notation on assumption that the two fields are co-propagating we can write

$$\begin{aligned} \chi^{(2)}E^2_{inc}(t) \quad = \quad & \chi^{(2)}[E_{seed}E^*_{seed}e^{-i2\omega_{seed}t} + E_{pump}E^*_{pump}e^{-i2\omega_{pump}t} + \\ & 2E_{seed}E_{pump}e^{-i(\omega_{seed}+\omega_{pump})t} + \\ & 2E_{seed}E^*_{pump}e^{-i(\omega_{pump}-\omega_{seed})t} + \\ & 2(|E_{seed}| + |E_{pump}|)]. \end{aligned} \tag{4.5}$$

In the DOPA, the term we are interested in is the difference frequency generation term

$$2E_{seed}E^*_{pump}e^{-i(\omega_{pump}-\omega_{seed})t}, \tag{4.6}$$

which describes the process of amplifying the field at ω_{seed} as seen in Equation 4.3.

4.4.2 The Non-Degenerate Optical Parametric Amplifier

The NDOPA can be used to create exotic states of light, particularly in cases where one might wish to separate the two output modes, such as separable entangled states [105, 106].

Here we only investigate the classical behaviour of the NDOPA. In this case, the frequency of the seed field is shifted from half of the pump frequency by an amount δ.

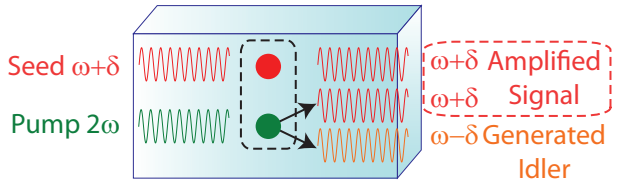

Figure 4.3: The non-degenerate optical parametric amplifier (NDOPA). The system is driven with a pump field at frequency 2ω and a seed field at frequency $\omega+\delta$. Inside the non-linear medium the presence of a seed photon causes the pump photon to split into two photons of frequency $\omega+\delta$ and $\omega-\delta$. This amplifies the seed field but also creates a second field, the idler or generated sideband field.

We see that the defining feature is the generation of the idler field. This field is generated much in the same way as in the DOPA 4.6. The idler field has the same frequency separation as the signal from the carrier, δ, but with a negative sign. This results in a beat signal at the frequency 2δ.

$$E \propto \omega_{pump} = \omega + \delta + \omega - \delta. \tag{4.7}$$

The classical behaviour of the NDOPA is important to the work presented in this thesis because it describes the coherent locking scheme, introduced in § 7.4. This scheme is used to control the vacuum squeezed states produced. In contrast to the DOPA, it is also shown in § 7.4 that the phase of the pump in this system does not affect the output field at the seed frequency, but instead alters the phase of the generated idler field relative to the seed.

4.4.3 The Optical Parametric Oscillator

The optical parametric oscillator can be regarded as an OPA with no bright seed field, or perhaps more informatively, as having a vacuum seed. The OPO is driven by this vacuum seed and by the pump field at 2ω. Vacuum fluctuations can be thought of as the spontaneous production of particle and anti-particle pairs that come into existence and swiftly annihilate. We can imagine that one of these particles seeds the OPO in exactly the same way as the classical seed does, resulting in the downconversion of a pump photon into a photon at the virtual particle frequency, δ, and a photon into the corresponding frequency necessary to conserve energy.

$$E \propto \omega_{pump} = \delta + (2\omega - \delta). \tag{4.8}$$

If we look at the non-linear response of the system then the relevant term is again the difference frequency generation

$$2E_{vacseed}E^*_{pump}e^{-i(\omega_{pump}-\omega_{vacseed})t} \tag{4.9}$$

where the seed field is now replaced with a vacuum seed term, $E_{vacseed}$. It has previously been mentioned that vacuum fluctuations can be regarded as the creation and annihilation of virtual particle pairs. It has also been mentioned that vacuum fluctuations exist at all frequencies and all spatial modes. What this means is that the vacuum seed frequency term, $\omega_{vacseed}$, in Equation 4.9 is constantly changing as a consequence of quantum mechanics. At some point in time the vacuum fluctuation will cause the pump photon to down-convert to a photon pair with some random frequency separation from the carrier. At the next instant in time, the photon pair will be created with a different frequency separation, but always conserving energy. In this way, the vacuum seed acts to populate all frequencies with these photon pairs. These photon pairs, seeded by the vacuum itself, reduce the quantum noise in the output field and are the source of squeezing.

A list is made detailing the important properties of this system that define the production and the spectral shape of the squeezing that exits the OPO system.

- Squeezing originates from the production of these sideband pairs. These pairs replace the vacuum fluctuations and tend to align in some quadrature and cancel in the orthogonal one. The quadrature where they cancel, and hence where the noise is reduced, is the squeezed quadrature.

- The alignment of the generated sidebands from these photon pairs is a function of the phase of the pump. Hence, relative to a carrier field, we can rotate our squeezing quadrature by rotating the phase of the pump.

- The squeezing as it is produced is equal at all frequencies, limited only by the phase matching range of the material. This is because the vacuum fluctuations are white, existing at all frequencies with equal magnitude. However, the OPO consists of a non-linear medium inside an optical cavity and the optical cavity will shape the squeezing through its spectral response.

- Squeezing is centred around the fundamental frequency. This is because the photon pairs are centred about half of the pump frequency due to conservation of energy.

Figure 4.4 shows the conceptual process of the OPO. Comparison with Figure 4.2 shows that the two systems share similarities.

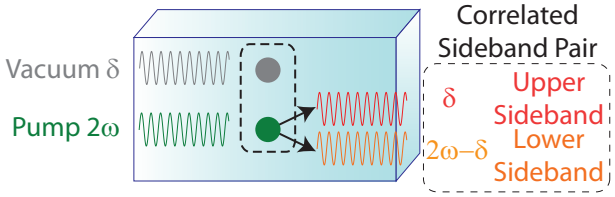

Figure 4.4: The optical parametric oscillator (OPO). The system is driven with a pump field at frequency 2ω and seeded by the vacuum field. Inside the non-linear medium the presence of a virtual photon causes the pump photon to split into two photons of frequency δ and $2\omega - \delta$. This process creates photon pairs across all frequencies.

4.5 Phase Matching

In the previous section, the various non-linear systems and the photon interactions which take place were introduced. Energy conservation was introduced but another quantity also has to be conserved, momentum. The technique of conserving the momentum is known as *phase matching*. The origin of phase mismatch is dispersion within the non-linear medium. In order for phase matching to occur, the wave vector of the pump field must be equal to twice the wave vector of the seed field, which can be written

$$\vec{k}_{pump} = 2\vec{k}_{seed}, \tag{4.10}$$

where $\vec{k}_{pump}$ is the wave vector of the pump field and $\vec{k}_{seed}$ is the wave vector of the seed field. The process typically occurs in a non-linear medium that has been placed inside an optical cavity. The two fields are thus co-propagating and the directional information is not important. We can then write

$$\frac{n_{pump}\,\omega_{pump}}{c} = 2\frac{n_{seed}\,\omega_{seed}}{c}, \tag{4.11}$$

where n_{pump} and n_{seed} are the refractive indices experienced by the pump and seed fields respectively and c is the speed of light in a vacuum.

Using Equation 4.2 we can simplify this to indicate that in order for phase matching to occur, the refractive index of the pump and seed fields must be equal. We can write

$$n_{pump} = n_{seed}. \tag{4.12}$$

The refractive index of the pump field is typically not equal to the refractive index of the seed field and so the phase relationship between the two fields varies, reducing the efficiency of the non-linear processes. Clever techniques are used to ensure that phase matching is satisfied. Figure 4.5 shows the phase relationship between a fundamental wave and its harmonic for the phase matched case and the phase mismatched case, respectively. In the phase matched case, a), the waves have a constant phase relationship whilst in the case where they are not phase matched, b), the waves do not maintain a constant relationship.

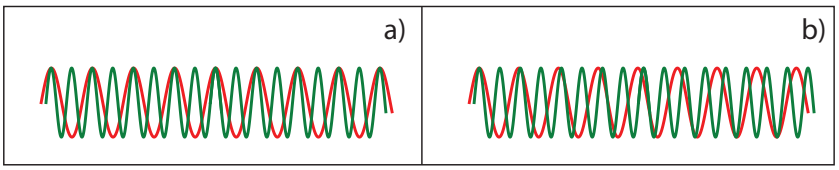

Figure 4.5: Two waves at ω, red, and 2ω, green, when the waves are phase matched a) and phase mismatched b).

We can also illustrate phase matching using a simple phasor diagram. Figure 4.6 shows the resultant second harmonic field in an SHG setup for the phase matched a), quasi-phase matched b) and phase mismatched c), cases. In the phase matched case, a), the wave vectors of the second harmonic and fundamental fields match (See § 4.5.1. In the quasi-phase matched case, b), the wave vectors do not match but periodic poling, marked by the dotted lines, ensures that the process does not reverse (See § 4.5.2). In the final

case, c), where the waves are phase mismatched, the energy oscillates between the second harmonic and fundamental fields.

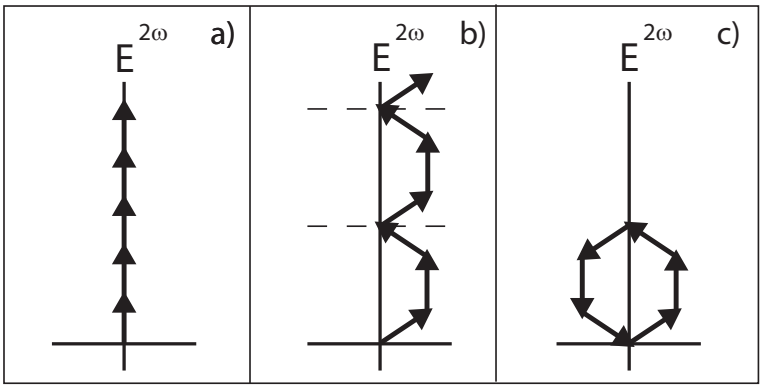

Figure 4.6: Phasor diagrams showing the generated second harmonic field, $E^{2\omega}$ in the phase matched, a), quasi-phase matched, b), and phase mismatched cases in an SHG setup.

4.5.1 Birefringent Phase Matching

One technique commonly used to achieve phase matching is *birefringent phase matching*, illustrated in Figure 4.6. The non-linear mediums used in these non-linear systems are often birefringent. This is in part due to the fact that the crystal has to lack inversion symmetry in order to exhibit the second order non-linearity [75]. The two fields will ordinarily experience non-equal refractive indices depending upon which crystal axis they are polarised along. Rotating the angle of polarization can give any refractive index between the refractive index of the ordinary and the extraordinary axis. These values can be altered by increasing the temperature of the crystal as described by the Sellmeier equation for the material. A crystal cut is then found where varying the angle of the input fields and the temperature of the crystal, will result in an operating regime where their refractive indices match.

The disadvantage to birefringent phase matching is that the angle where phase matching occurs is typically not in the direction of the strongest $\chi^{(2)}$ coefficient. For example, in lithium niobate the non-linear coefficient is 27 pm/V in the d_{33} crystal direction but at the birefringent phase matching angle, which lies along the d_{31} plane, the coefficient is 4.3 pm/V [107]. The conversion efficiency is proportional to the square of the non-linear coefficient for typical applications. Clearly, the birefringent phase matching technique is not harnessing the full potential of this material. Another disadvantage to the birefringent phase matching technique, particularly in this material, is that the temperature at which phase matching occurs cannot be tailored under most circumstances. This leaves lithium niobate with a phase matching temperature of typically around 100 degrees Celsius for a pump field of 532 nm, [108]. It is technically challenging to provide such a temperature environment for the material which is stable.

4.5.2 Quasi-Phase Matching and Periodic Poling

Periodic poling is an alternative method for achieving momentum conservation, one in which the phase matching temperature can be tailored and the largest non-linear coefficent

strength of the material can be utilised. This technique does not achieve a phase matching condition within the material, but instead compensates for dispersion by flipping the crystal structure at specific intervals, thus avoiding reversal of the non-linear processes, as illustrated in Figure 4.6. The most common method of achieving domain inversion is *electric field periodic poling*. In this technique, a very strong electric field is applied to metallic "fingers" that are placed on top of the crystal [109]. These large electric fields rearrange the crystal lattice, changing the sign of the non-linear interaction term. The spacing between these fingers and the electric field applied determines the width of the periodic poling.

The distance at which the non-linear process begins to reverse in a phase mismatched system is known as the coherence length and is defined as

$$L_C = \frac{2\pi}{|\Delta k|}, \tag{4.13}$$

where L_C is the coherence length and $\Delta k = \vec{k}_3 - \vec{k}_2 - \vec{k}_1$ is the phase mismatch term, and we have assumed that the fields are co-propagating. The three wavevectors, $\vec{k}_{1,2,3}$ correspond to the wave vectors of the three electric fields that interact in the three-wave-mixing process. For example, in the NDOPA we can write

$$\begin{aligned} \Delta k &= \vec{k}_3 - \vec{k}_2 - \vec{k}_1 \\ &= \vec{k}_3 - \vec{k}_1 - \vec{k}_1 \\ &= \vec{k}_{pump} - 2\vec{k}_{seed} \end{aligned} \tag{4.14}$$

For collinear beams and in a degenerate system, the phase matching condition is equivalent to writing

$$n_{pump} = n_{seed}, \tag{4.15}$$

where n_{pump} and n_{seed} are the refractive indices for the pump and seed fields.

The standard method of poling a non-linear medium is to pole the crystal at intervals equal to the coherence length. This is known as *first order periodic poling*. Sometimes, however, it is technically not feasible to achieve first order poling. This can be due to the non-linear material requiring very large electric fields to facilitate domain inversion or it can be due to a large phase mismatch in a particular crystal direction, which results in a small coherence length [109]. If first order phase matching is not possible then third order phase matching, where the domain is flipped every 3 coherence lengths, can be attempted.

Chapter 5

Optical Cavities

In the following chapter we introduce the framework for the investigation of optical cavities using the standard methods (detailed in such works as[110, 83, 108]) and use this framework to then investigate the theoretical amount of squeezing that the cavity can produce. First, the semi-classical cavity equations of motion are derived for a simple empty, single mode optical cavity. Through simplification of these equations, the classical amplitude and phase response of this cavity are derived. Simple extension of this model allows for the derivation of the semi-classical noise response of the system. From here, the cavity equations of motion are extended to allow for a second field and the exchange of photons between these two fields, facilitated by the second order response of a non-linear medium. The relevant cavity properties and the dependence of these properties upon one another are investigated.

5.1 Cavity Equations of Motion

We begin by introducing the cavity equations of motion for a simple single mode empty cavity. This is a semi-classical approach to the problem in which we describe the time behaviour of the intra-cavity and external fields involved using the methods put forth by Gardiner and Collett [111]. Two partially transmissive mirrors, the input and output couplers, with power reflectivities of R^{in} and R^{out} respectively, and a third mirror representing the loss, $T^l = 1 - R^l$, make up the optical components. The round trip time, τ, defined as the time taken for the light to travel one round-trip of the cavity, is defined as the optical path length, L, divided by the speed of light, c, written

$$\tau[s] = \frac{L}{c}. \tag{5.1}$$

A driving field, A^{dr}, is incident on the input coupling mirror, A^{ref} is the field that reflects off the input coupler and A^{trans} is the field that exits the output coupler. We treat the cavity as an open quantum system, a system into which photons can be added, through a driving field, and photons can be irreversibly lost, through intra-cavity field decay. Cavity decay rates are a measure of the rate at which photons exit, or enter, the system. The decay rate in its entirety is an infinite Taylor expansion, from which only the first two terms are generally retained. This approximation is most accurate for high reflectivities, but for moderate to high reflectivities, it has been shown by White [112] that we can achieve reasonable accuracy by defining the cavity decay rates, κ^x, as

$$\kappa^x[s^{-1}] = \frac{1 - \sqrt{R^x}}{\tau}, \tag{5.2}$$

for any mirror, x. The setup is shown in Figure 5.1.

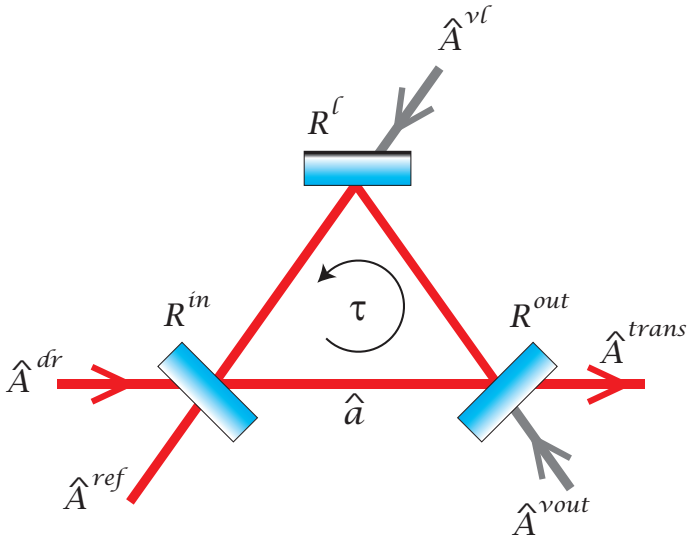

Figure 5.1: The optical cavity. Loss is modelled as transmission through one of the mirrors, $T^l = 1 - R^l$. A driving field, A^{dr}, enters the cavity through the input coupler, R^{in}. The reflected field, A^{out}, consists of the promptly reflected field and the escaping intra-cavity field, the transmitted field consists of the intra-cavity field escaping from the output mirror, with reflectivity R^{out}.

The equation of motion that describes the time evolution of the intra-cavity field, $\hat{a}$, for this system, is written [113]

$$\dot{\hat{a}} = i\Delta\hat{a} - \kappa^a\hat{a} + \sqrt{2\kappa^{in}}\hat{A}^{dr} + \sqrt{2\kappa^{out}}\hat{A}^{vout} + \sqrt{2\kappa^{l}}\hat{A}^{vl}, \tag{5.3}$$

where $\Delta = \omega_0 - \omega_A$ is the detuning of the driving field, ω_A, from the cavity resonance, ω_0, κ^{in} is the decay rate of the input coupler, κ^{out} is the decay rate of the output coupler, κ^l is the decay rate of the intra-cavity loss, $\hat{A}^{dr}$ is the external cavity driving field, and $\hat{A}^{vl}$ and $\hat{A}^{vout}$ are the external vacuum fields. The total cavity decay rate, κ^a, is defined as the sum of the individual cavity decay rates

$$\kappa^a = \kappa^{in} + \kappa^{out} + \kappa^l. \tag{5.4}$$

The external travelling fields have units of $\sqrt{\frac{\text{photons}}{s}}$ such that $\hat{A}^\dagger\hat{A}$, the number operator, gives the photons per second in the field and is thus proportional to the intensity. The intra-cavity fields have dimensions of $\sqrt{\text{photons}}$ such that $a^\dagger a$ gives the number of photons in the cavity mode.

The power in the external driving field, $\hat{A}^{dr}$, is proportional to the number of photons per second and can be determined via

$$P^{dr}[W] = \frac{\hat{A}^{\dagger dr}\hat{A}^{dr}hc}{\lambda^{dr}}, \tag{5.5}$$

where P^{dr} is the power in the external driving field, A^{dr}, in watts, h is Planck's constant, c is the speed of light, and λ^{dr} is the wavelength of the driving field.

To solve Equation 5.3 we move into the frequency domain by taking the Fourier trans-

form and find

$$i\omega\check{a} = i\Delta\check{a} - \kappa^a\check{a} + \sqrt{2\kappa^{in}}\check{A}^{dr} + \sqrt{2\kappa^{out}}\check{A}^{vout} + \sqrt{2\kappa^{l}}\check{A}^{vl}, \tag{5.6}$$

where the hats have been replaced with carons, or overturned hats, to signify that these operators are now in the frequency domain. The ω term arising from the Fourier transform is the frequency that a measurement of this state is made at, where a value of $\omega = 0$ indicates a measurement at the carrier frequency of the input field. A non-zero term implies investigation of the system when the cavity is off resonance, or equivalently, the frequency of the laser is shifted from the resonance condition of the cavity. To arrive at Equation 5.6 we make use of the identity

$$\mathcal{F}[\dot{X}(t)] = i\omega X(\omega), \tag{5.7}$$

where $\mathcal{F}[\dot{X}(t)]$ is the Fourier transform of the function $\dot{X}(t)$. Equation 5.6 can now be written

$$\check{a} = \frac{\sqrt{2\kappa^{in}}\check{A}^{dr} + \sqrt{2\kappa^{out}}\check{A}^{vout} + \sqrt{2\kappa^{l}}\check{A}^{vl}}{\kappa^a + i(\omega - \Delta)}, \tag{5.8}$$

from which the reflected and transmitted fields of the cavity can now be determined. The reflected and transmitted fields are determined using the input/output relations [111]

$$\check{A}^{ref} = \sqrt{2\kappa^{in}}\,\check{a} - \check{A}^{dr} \tag{5.9}$$

$$\check{A}^{trans} = \sqrt{2\kappa^{out}}\,\check{a} - \check{A}^{vout}. \tag{5.10}$$

This results in output fields that can be written

$$\begin{aligned}
\check{A}^{ref} &= \sqrt{2\kappa^{in}}\frac{\sqrt{2\kappa^{in}}\check{A}^{dr} + \sqrt{2\kappa^{out}}\check{A}^{vout} + \sqrt{2\kappa^{l}}\check{A}^{vl}}{\kappa^a + i(\omega - \Delta)} - \check{A}^{dr} \\
&= \frac{(2\kappa^{in} - \kappa^a - i\omega)\check{A}^{dr} + 2\sqrt{\kappa^{in}\kappa^{out}}\check{A}^{vout} + 2\sqrt{\kappa^{in}\kappa^{l}}\check{A}^{vl}}{\kappa^a + i(\omega - \Delta)}
\end{aligned} \tag{5.11}$$

$$\begin{aligned}
\check{A}^{trans} &= \sqrt{2\kappa^{out}}\frac{\sqrt{2\kappa^{in}}\check{A}^{dr} + \sqrt{2\kappa^{out}}\check{A}^{vout} + \sqrt{2\kappa^{l}}\check{A}^{vl}}{\kappa^a + i(\omega - \Delta)} - \check{A}^{vout} \\
&= \frac{2\sqrt{\kappa^{in}\kappa^{out}}\check{A}^{dr} + (2\kappa^{out} - \kappa^a - i\omega)\check{A}^{vout} + 2\sqrt{\kappa^{out}\kappa^{l}}\check{A}^{vl}}{\kappa^a + i(\omega - \Delta)}.
\end{aligned} \tag{5.12}$$

5.2 Classical Cavity Phase and Amplitude Response

Now that the equations describing the reflected and transmitted fields have been derived, we will first investigate the classical response of the cavity. This is done by ignoring the terms involving vacuum fields in Equation 5.12, $\check{A}^{vout} = \check{A}^{vl} = 0$. We also assume that the wavelength of the laser matches the resonance condition of the cavity, $\Delta = 0$. The reflected and transmitted fields can then be written

$$\check{A}^{ref} = \frac{(2\kappa^{in} - \kappa^a - i\omega)\check{A}^{dr}}{\kappa^a + i\omega} \tag{5.13}$$

$$\check{A}^{trans} = \frac{2\sqrt{\kappa^{in}\kappa^{out}}\check{A}^{dr}}{\kappa^a + i\omega}. \tag{5.14}$$

It was shown in Equation 5.5 that the intensities of these fields are proportional to the number operator. The phases of the fields can be found by taking their arguments. Figure 5.2 shows the classical response of the cavity.

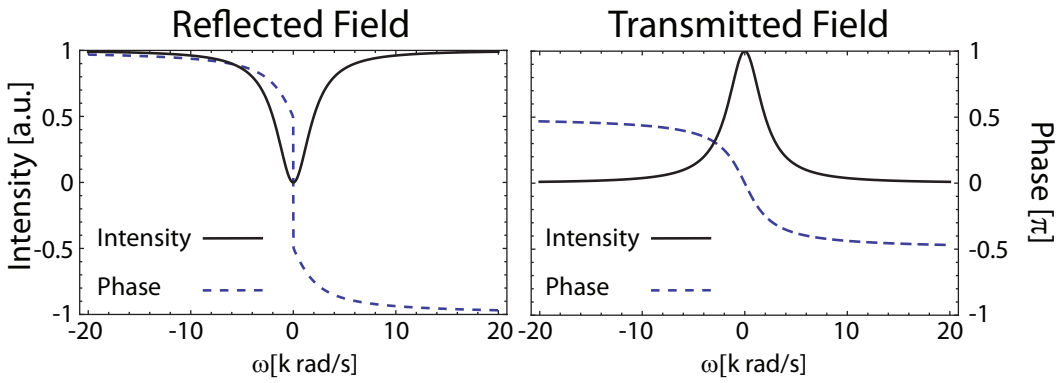

Figure 5.2: The classical response of the two-ended triangle cavity. A critically coupled, lossless cavity is chosen ($\kappa^{in} = \kappa^{out} = 1000$, $\kappa^{l} = 0$)

5.2.1 Circulating Power and Finesse

On resonance, the cavity provides enhancement of the optical field. A relationship between the incident field and the circulating field can be calculated, the result is [114]

$$\frac{P^{circ}}{P^{inc}} = \frac{1 - R^{in}}{(1-r)^2}, \tag{5.15}$$

where r is defined as the product of the square root of the reflectivity coefficients of all sources of cavity decay, in this case

$$r = \sqrt{R^{in} \times R^{out} \times R^{l}}. \tag{5.16}$$

The enhancement of the field results in a large circulating power. The circulating power is related to another cavity parameter, the finesse. For relatively high mirror reflectivities, we can define the unitless finesse of our cavity as [115]

$$\mathcal{F} = \frac{\pi\sqrt{r}}{1-r}. \tag{5.17}$$

The finesse is a measure of how efficiently the cavity resonates, which is equivalent to the number of times, on average, that the photons will bounce around the cavity before exiting the system. As can be seen in Equation 5.17, it has no dependence on the length of the cavity. In cavity systems where the intra-cavity loss is much less or similar to the intra-cavity mode loss due to the coupling mirrors, the finesse, although difficult to measure accurately, can provide a good indication of the intra-cavity loss.

The finesse is often used as a means of estimating the circulating power inside a cavity. Figure 5.3 shows the finesse and the circulating power as the power reflectivity of the input coupler is varied. The two values follow a similar trend but using the finesse as an estimate for the circulating power will result in higher circulating power, with the

discrepancy between the two values becoming larger as the finesse increases.

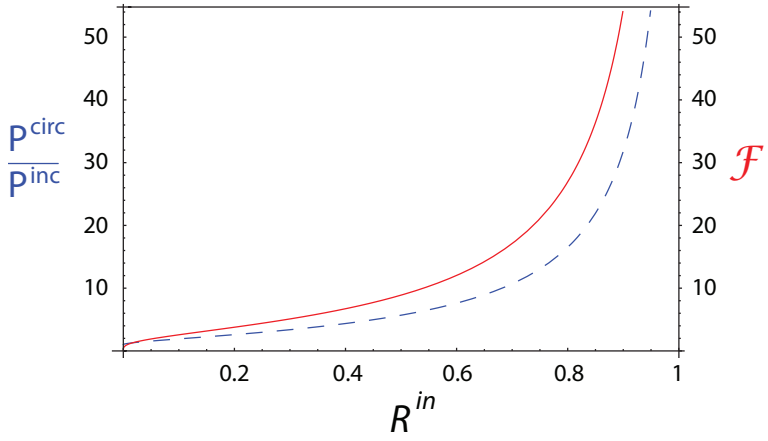

Figure 5.3: The finesse, solid red line, and the circulating power gain, dashed blue line, as the input coupler reflectivity, R^{in}, is varied.

5.2.2 Free Spectral Range

The Free Spectral Range, or FSR, of the cavity is a measure of the spacing between resonances and is defined as [75]

$$\text{FSR[Hz]} = \frac{c}{L}, \tag{5.18}$$

where c is the speed of light and L is the optical path length of one round trip of the cavity. The optical path length is the physical length multiplied by the refractive index of the material traversed through this length.

5.2.3 Linewidth

The linewidth, or Full Width at Half Maximum (FWHM), is a measure of the bandwidth of each resonance of the cavity, it can be defined as the ratio of the FSR to the finesse

$$\Delta_\nu\text{[Hz]} = \frac{\text{FSR}}{\mathcal{F}}. \tag{5.19}$$

This value is important to squeezed light generation because the bandwidth of the cavity limits the bandwidth of the squeezing produced. This is due to the fact that the bandwidth of the non-linear gain is limited by the bandwidth of the cavity. The linewidth also defines the transmission and reflection characteristics of the cavity, which plays a role in how the various locking loops are constructed.

5.3 Semi-Classical Cavity Noise Response

Investigation of Equations 5.12 in their entirety facilitates the analysis of the noise response of the cavity. This analysis includes effects originating from the vacuum fluctuations that enter the system through the various cavity decay mechanisms. The steps towards finding

an expression for the noise response of the cavity are as follows; the operators in the cavity equation of motion are first linearised, the quadrature operators are then calculated, and finally, the spectra of the fields are determined.

Linearisation follows the method described in 3.3. Note that the vacuum fields, $\check{A}^{vout}$ and $\check{A}^{vl}$, do not have any coherent amplitude and as such, linearisation of these terms results in only the first order fluctuating term. These steps results in

$$\check{A}^{ref} = \frac{(2\kappa^{in} - \kappa^a - i\omega)(\alpha^{dr} + \delta\check{A}^{dr}) + 2\sqrt{\kappa^{in}\kappa^{out}}\delta\check{A}^{vout} + 2\sqrt{\kappa^{in}\kappa^{l}}\delta\check{A}^{vl}}{\kappa^a + i\omega} \quad (5.20)$$

$$\check{A}^{trans} = \frac{2\sqrt{\kappa^{in}\kappa^{out}}(\alpha^{dr} + \delta\check{A}^{dr}) + (2\kappa^{out} - \kappa^a - i\omega)\delta\check{A}^{vout} + 2\sqrt{\kappa^{out}\kappa^{l}}\delta\check{A}^{vl}}{\kappa^a + i\omega}. \quad (5.21)$$

The next step is to calculate the quadrature operators. These were defined in Equations 3.1 and 3.2 but are written again in the frequency domain for clarity

$$\begin{aligned} \check{X}^{+} &= \mathcal{F}[\hat{X}^{+}] \\ &= \mathcal{F}[\hat{A}] + \mathcal{F}[\hat{A}^{\dagger}] \\ &= \check{A}(\omega) + \check{A}^{\dagger}(-\omega) \quad (5.22) \\ \check{X}^{-} &= \mathcal{F}[\hat{X}^{-}] \\ &= i(\mathcal{F}[\hat{A}^{\dagger}] - \mathcal{F}[\hat{A}]) \\ &= i(\check{A}^{\dagger}(-\omega) - \check{A}(\omega)). \quad (5.23) \end{aligned}$$

Equations 5.22 have been achieved using the identity [83]

$$\mathcal{F}[\hat{A}^{\dagger}(t)] = \check{A}^{\dagger}(-\omega). \quad (5.24)$$

These steps result in the quadrature operator equations. All terms without a fluctuating component are dropped because they do not contribute to the noise spectra and all second order terms are removed because, under the assumptions for linearisation (see § 3.3), these terms are small enough to be discarded, resulting in

$$\check{X}^{\pm ref} = \frac{(2\kappa^{in} - \kappa^a - i\omega)\delta\check{X}^{\pm dr} + 2\sqrt{\kappa^{in}\kappa^{out}}\delta\check{X}^{\pm vout} + 2\sqrt{\kappa^{in}\kappa^{l}}\delta\check{X}^{\pm vl}}{\kappa^a + i\omega} \quad (5.25)$$

$$\check{X}^{\pm trans} = \frac{2\sqrt{\kappa^{in}\kappa^{out}}\delta\check{X}^{\pm dr} + (2\kappa^{out} - \kappa^a - i\omega)\delta\check{X}^{\pm vout} + 2\sqrt{\kappa^{out}\kappa^{l}}\delta\check{X}^{\pm vl}}{\kappa^a + i\omega}. \quad (5.26)$$

Finally, we wish to calculate the noise spectra, $V[\omega]$, of these quadrature operators. The noise spectra is defined as the variance of the quadrature operators

$$V[\omega] = \langle \delta\check{X}^{\dagger}(\omega)\delta\check{X}(\omega)\rangle, \quad (5.27)$$

for any quadrature operator, $\check{X}$, in the frequency domain. Calculation of the noise spectra from Equations 5.25 and 5.26 results in

$$V^{\pm ref} = \frac{|2\kappa^{in} - \kappa^a - i\omega|^2 V^{\pm dr} + 4\kappa^{in}\kappa^{out} + 4\kappa^{in}\kappa^{l}}{|\kappa^a + i\omega|^2} \quad (5.28)$$

$$V^{\pm trans} = \frac{4\kappa^{in}\kappa^{out}V^{\pm dr} + |2\kappa^{out} - \kappa^a - i\omega|^2 + 4\kappa^{out}\kappa^{l}}{|\kappa^a + i\omega|^2}, \quad (5.29)$$

where the variances of the vacuum terms have been replaced with unity, the noise of the vacuum state. Using the fact that $\kappa^a = \kappa^l + \kappa^{in} + \kappa^{out}$, Equations 5.28 and 5.29 can be rearranged to the more succinct forms

$$V^{\pm ref} = 1 + \frac{((2\kappa^{in} - \kappa^a)^2 + \omega^2)(V^{\pm dr} - 1)}{(\kappa^a)^2 + \omega^2} \tag{5.30}$$

$$V^{\pm trans} = 1 + \frac{4\kappa^{in}\kappa^{out}(V^{\pm dr} - 1)}{(\kappa^a)^2 + \omega^2}. \tag{5.31}$$

The cavity noise response given by Equations 5.31 is illustrated in Figure 5.4. It can be seen that, in transmission, the cavity acts as a low pass filter around the resonance frequency. Consequently, the cavity acts as a high pass filter in reflection. Classical laser intensity noise above the characteristic frequency of the cavity can therefore be removed through the use of such a cavity. It can also be seen that the noise does not drop below the quantum noise level (QNL), where the noise is unity. This is a direct consequence of quantum mechanics that arises due to the presence of vacuum fields.

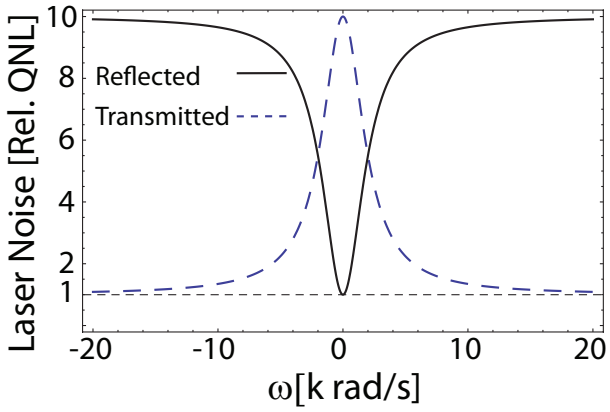

Figure 5.4: The noise response of the optical cavity. A critically coupled, lossless cavity was chosen, $\kappa^{in} = \kappa^{out} = 1000$, $\kappa^l = 0$, and the driving laser field, $\check{A}^{dr}$, has noise equal to ten times the quantum limit, $V^{dr} = 10$.

5.4 The Optical Parametric Oscillator

By extending the techniques presented up to this point, we can now investigate the squeezing response of an optical parametric oscillator. The next step is to take the equations of motion for the empty cavity (Equation 5.3) and introduce additional fields and a non-linear medium. The non-linear medium facilitates the exchange of photons between the seed and idler fields, A_1 and A_2 respectively, and the second harmonic, or pump field, A_3. The formalisms used here are those introduced by Drummond [110]. We begin by introducing the most general form of the equations that we will require and from these, derive the behaviour of the OPO. In Chapter 6 we will use these equations to investigate coherent locking. The first step is to define the equations of motion for three fields, a pump field and nondegenerate signal and idler fields, in much the same way as shown in

§ 5.1. They are written

$$\begin{aligned}
\dot{\hat{a}}_1 &= i\Delta_1\hat{a}_1 - \kappa_1\hat{a}_1 + g\hat{a}_3\hat{a}_2^\dagger + \sqrt{2\kappa_1^{in}}\hat{A}_1^{dr} + \sqrt{2\kappa_1^{out}}\hat{A}_1^{vout} + \sqrt{2\kappa_1^{l}}\hat{A}_1^{vl} \\
\dot{\hat{a}}_2 &= i\Delta_2\hat{a}_2 - \kappa_2\hat{a}_2 + g\hat{a}_3\hat{a}_1^\dagger + \sqrt{2\kappa_2^{in}}\hat{A}_2^{dr} + \sqrt{2\kappa_2^{out}}\hat{A}_2^{vout} + \sqrt{2\kappa_2^{l}}\hat{A}_2^{vl} \\
\dot{\hat{a}}_3 &= i\Delta_3\hat{a}_3 - \kappa_3\hat{a}_3 - g\hat{a}_1\hat{a}_2 + \sqrt{2\kappa_3^{in}}\hat{A}_3^{dr} + \sqrt{2\kappa_3^{out}}\delta\hat{A}_3^{vout} + \sqrt{2\kappa_3^{l}}\hat{A}_3^{vl}. \qquad (5.32)
\end{aligned}$$

Properties relating to the non-degenerate signal and idler fields are written with subscripts 1 and 2 respectively, and the pump field properties with subscript 3. The strength of the non-linear interaction is given by $g\left[s^{-\frac{1}{2}}\right]$ and describes the rate at which photons transfer between fields. The Equations in 5.32 can be used to describe the classical and quantum behaviour of OPO, NDOPA and DOPA systems. Assumptions for various operating regimes can be made which will result in simple analytical solutions to the intra-cavity field solutions. Most treatments of these equations assume that the OPO is not resonant at the pump frequency. This allows for the adiabatic elimination of the pump field, allowing one to assume $\dot{\hat{a}}_3 = 0$. This thesis investigates doubly resonant systems and as such this assumption is generally not valid.

The fact that we are operating the cavity as an OPO does however allow us to simplify the situation in other ways. First, the system is degenerate because it is vacuum seeded, with no coherent amplitude and a variance equal to unity. Finally, we choose to assume that the frequency of our fields match the resonant frequency of the cavity, removing the detuning terms, $\Delta_1 = \Delta_3 = 0$. This results in [110]

$$\begin{aligned}
\dot{\hat{a}}_1 &= -\kappa_1\hat{a}_1 + g\hat{a}_1^\dagger\hat{a}_3 + \sqrt{2\kappa_1^{in}}\delta\hat{A}_1^{dr} + \sqrt{2\kappa_1^{out}}\delta\hat{A}_1^{vout} + \sqrt{2\kappa_1^{l}}\delta\hat{A}_1^{vl} \\
\dot{\hat{a}}_3 &= -\kappa_3\hat{a}_3 - \frac{g}{2}\hat{a}_1\hat{a}_1 + \sqrt{2\kappa_3^{in}}\hat{A}_3^{dr} + \sqrt{2\kappa_3^{out}}\delta\hat{A}_3^{vout} + \sqrt{2\kappa_3^{l}}\delta\hat{A}_3^{vl}. \qquad (5.33)
\end{aligned}$$

Although we are operating as an OPO, the coherent amplitude of the seed field, $\alpha_1 = 0$, has not yet been removed because it will be used to illustrate noise couplings in Appendix 1. The next step is to linearise the field operators and remove all second order fluctuation terms and terms that have no fluctuating component. At this point we also make the assumption that the coherent amplitude terms are real. This assumption is valid assuming two things; that the driving fields are real, and that the OPO is operated below threshold. It can be shown that below threshold, the phase of the intra-cavity fields follows the phase of the driving fields [110]. In intra-cavity field units, the threshold of the OPO is defined as

$$a_3^{crit} = \frac{\kappa_1\kappa_3}{g}, \qquad (5.34)$$

whilst the external cavity threshold is written

$$A_3^{crit} = \frac{\kappa_1\kappa_3}{g\sqrt{2k_3^{in}}}, \qquad (5.35)$$

and the threshold in terms of pump field driving power is written

$$P_3^{crit}[W] = \left(\frac{\kappa_1\kappa_3}{g\sqrt{2k_3^{in}}}\right)^2 \frac{hc}{\lambda_3}. \tag{5.36}$$

The OPO threshold defines a point where the system enters a new mode of operation. It is the point where the round trip loss of the generated field at the fundamental frequency is equal to the round trip gain from the non-linear down-conversion of pump photons into fundamental photons. Operating near to this point, but not over it, produces stronger levels of squeezing as more photon pairs are produced. Above this point, the cavity can behave erratically and new noise couplings are introduced [116].

The next assumption made is that the non-linear interaction term is real. This assumes perfect phase matching within the non-linear medium which relies on sufficient temperature control and is a reasonable assumption for most OPO systems. Making these simplifications and calculating the hermitian conjugate of the intra cavity fields results in

$$\begin{aligned}
\delta\dot{\hat{a}}_1 &= -\kappa_1\delta\hat{a}_1 + g\alpha_1\delta\hat{a}_3 + g\alpha_3\delta\hat{a}_1^\dagger + \sqrt{2\kappa_1^{in}}\delta\hat{A}_1^{dr} + \sqrt{2\kappa_1^{out}}\delta\hat{A}_1^{vout} + \sqrt{2\kappa_1^{l}}\delta\hat{A}_1^{vl} \\
\delta\dot{\hat{a}}_1^\dagger &= -\kappa_1\delta\hat{a}_1^\dagger + g\alpha_1\delta\hat{a}_3 + g\alpha_3\delta\hat{a}_1 + \sqrt{2\kappa_1^{in}}\delta\hat{A}_1^{\dagger dr} + \sqrt{2\kappa_1^{out}}\delta\hat{A}_1^{\dagger vout} + \sqrt{2\kappa_1^{l}}\delta\hat{A}_1^{\dagger vl} \\
\delta\dot{\hat{a}}_3 &= -\kappa_3\delta\hat{a}_3 - g\alpha_1\delta\hat{a}_1 + \sqrt{2\kappa_3^{in}}\delta\hat{A}_3^{dr} + \sqrt{2\kappa_3^{out}}\delta\hat{A}_3^{vout} + \sqrt{2\kappa_3^{l}}\delta\hat{A}_3^{vl} \\
\delta\dot{\hat{a}}_3^\dagger &= -\kappa_3\delta\hat{a}_3^\dagger - g\alpha_1\delta\hat{a}_1^\dagger + \sqrt{2\kappa_3^{in}}\delta\hat{A}_3^{\dagger dr} + \sqrt{2\kappa_3^{out}}\delta\hat{A}_3^{\dagger vout} + \sqrt{2\kappa_3^{l}}\delta\hat{A}_3^{\dagger vl}.
\end{aligned} \tag{5.37}$$

From these equations we can now write the amplitude and phase quadrature operator equations of motion using Equations 3.1 and 3.2. For our purposes, it is sufficient to determine only one of the quadrature operators. It can be shown that the sign of the non-linear interaction term, g, completely determines whether one observes the amplitude or phase quadrature output variances [83]. The amplitude quadrature noise operators can be written

$$\begin{aligned}
\delta\dot{\hat{X}}_1 &= -\kappa_1\delta\hat{X}_1 + g\alpha_1\delta\hat{X}_3 + g\alpha_3\delta\hat{X}_1^\dagger + \sqrt{2\kappa_1^{in}}\delta\hat{X}_1^{dr} + \sqrt{2\kappa_1^{out}}\delta\hat{X}_1^{vout} + \sqrt{2\kappa_1^{l}}\delta\hat{X}_1^{vl} \\
\delta\dot{\hat{X}}_3 &= -\kappa_3\delta\hat{X}_3 - g\alpha_1\delta\hat{X}_1 + \sqrt{2\kappa_3^{in}}\delta\hat{X}_3^{dr} + \sqrt{2\kappa_3^{out}}\delta\hat{X}_3^{vout} + \sqrt{2\kappa_3^{l}}\delta\hat{X}_3^{vl}.
\end{aligned} \tag{5.38}$$

Now we take the Fourier transform of Equations 5.38 to transform the quadrature operators into the frequency domain such that we can determine the spectra. It is important to note that two of these operators are still in intra-cavity units, $\delta\check{X}_1$ and $\delta\check{X}_3$, whilst the rest are in travelling wave units. Taking the Fourier transform results in

$$\begin{aligned}
i\omega\delta\check{X}_1 &= -\kappa_1\delta\check{X}_1 + g\alpha_1\delta\check{X}_3 + g\alpha_3\delta\check{X}_1^\dagger + \sqrt{2\kappa_1^{in}}\delta\check{X}_1^{dr} + \sqrt{2\kappa_1^{out}}\delta\check{X}_1^{vout} + \sqrt{2\kappa_1^{l}}\delta\check{X}_1^{vl} \\
i\omega\delta\check{X}_3 &= -\kappa_3\delta\check{X}_3 - g\alpha_1\delta\check{X}_1 + \sqrt{2\kappa_3^{in}}\delta\check{X}_3^{dr} + \sqrt{2\kappa_3^{out}}\delta\check{X}_3^{vout} + \sqrt{2\kappa_3^{l}}\delta\check{X}_3^{vl}.
\end{aligned} \tag{5.39}$$

We want to solve these equations for the intra-cavity field quadratures, $\delta\check{X}_1$ and $\delta\check{X}_3$. At this point we will set the coherent amplitude of the seed field to zero, $\alpha_1 = 0$, and leave the details of the derivation of the intra-cavity field quadratures for Appendix 1.

The result is that we can write $\delta\check{X}_1$ as

$$\delta\check{X}_1 = \frac{\sqrt{2\kappa_1^{in}}(\kappa_3 + i\omega)}{\alpha_1\alpha_1 g^2 - (g\alpha_3 - \kappa_1 - i\omega)(\kappa_3 + i\omega)} \times \left(\delta\check{X}_1^{dr} + \frac{\sqrt{2\kappa_1^{out}}}{\sqrt{2\kappa_1^{in}}}\delta\check{X}_1^{vout} + \frac{\sqrt{2\kappa_1^{l}}}{\sqrt{2\kappa_1^{in}}}\delta\check{X}_1^{vl}\right). \quad (5.40)$$

The final steps are to use Equation 5.40 to determine the amplitude quadrature operator for the output field using the input-output relations, Equation 5.9, and then to determine the variance of the output field, using Equation 3.7. From the variance of the amplitude quadrature, one can determine the variance of the phase quadrature. The details of these steps are given in the appendix. The resulting amplitude and phase quadrature variances are

$$V_{out}^{+} = 1 + \frac{4g\kappa_1^{out}\alpha_3}{(\kappa_1 - g\alpha_3)^2 + \omega^2} \quad (5.41)$$

$$V_{out}^{-} = 1 - \frac{4g\kappa_1^{out}\alpha_3}{(\kappa_1 + g\alpha_3)^2 + \omega^2}. \quad (5.42)$$

Figure 5.5 shows the variance in the squeezed quadrature and the variance in the orthogonal anti-squeezed quadrature for various internal losses. The detection frequency, ω, is set to a value of zero because we assume that we are looking at frequencies well within the linewidth of the cavity and hence the filtering behaviour of the cavity is negligible.

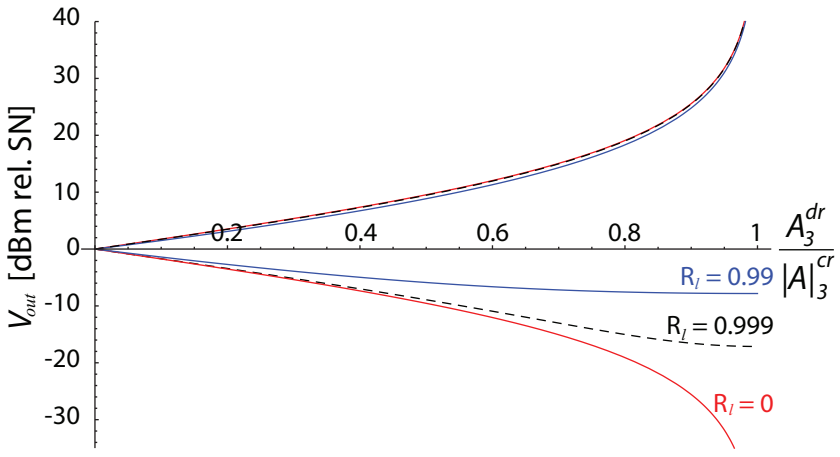

Figure 5.5: The variance of the squeezing and anti-squeezing at the output of an OPO as the system is driven towards threshold power, A_3^{crit}. The variance is shown for the same cavity with varying internal losses of; 0%, shown by the red lines, 0.1%, shown by the dotted black lines, and 1%, indicated by the blue lines. The cavity parameters are; cavity length, $L = 0.3\,\mathrm{m}$, output coupler reflectivity, $R_1^{out} = 0.95$ and input coupler reflectivity, $R_1^{out} = 1$. By setting $R_1^{out} = 1$ we have assumed that the OPO is single-ended for the fundamental field. Note that the losses and coupling reflectivities of the pump are irrelevant because we have normalised to threshold.

Figure 5.5 illustrates a number of important features of the OPO. Firstly, the squeezing gets greater the closer the OPO is to threshold. However, it is important to ensure that

the system does not drift above threshold as the system enters a new mode of operation. Second, intra-cavity loss affects the squeezing much more than it affects the anti-squeezing. This is simply due to the fact that the vacuum noise is relatively large compared to the noise of the squeezing but relatively small compared to the noise in the anti-squeezed quadrature. Mixing the state with vacuum therefore results in greater degradation of the squeezing than it does for the anti-squeezing. It is evident that the measured anti-squeezing is thus a relatively good measure of the proximity to threshold of an OPO system.

5.4.1 Escape Efficiency

The escape efficiency, η_{esc}, of an OPO is defined as the ratio of the decay rate of the squeezed field through the output coupler over the total decay rate of the cavity at the fundamental frequency

$$\eta_{esc} = \frac{\kappa_1^{out}}{\kappa_1}. \tag{5.43}$$

The escape efficiency of an OPO limits the maximum amount of squeezing that the system is capable of producing. It is essentially a measure of how many times the intra-cavity field will interact with the loss sources inside the cavity before it escapes through the output coupler. The number of round trips for the squeezed state can be quite high, therefore the intra-cavity field samples this loss many times. The effect of the escape efficiency is shown in Figure 5.6.

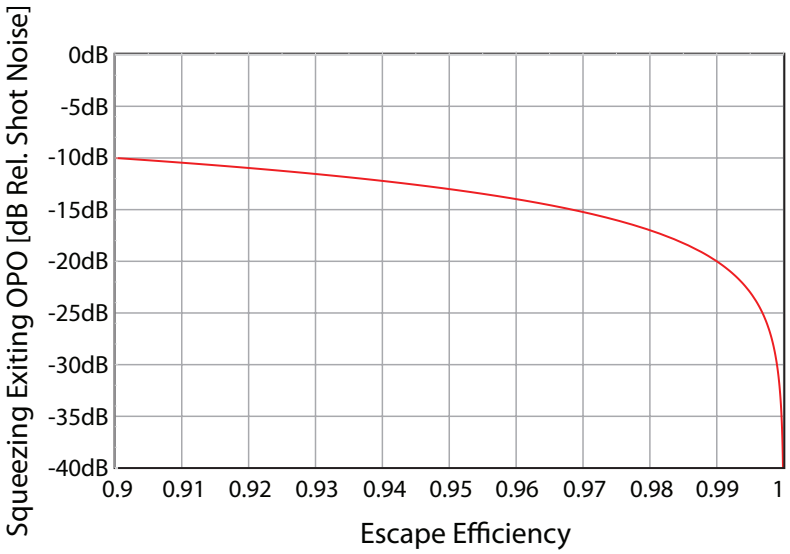

Figure 5.6: The effect of the escape efficiency on the maximum amount of squeezing that can be produced from any cavity.

There are two ways to improve the escape efficiency, one can reduce the intra-cavity losses, or one can reduce the reflectivity of the input/output coupler at the fundamental wavelength. From a design perspective, reducing the intra-cavity losses is achieved by reducing the number of surfaces that the intra-cavity field interacts with. In particular, anti-reflection (AR) coatings, tend to be relatively lossy. In this regard a monolithic cavity,

with no internal AR surfaces and one HR coating, is better than a hemilithic resonator, with two AR surfaces and one HR coating per round trip, which is better than a bow-tie cavity, with two AR surfaces and three HR coatings per round trip. However, the major source of loss is often absorption from the non-linear medium. This is why the various cavity designs can currently perform at similar levels. The best AR coatings can have a reflectivity less than 0.01% and the best HR coatings can have a reflectivity greater than 99.999%. Typical non-linear crystals currently have an absorption of approximately 0.1 % per centimetre (See Table 6.2). If advancements in crystal growing techniques result in reduced absorption, then loss from mirror coatings will become the limitation to improving the escape efficiency.

Reducing the reflectivity of the input coupling mirror in order to increase the escape efficiency unfortunately also changes other cavity parameters. Reducing the reflectivity of the input coupler will reduce the finesse of the cavity, which will increase the the linewidth and, more importantly, will also increase the threshold power of the system (this effect is later discussed in § 6.2.2). At some point it will not be possible to provide enough pump power to reach threshold. It has previously shown that the greatest levels of squeezing occur near to threshold and as such it is a requirement that we can produce an adequate amount of pump power. A solution to this problem is to move to a doubly resonant system. This enhances the pump field, reducing the required amount of driving pump power required to reach threshold. This will be explained in detail in § 6.2.1. However, large circulating powers may damage the crystal [117, 118, 119] and can lead to photothermal instabilities [60]. Squeezers typically operate in a regime where the squeezing is maximized whilst the stability of the OPO is kept at a level that is suitable for the application.

The escape efficiency is such an important parameter that it is worthwhile rearranging the squeezed field variances, Equations 5.41 and 5.42, to highlight the effect of the escape efficiency. Doing this results in

$$V_{out}^{+} = 1 + \eta_{esc}\frac{4g\alpha_3}{\kappa_1(1-\frac{g\alpha_3}{\kappa_1})^2+\frac{\omega^2}{\kappa_1}} \tag{5.44}$$

$$V_{out}^{-} = 1 - \eta_{esc}\frac{4g\alpha_3}{\kappa_1(1+\frac{g\alpha_3}{\kappa_1})^2+\frac{\omega^2}{\kappa_1}}. \tag{5.45}$$

Equations 5.44 and 5.45 illuminates the fact that the escape efficiency can be regarded as a beamsplitter operation directly after the OPO. It is often useful to consider the OPO as having produced a pure state which then passes through a beamsplitter of power transmittivity η_{esc}. The escape efficiency is then treated as another loss source on the squeezed state before detection. By treating it this way, it becomes evident that the escape efficiency completely determines the maximum amount of squeezing that a cavity system can produce.

5.5 The Classical Degenerate Optical Parametric Amplifier

Using Equations 5.32 we can also determine the behaviour of the system when operated as a degenerate optical parametric amplifier (DOPA or simply OPA). This is the case when a bright driving field is present at the fundamental frequency. The presence of a bright seed, which may temporarily be injected into an OPO setup, allows one to determine the threshold power of the system through investigation of the amplification and de-

amplification of the seed field. The equations describing the classical, degenerate OPA are written

$$\begin{aligned}\dot{\alpha}_1 &= -\kappa_1\alpha_1 + g\alpha_3\alpha_1^* + \sqrt{2\kappa_1^{in}}A_1^{dr} \\ \dot{\alpha}_3 &= -\kappa_3\alpha_3 - g\alpha_1\alpha_1 + \sqrt{2\kappa_3^{in}}A_3^{dr}.\end{aligned} \tag{5.46}$$

At this point we combine the non-linear gain term with the intra-cavity pump field and write $g\alpha_3 = G$. This is done under the assumption that the seed field is much smaller in magnitude than the pump field, $A_{dr}^1 << A_{dr}^3$, such that the pump field is not depleted by the parametric process to some approximation. This results in

$$\dot{\alpha}_1 = -\kappa_1\alpha_1 + G\alpha_1 + \sqrt{2\kappa_1^{in}}A_1^{dr}. \tag{5.47}$$

We are looking for the steady state solution, and as such set $\dot{\hat{a}}_1 = 0$ and solve for the intra-cavity field, α, resulting in

$$\alpha = \frac{\sqrt{2\kappa_1^{in}}\,(1 + G/\kappa_1)}{\kappa_1(1 - |G|^2/\kappa_1^2}A_1^{dr}. \tag{5.48}$$

This equation holds only for below threshold operation of the system. We now use the input/output relations given by Equation 5.9 to determine the output field, which is written

$$A_1^{out} = \frac{2\sqrt{\kappa_1^{in}\kappa_1^{out}}\,(1 + G/\kappa_1)}{\kappa_1\left(1 - |G|^2/\kappa_1^2\right)}A_1^{dr}. \tag{5.49}$$

The ratio of output power without the non-linear interaction to the output power with the non-linear interaction can then be calculated in order to determine the parametric gain of the system. Calculating the ratio we find

$$\begin{aligned}\frac{\mathrm{P}_1^{out}}{\mathrm{P}_1^{out}|_{G=0}} &= \frac{A_1^{out*}A_1^{out}}{A_1^{out*}|_{G=0}A_1^{out}|_{G=0}} \\ &= \frac{(1 + G/\kappa_1)^2}{\kappa_1\left(1 - |G|^2/\kappa_1^2\right)}.\end{aligned} \tag{5.50}$$

Noting that the steady state intra-cavity second harmonic field, $\alpha_3 = \frac{\sqrt{2\kappa_3^{in}}}{\kappa_3}A_3^{dr}$, divided by the intra-cavity threshold value, $\alpha_3^{crit} = \frac{\kappa_1\kappa_3}{g\sqrt{2\kappa_3^{in}}}$, results in one of the terms in this expression

$$\frac{\alpha_3}{\alpha_3^{crit}} = \frac{\kappa_1}{G}, \tag{5.51}$$

allows us to rearrange the non-linear gain into an expression written in terms of the external driving fields

$$\frac{\mathrm{P}_1^{out}}{\mathrm{P}_1^{out}|_{G=0}} = \frac{\left(1 + A_3^{dr}/|A_3^{crit}|\right)^2}{\left(1 - |A_3^{dr}|/A_3^{crit}|^2\right)}. \tag{5.52}$$

This expression will later be used to determine the threshold of our cavity systems. By changing the phase of the pump field by 180 degrees, the pump field term, A_3^{dr}, becomes negative and the system moves from amplification of the seed field to de-amplification. This effect is illustrated in Figure 5.7.

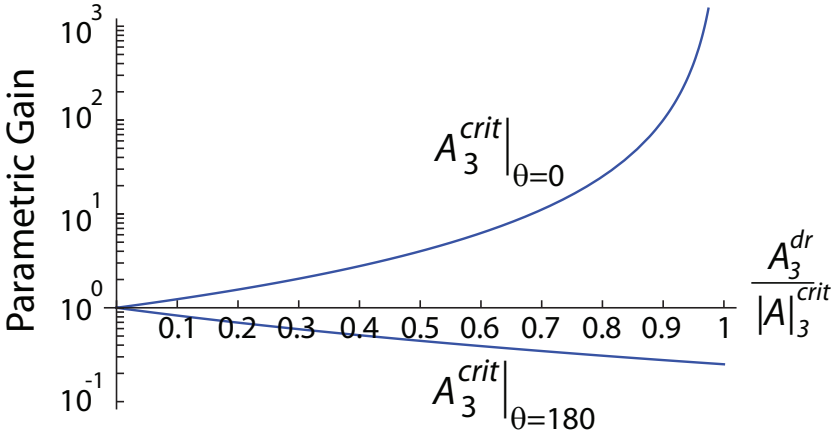

Figure 5.7: Non-linear gain of an OPA system as the input pump power, A_3^{dr}, is driven to threshold, A_3^{crit}.

Chapter 6

The Doubly Resonant Bow-Tie Optical Parametric Oscillator

In this chapter we introduce the details of the doubly resonant bow-tie OPO used to produce the results in this thesis and explain the decisions for arriving at the final design. We investigate the advantages and disadvantages of the various cavity geometries, non-linear media and cavity optical properties. The work in this chapter was undertaken by me in order to determine the optimal cavity design for the LIGO application.

6.1 Cavity Geometry

The first design consideration that we will investigate is the cavity geometry. The cavity geometry affects a number of things; the cavity mode shape, the number of HR and AR surfaces, the number of mirrors available for input and output coupling of external fields and whether the forward and reverse directions in the cavity are degenerate or not. The various cavity geometries are illustrated in Figure 6.1 for clarity.

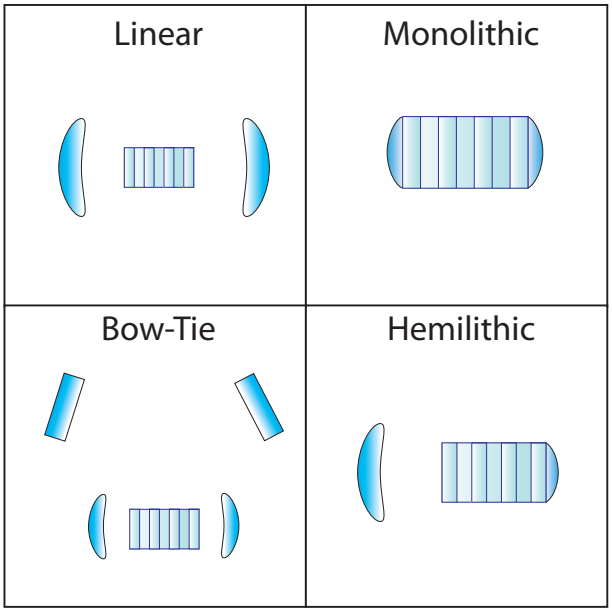

Figure 6.1: The various cavity geometries; linear, monolithic, bow-tie and hemilithic.

6.1.1 Travelling Wave vs. Standing Wave

The first decision we will investigate is whether to choose a standing wave or a travelling wave, ring cavity design. In a travelling wave design the forward and reverse directions of beam propagation exit the cavity at a different angle and hence are non-degenerate. In the standing wave case, light travelling in both the forward and reverse directions occupy the same mode when exiting the cavity. We can see from Figure 6.1 that the bow-tie cavity is a travelling wave cavity and that the three other cavities are standing wave designs.

The standing wave design has three major advantages. The first is the reduced number of surfaces per round trip. As discussed in § 5.6, reducing the number of HR and AR surfaces will reduce the intra-cavity loss and thus increase the escape efficiency. Thus, in theory standing wave cavities, particularly monolithic and hemilithic designs, are capable of producing higher levels of squeezing. However, this is only technically true provided that the loss due to the non-linear medium does not dominate the total intra-cavity loss.

The second advantage to standing wave cavities is that it is easier to make them mechanically stable due to the smaller number of optical elements and a fixed cavity geometry. An example of this is presented by Vahlbruch *et al.* [120], where a very solid modular hemilithic cavity is introduced. By design, the cavity is isolated from both air currents and thermal fluctuations. This aids in both the long term and short term stability of the cavity.

Finally, astigmatism is generally not an issue in these standing wave cavities. Due to the geometry of these cavities, there are no reflections from any curved mirrors which occur at an angle, hence astigmatism does not occur. Astigmatism can make it more difficult to match the mode of the squeezed light to the mode of the interferometer, an issue that should theoretically be relatively easy to overcome, but can also reduce the non-linear coupling between the intra-cavity fields in extreme cases.

The advantages of the bow-tie cavity are flexibility and isolation to backscatter. Access to an increased number of mirrors leaves more locations for the input and output of optical fields, providing flexibility in locking. Also, if a crystal degrades over time then a replacement crystal of the same material can be put in its place in less than a few hours without altering any of the mode matching. If a new material is desired in the setup then the separation of the curved mirrors can be altered to account for changes in refractive index of the non-linear medium and it is theoretically possible to return to a nearly identical cavity geometry.

The second advantage, and the deciding factor in choosing a bow-tie design for the work in this thesis, is the isolation to backscattered light that the travelling wave geometry affords, due to the ability of the cavity to separate the forward and reverse travelling modes. The effect is illustrated in Figure 6.2.

Figure 6.2 shows that scattered light from the interferometer may reflect at the Faraday isolator and thus be directed towards the squeezer. If this light is able to re-enter the interferometer, it will adversely impact on the sensitivity of the device. If the travelling wave cavity in the figure were to be replaced with a standing wave cavity, then virtually all of the scattered light that travels towards the squeezer will reflect off the linear cavity and re-enter the interferometer. This light will pick up random phase shifts as it travels towards the OPO, reflects off it, and travels back into the interferometer. These random phase shifts on the light are detected as a spurious signal. Additionally, this light will seed the OPO, making it operate as an OPA, which will couple pump noise into the squeezed field and degrade the low-frequency squeezing, as discussed in Appendix 1.

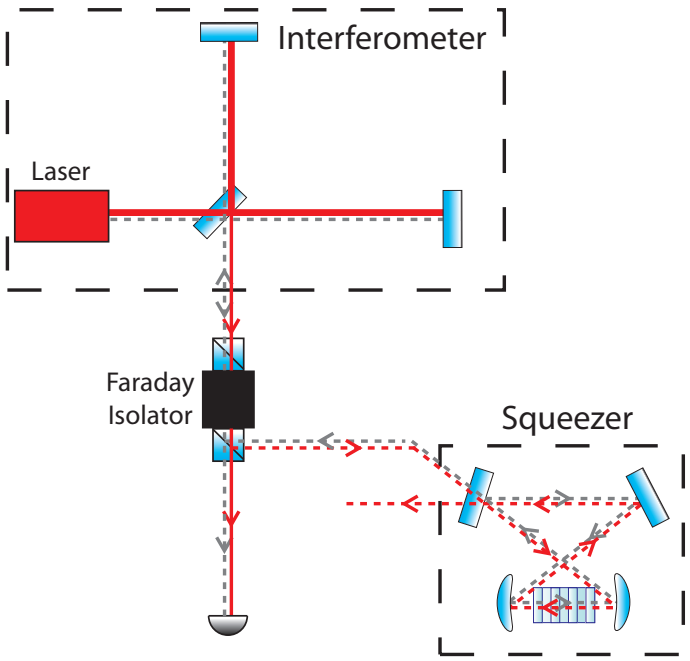

Figure 6.2: Backscattered light from the interferometer, dashed red trace, travelling towards the squeezer. The squeezed state, injected into the interferometer through a Faraday isolator in the signal path, is marked in dashed grey whilst the interferometer laser is marked in red. In the absence of scattering from within the cavity, all of the backscattered light from the interferometer does not re-enter the interferometer.

In order to remove this effect it is necessary to place a number of Faraday isolators between the interferometer and the squeezer. Unfortunately, this adds loss to the squeezed state, reducing the amount of squeezing entering the interferometer. A Faraday isolator can be expected to have an isolation factor of around 40 dB and a loss of anywhere from around 3 to 5 percent. With high levels of squeezing, this loss is substantial, particularly when multiple Faraday isolators are required.

Figure 6.2 shows that with the travelling wave design, the backscattered light from the interferometer will exit the cavity at some angle that does not direct it back towards the interferometer. The scattered light can then be dumped in order to ensure that it does not scatter again and end up being redirected towards the interferometer. Also, light that has scattered at the interferometer and enters the cavity is traversing the cavity in the opposite direction to the pump field and will not seed the OPO process.

However, it is useful to consider the experimental amount of backscattered light rejection that the travelling wave cavity affords. Scatter within the OPO may cause the backscattered light from the interferometer to enter the forward travelling mode of the cavity. If this occurs, then this light will seed the OPO and will be directed back towards the interferometer. The technical limitation to the isolation of forward (direction of propagation of the pump) and reverse modes is scatter off the intra-cavity surfaces, the mirrors and in particular the AR coatings on the crystal. The crystal is very close to normal to the beam direction and near a waist, light that reflects off this surface has a good chance of entering the cavity mode in the forward direction. The amount of isolation between the forward and reverse travelling cavity modes for the ANU squeezer has been measured at

41 dB [102]. This is nearly identical to the isolation offered by a good Faraday isolator. By using a travelling wave design, the loss outside of the cavity can therefore be reduced by an amount equal to the loss introduced by a single Faraday isolator. Different crystal geometries and super-polished cavity mirrors should increase the isolation offered.

6.1.2 Choosing a Bow-Tie Geometry

Due to the advantages detailed previously, it was decided that a bow-tie cavity was the preferred geometry. Using the standard treatment of ABCD matrices we can determine the spatial properties of the intra-cavity field for one of these cavities such that suitable cavity lengths can be found [114]. For Gaussian beams we can fully describe the beam by determining the complex beam parameter, $q(z)$, at some location z relative to the position of the beam waist z_0 as

$$q(z) = z + z_R i = \left(\frac{1}{R(z)} - \frac{i\lambda}{\pi n w(z)^2} \right)^{-1}, \tag{6.1}$$

where λ is the wavelength of the beam, $R(z)$ is the radius of curvature of the phase front, w_0 is the beam waist, n is the refractive index, $w(z)$ is the beam radius at position z and z_R is the Rayleigh range defined by

$$z_R = \frac{\pi w_0^2}{\lambda}. \tag{6.2}$$

The ABCD matrix method allows us to determine a relationship between an input field, and an output field that has undergone a system of optical elements. We can write

$$\begin{pmatrix} q_i \\ 1 \end{pmatrix} = k \begin{pmatrix} A & B \\ C & D \end{pmatrix} \begin{pmatrix} q_o \\ 1 \end{pmatrix} \tag{6.3}$$

for the input and output beam parameters, q_i and q_o, respectively, passing through an optical system with some ray transfer matrix. The k term is merely a normalisation factor to aid in manipulation of the equations. Equation 6.3 allows us to write for the input and output fields

$$q_o = \frac{Aq_i + B}{Cq_i + D}. \tag{6.4}$$

In order for the cavity to resonate, we require our beam at some location to match the shape of the beam after one round trip. This is equivalent to assuming that the beam parameter at some location, the input, is equal to the beam parameter after traversing the cavity once, the output field. Setting this requirement results in a quadratic equation for the complex beam parameter that can be solved in order to determine the complex beam parameter that matches the cavity mode.

From the complex beam parameter, one can then determine any property of the beam. The beam radius at position z is given by

$$w(z) = \sqrt{\frac{\lambda \, \mathrm{Im}[\mathrm{q_o}]}{\pi}}, \tag{6.5}$$

where $\mathrm{Im}[q_o]$ is the imaginary part of the complex parameter for the cavity mode.

The ABCD matrices for propagation of distance d through a medium of refractive index

Propagation	**Interface**	**Tangential Reflection**	**Sagittal Reflection**
$M_d = \begin{pmatrix} 1 & \frac{d}{n} \\ 0 & 1 \end{pmatrix}$	$M_i = \begin{pmatrix} 1 & 0 \\ 0 & \frac{n_1}{n_2} \end{pmatrix}$	$M_{rt} = \begin{pmatrix} 1 & d \\ \frac{-R}{2\mathrm{Cos}\theta} & 1 \end{pmatrix}$	$M_{rs} = \begin{pmatrix} 1 & d \\ \frac{-R\mathrm{Cos}\theta}{2} & 1 \end{pmatrix}$

Table 6.1: ABCD matrices for various propagation events.

n, transmission through an interface from a refractive index of n_1 into a material with a refractive index of n_2, and reflection off a spherical mirror with a radius of R are shown in Table 6.1. The reflection off the concave mirror is shown for both the tangential (in the plane of incidence between the ray and the mirror) plane and the orthogonal sagittal plane for a mirror that has an angle of θ relative to the beam axis and the normal direction.

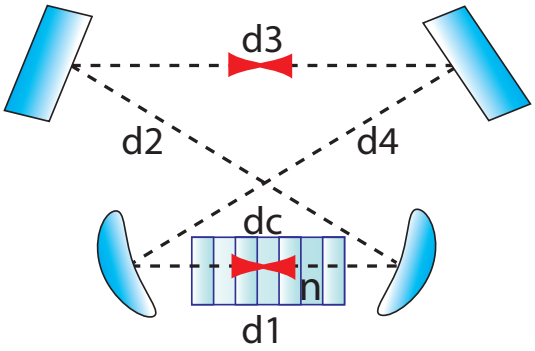

Figure 6.3: The geometry of the bow-tie cavity with the distances involved and the location of the two waists illustrated. The distance through the crystal, of refractive index n, is marked dc whilst d1 is the distance between the two curved mirrors.

The layout of the bowtie cavity is shown in Figure 6.3. The cavity consists of two curved mirrors, focussing the light to a small waist inside the non-linear crystal, and two flat mirrors. The term dc denotes the distance through the crystal whereas the remaining dx terms are used to represent the various distances from mirror to mirror in the cavity, whilst n is the refractive index of the non-linear medium. Reflection off a plane mirror is simply equal to unity. A full round-trip of the cavity for the tangential axis, beginning and ending mid-way through the non-linear medium, can thus be written

$$M = M_{dc/2} M_{i(1\to n)} M_{(d1-dc)/2} M_{rt} M_{d4} M_{d3} M_{d2} M_{rt} M_{(d1-dc)/2} M_{i(n\to 1)} M_{dc/2}, \tag{6.6}$$

where it is important to note that the refractive index as the light travels through the crystal, $M_{dc/2}$, must be accounted for and that the two interface terms vary depending on whether the material is exiting or entering the crystal. The same can be written for the sagittal plane, replacing all instances of M_{rt} with M_{rs}. The distances d2 and d4 are equal and can be determined from the angle of the bow-tie

$$d2 = d4 = \frac{d1 + d3}{2\mathrm{Cos}\theta}. \tag{6.7}$$

In order to solve this problem, we need to fix some of these parameters. The method

chosen was to set the distance between the two plane mirrors (90 millimetres), the angle of the bow-tie (twelve degrees), the radius of curvature of the curved mirrors (-38 millimetres) and then to vary the distance between the two curved mirrors. The angle of the cavity is chosen to be as small as possible in order to reduce astigmatism but not so small as to make clipping of the beam on mirror mounts an issue. The distance between the two curved mirrors was chosen after varying this value a number of times and finding a region that resulted in a suitable waist size (The waist size can be optimised using the Boyd-Kleinman method [121]). The radius of curvature of the curved mirrors was chosen to provide the necessary focussing to achieve the desired waist size without a large separation between the mirrors. A small radius of curvature is favoured such that the waist size within the crystal is small with a reasonable separation between the two mirrors.

After setting these values we can then plot the radii of the two waists of the bow-tie cavity. One waist is situated between the flat mirrors and the other between the curved mirrors. In order to determine the size of the waist outside the crystal we need only propagate the complex beam parameter through Equation 6.4 with a new transfer matrix that only transfers the beam the required distance. We can write for the propagation matrix, M2, from the crystal waist to the free-space waist

$$M2 = M_{d3/2} M_{d2} M_{rt} M_{(d1-dc)/2} M_{i(n\to 1)} M_{dc/2}, \tag{6.8}$$

where we note again that the transfer matrices have been applied in reverse order to the order of propagation of the beam.

Figure 6.4 shows the resulting waist sizes. It is evident that astigmatism within the non-linear medium is near zero for some separation between the curved mirrors. There is some astigmatism at the larger waist, situated outside the crystal, and this means that there will be astigmatism on the field exiting the cavity. This is because the portion of light that transmits through the coupling mirror has the same mode shape as the cavity mode and will therefore have an identical waist at the same distance from the mirror, albeit outside the cavity. It is important to remember that the squeezing will have this shape upon exiting the cavity when attempting to mode match the squeezed light to other fields or cavities.

Figure 6.4 shows the waist size for the cavity at the fundamental wavelength of 1064 nm. Due to the fact that we are using a quasi-phase matched system, the refractive indices for the fundamental and the pump fields are different. By changing the wavelength and the refractive index, we can repeat the process followed for the fundamental field to determine the cavity mode for the pump. The result is shown in Figure 6.5

6.2 Cavity Optical Design Considerations

Now that a cavity geometry is decided, the next step is to determine the properties of the mirror coatings. The coatings of the mirrors will dictate the loss dynamics of the optical field within the cavity, defining the escape efficiency, linewidths, finesse and threshold power for the system.

6.2.1 Doubly Resonant System

A choice must be made as to whether the system is operated in a doubly resonant configuration, one in which both the pump and fundamental fields resonate, or in a singly

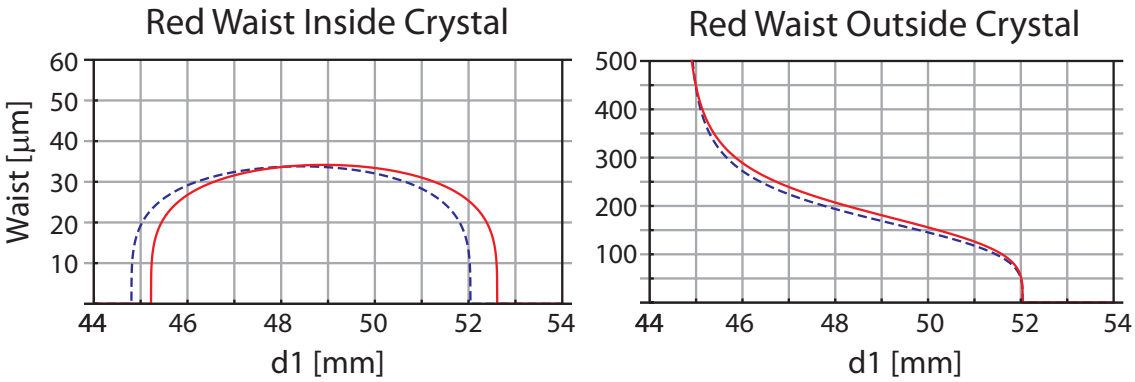

Figure 6.4: The tangential (dashed blue) and saggital (solid red) beam radii of the two fundamental waists in the bow-tie cavity as the distance between the curved mirrors, d1, is varied. The length of the crystal, dc, is 10.5 mm with a refractive index, n, of 1.830 [122]. The distance, d3, is set to 90 mm, the bow-tie cavity has an angle of 12 degrees and the curved mirrors have a radius of curvature of -38 mm.

resonant configuration, where only the fundamental field resonates. The advantages of a doubly resonant system are that the threshold pump power is reduced, the resonant green field provides an additional control field and the optimal spatial overlap between the fundamental and pump fields is ensured.

The optimal overlap between the pump field with waist w_p and fundamental field with waist w_f is given by the relation [121]

$$w_p = \sqrt{2} w_f. \tag{6.9}$$

Investigation of Equation 6.5 reveals that the cavity ensures that, on resonance, this condition is met for the two fields when using a phase matched material. This is not strictly the case for quasi-phase matched materials as will be shown in § 6.3.6. However, Figure 6.5 shows that the slight difference in refractive indices between the fundamental and pump fields has very little impact on the fundamental and pump field modes within the cavity. Figures 6.5 and 6.4 show that, with the correct separation between the curved mirrors, the waist sizes are very well matched, which is to say that Equation 6.9 holds.

As for cavity locking. The fact that the pump field is resonating allows for the pump field to be used as a reference for locking schemes, such as a Pound-Drever-Hall technique. Additionally, the pump field will likely have a different finesse to the fundamental field and may facilitate different modulation frequencies for such a lock.

Finally, the doubly resonant system is a means of reducing the threshold power. The threshold power of the cavity is given by Equation 5.36, but is written again for reference

$$P_3^{crit}[W] = \left(\frac{\kappa_1 \kappa_3}{g\sqrt{2k_3^{in}}} \right)^2 \frac{hc}{\lambda_3}. \tag{6.10}$$

By resonating the second harmonic field, we are decreasing the rate at which photons decay from the cavity, thus decreasing the value of κ_3^{in}. Expanding $\kappa_3 = \kappa_3^{in} + \kappa_3^{out} + \kappa_3^{l}$ in Equation 5.36 will result in a term proportional to $\frac{\kappa_3^{in}}{\sqrt{\kappa_3^{in}}}$, which reduces as the decay

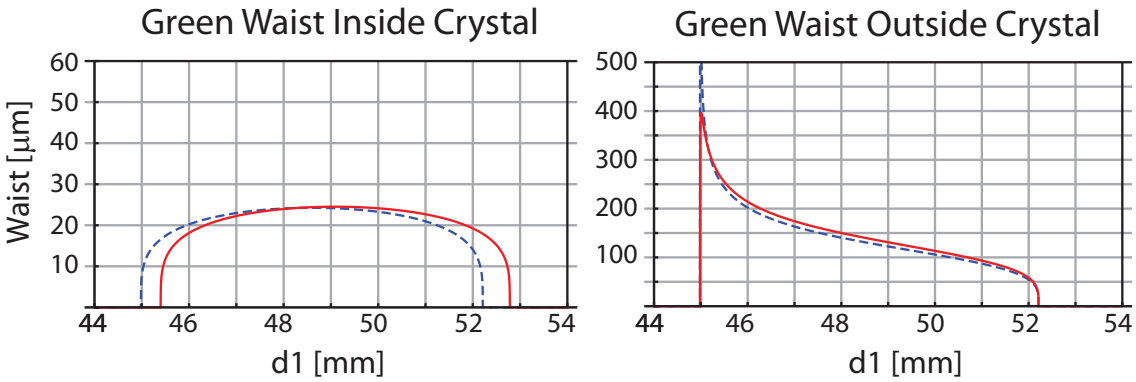

Figure 6.5: The tangential (dashed blue) and saggital (solid red) beam radii of the two pump waists in the bow-tie cavity as the distance between the curved mirrors, d1, is varied. The length of the crystal, dc, is 10.5 mm with a refractive index, n, of 1.830 [123]. The distance, d3, is set to 90 mm, the bow-tie cavity has an angle of 12 degrees and the curved mirrors have a radius of curvature of -38 mm.

rate of the input coupler reduces, thus decreasing threshold power.

The advantage to the singly resonant system is simplicity, and there are alternative solutions to many of the issues that the doubly resonant system offers. Techniques can be employed in singly resonant systems to ensure that the spatial overlap is close to optimal [97]. The threshold power can be lowered by reducing the intra-cavity loss or increasing the reflectivity of the fundamental output coupling mirror, rather than increasing the resonant enhancement of the pump. The phase matching bandwidth, the temperature over which the non-linear interaction is optimised, is also typically larger in the singly resonant case [108]. It is reduced in the doubly resonant system because a temperature shift will result in a differential phase shift on both fields. The cavity length is typically locked through deriving an error signal from one of these intra-cavity fields and hence the cavity will only track the resonance condition of that field. Finally, in the singly resonant system, no techniques are required to ensure that the pump field and fundamental field are co-resonant. Co-resonance is an issue because intra-cavity dispersion shifts the phase relationship between the two fields as they travel around the cavity.

Intra-Cavity Dispersion

The resonance condition of the cavity requires that the phase of a particular field at some location in the cavity be equal to the phase after the field has undergone a complete round-trip and returned to the same location. If the phase relationship between the two fields varies after one round trip then the two fields will now resonate at different cavity lengths. This effect is shown in Figure 6.6

We see that at location 5 the two fields now have a very different phase relationship to that when they started their journey, at location 1. A control loop designed to lock the pump field, for example, will now change the cavity length such that the phase of pump field at location 5 matches the initial phase. However, due to the changed relationship between the two fields, the fundamental field will no longer resonate. If this field is not resonant then many effects arise, but the final result is that squeezing is degraded. With this in mind, it is helpful to resonate the pump field by only a moderate amount, such

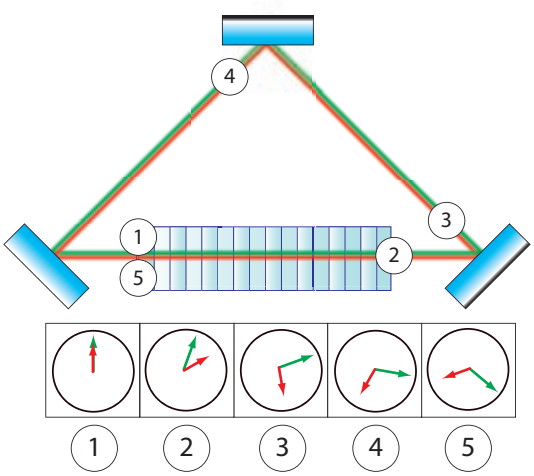

Figure 6.6: Cavity dispersion as the pump and fundamental fields traverse one round-trip of the cavity. As the fields complete one round-trip, they pick up phase shifts from each mirror surface and from the nonlinear medium. As they complete one round trip, from location 1 to location 5, the phase relationship between the two fields has changed.

that the pump field linewidth is much broader than the fundamental field linewidth, such that co-resonance is more easily achieved. By doing this, the sensitivity of the cavity to temperature and length fluctuations is reduced.

Historically, cavity dispersion between the two cavity modes has been overcome by detuning the temperature of the non-linear medium. This allows for dispersion within the material to compensate for dispersion from the various sources of dispersion. In a monolithic geometry, varying the temperature is the only method of overcoming intra-cavity dispersion. This technique is not ideal, as it forces the system away from the ideal phase matching temperature, reducing the efficiency of the non-linear process. The magnitude of this effect is dependant upon the FWHM of the non-linear conversion process, which varies significantly between materials [108].

A simple method for overcoming intra-cavity dispersion is to use a dispersion plate [124]. The dispersion plate is simply a "window" of dispersive material that has been anti-reflection coated at both wavelengths in order to minimise losses. The angle of incidence between this plate and the two fields, inside the cavity, is varied in order to change the path that the two fields travel through the material. By tuning the angle of the plate, a position can be found where the dispersion introduced by the plate compensates for that introduced by the crystal and the cavity mirrors. The disadvantage of this method is the extra loss introduced, decreasing the escape efficiency and hence the squeezing produced. Such a plate might will also likely reduce the forward to reverse direction rejection ratio of the bow-tie cavity.

An alternative method of overcoming intra-cavity dispersion, wedged quasi-phase matched crystals, is described in detail in 6.3.6. This method does not introduce additional loss or scattering into the OPO and allows the non-linear medium to operate at the optimum phase-matching temperature.

6.2.2 Escape Efficiency and the Doubly Resonant System

As mentioned previously, the bow-tie cavity has the disadvantage over other cavity designs of having a relatively larger number of HR and AR surfaces per round trip. This higher intra-cavity loss results in a decreased escape efficiency. The escape efficiency was introduced in § 5.6 and is defined

$$\eta_{esc} = \frac{\kappa_1^{out}}{\kappa_1}. \tag{6.11}$$

Seeing as the losses in the cavity cannot be easily tailored, the remaining means of increasing the escape efficiency is then to increase the decay rate of the output coupler by reducing the reflectivity of the output coupler for the squeezed field. This comes with the unwanted side-effect of increasing the threshold power, given by Equation 5.36. However, the threshold power depends upon the decay rates of both the fundamental and pump fields. By resonating the pump field, thereby decreasing the decay rate of the pump field, the threshold power can be tailored to suit the application. Figure 6.7 uses Equation 5.42 to illustrate the effect on the squeezing produced by the cavity as the reflectivity of the fundamental and pump fields are varied on a singly-ended cavity, $\kappa_1 = \kappa_1^{in/out} + \kappa_1^l$ and $\kappa_3 = \kappa_3^{in/out} + \kappa_3^l$. The sole coupling mirror has a power reflectivity for the pump of $R_3^{in/out}$ and a power reflectivity for the fundamental of $R_1^{in/out}$.

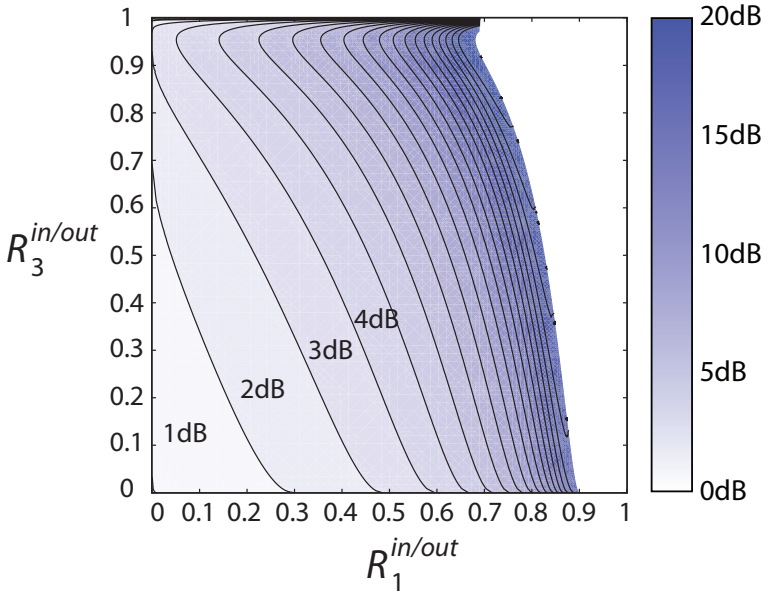

Figure 6.7: Contour plot of the vacuum squeezing produced, in dB relative to shot noise, from a singly-ended doubly resonant OPO cavity as the reflectivities of the input coupler at the fundamental, $R_1^{in/out}$, and pump, $R_3^{in/out}$, wavelengths are varied. The white region in the top right of the figure indicates the region where the system has moved above threshold. Darker regions indicate more squeezing, with each contour indicating an increase of the squeezing by 1 dB. Parameters are; cavity length $L = 0.273m$, non-linear interaction strength, $g = 1891$, intra-cavity loss at fundamental and pump, 0.26% and 4.6%, respectively, detection frequency, $\omega = 0$, and incident pump field power of 100 mW.

It is apparent that as the reflectivity of the coupling mirror at the fundamental is decreased and the escape efficiency increases, more squeezing becomes theoretically available. However, without changing the pump power, it is necessary to increase the reflectivity of the same mirror at the pump such that the incident power stays near to the threshold of the system. This can be seen by tracing the contour that separates the squeezing from the above threshold regime. This type of plot is particularly useful in situations where the maximum amount of pump power is known, as is often the case in experimental setups. The final thing to mention is that this figure does not indicate the amount of circulating pump field power. As the value of $R_3^{in/out}$ is increased, the circulating power also increases, by Equation 5.15. If the circulating power becomes too high then photothermal effects will reduce the stability of the system and may even lead to damage of the non-linear medium. This is explained in more detail in § 6.3.4.

It is important to understand the effect varying one property of the cavity system will have on the other properties. Improving one parameter often leads to the degradation of another. One of the most important and defining properties of the system is the reflectivity of the output coupler at the fundamental wavelength (or input/output coupler in the case of a singly-ended cavity). The interplay between the various parameters that depend upon the reflectivity of the input/output coupler at the fundamental wavelength for a singly ended cavity is shown in Figure 6.8. To find the right reflectivity is a balancing act between the various cavity parameters, particularly the escape efficiency and the threshold power. For example, lower threshold powers are generally preferred because of reduced photothermal effects. However, increasing $R_1^{in/out}$ to achieve this, decreases the escape efficiency and the linewidth, and increases the finesse.

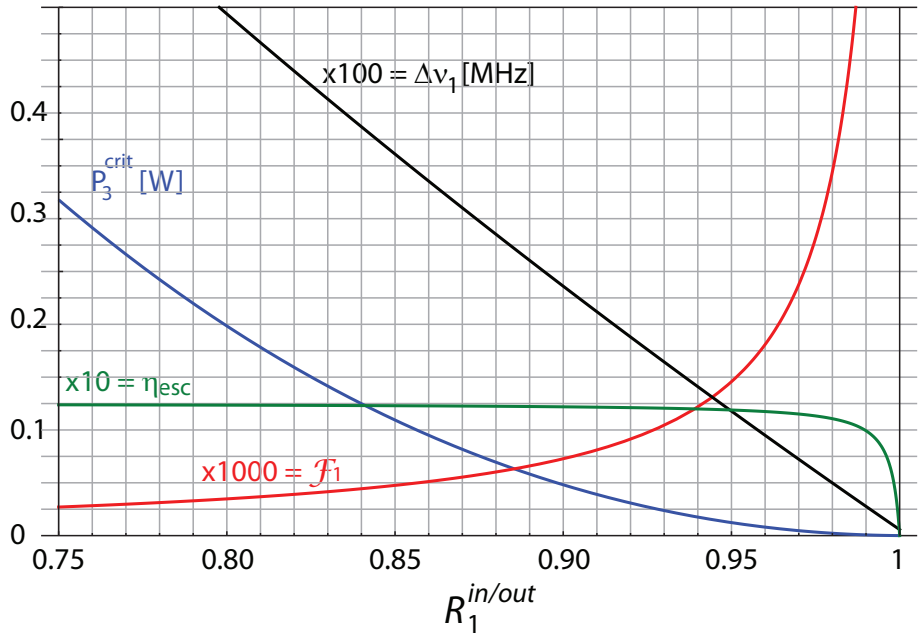

Figure 6.8: The fundamental finesse, $\mathcal{F}_1$, fundamental linewidth, $\Delta\nu_1$, escape efficiency, η_{esc}, and the threshold power P_3^{crit} of the cavity as the reflectivities of the input/output coupler for the fundamental, $R_1^{in/out}$, is varied. Parameters are; cavity length $L = 0.273m$, non-linear interaction strength, $g = 1891$, reflectivity of the input/output coupler at the pump wavelength, $R_3^{in/out} = 0.722$, and intra-cavity loss at fundamental and pump, 0.26% and 4.6%, respectively.

6.2.3 Linewidths and Finesse

The linewidth of the cavity at the fundamental wavelength was tailored specifically for the coherent locking field used. The cavity mirrors and length were chosen such that the linewidth was 25.9 MHz, placing the coherent locking field, which is detuned from the carrier frequency by 29.8 MHz, just outside the cavity linewidth. This will be explained in more detail in § 7.4 but the philosophy was to ensure that the coherent locking field inside the cavity was kept as small as possible. The linewidth of the cavity at the pump frequency was 71 MHz, chosen to be as broad as possible to ensure that the non-linear gain sensed by the coherent locking field was as large as possible. However, increasing the linewidth of the cavity at the pump frequency increases the necessary pump power to reach threshold, and the PDH lock controlling the cavity length on this field performs better with higher finesse, and hence smaller linewidth, cavities.

6.2.4 Threshold Power

As mentioned in the section on escape efficiency (§ 6.2.2), increasing the escape efficiency by reducing the reflectivity of the fundamental coupling mirror, $R_1^{in/out}$, results in a higher threshold power. This effect can be counteracted by increasing the reflectivity of this coupler at the pump frequency. Figure 6.9 has the same parameters as Figure 6.7, but this time shows the threshold power as the reflectivity at the fundamental and pump frequencies is varied.

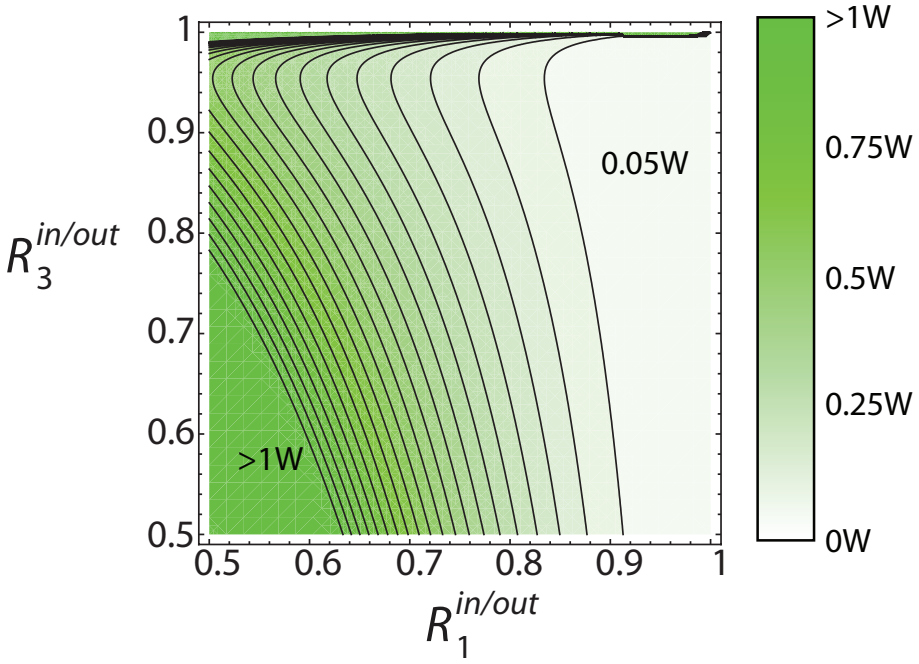

Figure 6.9: Contour plot of threshold power, P_3^{crit}[W], for a singly-ended doubly resonant OPO cavity as the reflectivities of the input coupler at the fundamental, $R_1^{in/out}$, and pump ,$R_3^{in/out}$, wavelengths are varied. Greener regions indicate a higher threshold, with each contour indicating an increase in the threshold power of 50 mW. Parameters are; cavity length $L = 0.273$m, non-linear interaction strength, $g = 1891$, intra-cavity loss at fundamental and pump, 0.26% and 4.6%, respectively.

It can be seen that the threshold power depends very strongly upon the reflectivity of the coupling mirror. As the reflectivity at the fundamental drops below a value of around 0.8, the threshold increases very quickly and the system becomes impractical. Increasing the reflectivity of this mirror at the second harmonic reduces the threshold value but will also increase the circulating power. An operating condition must be found where the escape efficiency and the threshold power are both reasonable.

6.3 Non-Linear Crystal Considerations

There are many choices of non-linear crystals available when building an OPO. The ideal material would possess high non-linear gain, low absorption and a high damage threshold. Below is a summary of the properties of some of the more commonly used periodically poled materials. Many of the absorption values are for materials that have not been periodically poled. A number of experiments have qualitatively found the absorption in periodically poled materials to be nearly identical to those without poling [109]. Multiplying the GRIIRA values by the absorption of the medium in the absence of green light results in the absorption value found in the presence of a 532 nm pump field.

Crystal	**n**	d_{eff} **[pm/V]**	α **[%/cm]**	**Dam. [W/cm^2]**	GRIIRA
PPMgO:LN	2.1494//2.2279	15.9	< 0.1 [125]	> 400 [126]	1 [127]
PPKTP	1.8296//1.8868	9.3	0.02 [109]	89k [128]	7 [109]
PPLT	2.1399//2.2078	8.8	0.1 [129]		1 [125]
PPKN	2.1201//2.2041	12.5	< 0.5 [130]		

Table 6.2: Crystal properties of some of the more commonly used periodically poled materials; the refractive indices, n, non-linear strength, d_{eff}, absorption, α, damage threshold, Dam., and green induced infra-red absorption, GRIIRA. Values for refractive indices and non-linear coefficients are from Shoji *et al.* [122]. Values which could not be found or verified have been left blank.

A periodically poled material was necessary for the cavity because a doubly resonant system was desired and dispersion compensation was to be achieved through the use of a wedged crystal. This is explained in detail in § 6.3.6.

6.3.1 Periodic Poling and Non-Linear Strength

Periodic poling was introduced in § 4.5.2. It is a means of achieving quasi-phase matching within a material. Periodically poled materials typically exhibit larger non-linear interaction strengths than their birefringent matched counterparts due to the fact that the poling can be designed for use with the optimal non-linear coefficient of the crystal. Birefringent phase matching [131], requires cutting the crystal at a particular angle such that the refractive indices of the fundamental and pump fields are equal at some temperature. The temperature at which birefringent phase matching occurs can also be rather inconvenient, as in the case of lithium niobate, whose phase matching temperature is 60 degrees Celsius or higher [108]. With periodic poling the quasi-phase matching temperature can be chosen by varying the domain size of the poling, choosing them to match the coherence length (defined in Equation 4.13) at a particular temperature. The limitation to this is when the domain periods required become too small to physically manufacture.

6.3.2 Absorption and Scattering

As discussed in § 5.6, the loss due to the crystal is often the limiting factor for the amount of squeezing that a system can produce. With this in mind, it is important to choose a non-linear material with as small an absorption coefficient as possible. Table 6.2 shows the expected absorption values for the various non-linear materials. These values are difficult to measure and as such there are limited papers detailing these properties. Quoted values for these materials can vary substantially, and is likely related to the specific growth conditions. This makes it hard to get a good estimate on the actual absorption one might expect. From experience, the loss can also vary greatly between different crystal growth batches. Local defects in the materials can have an enormous impact on the crystal loss. It is often necessary to translate individual crystals and search for the location where the intra-cavity loss is at a minimum.

6.3.3 Green Induced Infra-Red Absorption (GRIIRA)

Many non-linear materials exhibit a property known as GRIIRA. In the presence of green light, the absorption of these materials in the infra-red increases. The phenomenon has been studied in detail for many materials and is believed to be due to the formation of "colour centres" [127, 125, 132, 109]. The infrared absorption for some materials can increase by as much as a factor of 35 in the presence of green light [125] and as such it is worth understanding which materials exhibit this property and how it can be avoided.

Wang [109] meaured the GRIIRA response of KTP and PPKTP after illumination with a 532 nm pump intensity of 320 $\mathrm{MW/cm^2}$. In this material, the absorption of KTP was seen to increase by greater than a factor of 5 and the absorption of PPKTP was seen to increase by greater than a factor of 7. In the absence of GRIIRA the absorption of this material is that quoted in table 6.2, a value of 0.2 %/cm. GRIIRA in lithium niobate was a limiting factor until it became standard practice to dope the crystal with magnesium oxide. Furukawa *et al.* [127] showed that with sufficient doping, GRIIRA could essentially be eliminated from both congruent and stoichiometric growths of lithium niobate.

GRIIRA has been studied well enough that in most commonly used materials GRIIRA is no longer an issue under standard operating conditions. It is worth noting, however, that loss in PPMgO:LN may be less than in PPKTP under high circulating pump fields at 532 nm.

6.3.4 Damage Threshold and Photothermal Effects

The powers used in these experiments are typically very far from the damage threshold of the crystals. With a typical circulating power gain of 10 for the pump field in a doubly resonant system, a threshold power of 200 mW and a waist size of 30 μm, the intensity of the light hitting the non-linear medium is approximately 0.7 $\mathrm{kW/cm^2}$ at threshold. This is very close to the damage threshold of non-doped congruent lithium niobate, at 1 $\mathrm{kW/cm^2}$ [127], but most lithium niobate crystals are now doped in order to increase this value. Doped and/or stoichiometric growths can lead to lithium niobate damage thresholds greater than 8000 $\mathrm{kW/cm^2}$ [127]. For comparison, potassium titanyl phosphate is reported to have a damage threshold of 41 $\mathrm{MW/cm^2}$ [128]. Interestingly, periodic poling can also increase the damage threshold of both KTP and LN [128]. These power levels are generally not reached in OPO setups because photothermal effects, such as lensing and localised heating, from the relatively high absorption of the pump field in most of these

materials, will destroy the stability of the OPO well before the large laser powers needed to damage the crystal are ever reached.

6.3.5 Grey Tracking

Whilst the damage threshold of KTP is generally considered significantly higher than that for LN, it can exhibit a phenomenon known as grey tracking. Grey tracking, or photochromic damage, is not completely understood but it is an effect whereby the refractive index of the material and the loss changes after some time of exposure to bright radiation [118, 117, 119]. It has been shown that grey tracking only occurs in the presence of both fundamental and second harmonic fields [117] and that it also occurs in non-degenerate OPA systems. The effect can typically be removed through heating of the crystal, although long term effects of this damage have not been investigated. PPKTP is the only material from Table 6.2 that is known to exhibit this effect.

6.3.6 Wedged Crystal

In doubly resonant cavity systems, in which the pump and the fundamental field are both resonant, cavity dispersion must be overcome. Intra-cavity dispersion is introduced in detail in § 6.2.1. It was discussed that intra-cavity dispersion was historically overcome with the use of a dispersion plate but that this introduces additional intra-cavity losses.

An alternative solution, one that does not introduce additional intra-cavity loss, is to use a wedged quasi-phase matched crystals. This technique exploits the fact that quasi-phase matched materials inherently have different refractive indices for the fundamental and pump fields. At the phase matching temperature, the coherence length matches the poling length, compensating for dispersion. However, dispersion is still present. By leaving a wedged section at the end of the crystal that is free of poling, one can vary the phase relationship between the two fields as they exit the non-linear medium by shifting the crystal laterally to the path of the beams, thus varying the distance travelled through the dispersive medium. In this way, the intra-cavity dispersion can be compensated for such to ensure that the pump and the fundamental fields are co-resonant. The physical parameters of the wedged PPKTP crystals used throughout the work in this thesis are shown in Figure 6.10.

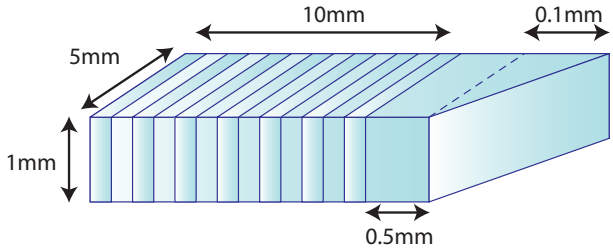

Figure 6.10: The periodically poled wedged crystal. The wedge is cut at an angle of approximately 1 degree.

One thing to note is that the wedge will cause the two fields to undergo different angles of refraction upon entering or exiting the medium due to the different refractive indices of the two fields. Using refractive indices for KTP given in Table 6.2 we can examine the

effect that the wedge will have on the propagation of the fields using Snell's law [114]. We choose to investigate only the effect on the pump field. The pump field is propagated through the non-linear medium and the cavity equations are then solved, taking into account the change in angle of incidence of the pump field on the first curved mirror it reflects off. Snell's law is written

$$n_1 \mathrm{Sin}\theta_1 = n_2 \mathrm{Sin}\theta_2, \tag{6.12}$$

where n_1 is the refractive index of air, n_2 is the refractive index of the medium, θ_1 is the angle between the normal of the mirror and the ray in free-space and θ_2 is the angle between the normal and the ray in the crystal. For the pump field we find, with a 1 degree wedge, that the refracted field has an angle of 0.53 degrees. If we then propagate this through the end of the crystal we find that the pump field exiting the crystal has an angle of 0.89 degrees from the normal. The situation is shown in Figure 6.11.

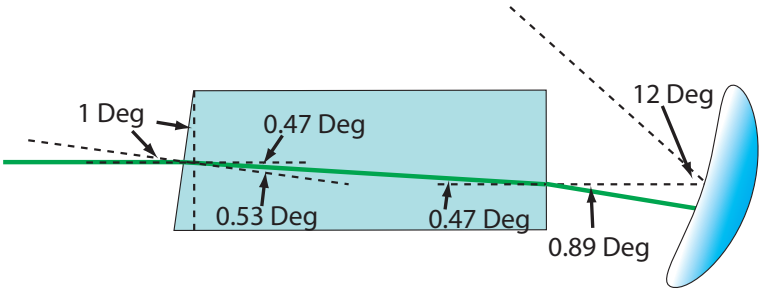

Figure 6.11: Propagation of the pump field through a PPKTP crystal with a 1 degree wedge.

To solve for the intra-cavity field then requires that the θ term describing the angle that the pump field hits the first curved mirror, matrix M_{rt} from Equation 6.6, have the additional angle from the wedge added to it before it. Without the wedge the intra-cavity pump field mode has a tangential waist of 23.81 μm that is 0.14 μm from the centre of the crystal. With the wedge, the pump mode has a tangential waist of 23.01 μm that is 0.55 μm from the centre of the crystal. The results for the sagittal waists are very similar. We therefore conclude that the wedge has only a minor effect on the intra-cavity modes.

Chapter 7

The ANU Squeezer

In this chapter the details of the squeezer that was constructed and operated at the ANU, the prototype for the LIGO squeezer, are discussed. The properties of this cavity are first introduced and the coherent locking scheme, used to control the angle of the squeezing, is modelled using the cavity equations of motion. A variant of the original coherent locking scheme, resulting in improved locking signals, is then investigated. The squeezing results from this system are presented and discussed in Chapter 8.

7.1 ANU Cavity Properties

An overview of many of the design decisions were addressed in Chapter 6 and included cavity geometry, choice of non-linear media, the escape efficiency and the physical distances between mirrors. With these in mind, the properties of the squeezer constructed at The Australian National University, henceforth referred to as the "ANU Squeezer" can be understood. A photo of the cavity is shown in Figure 7.1

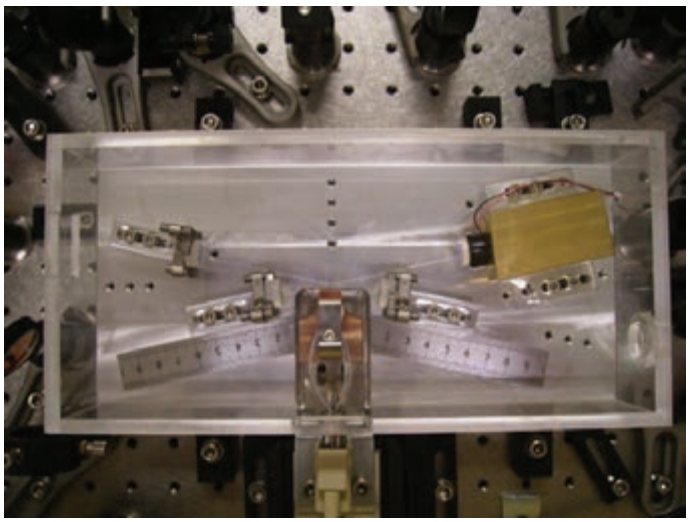

Figure 7.1: The doubly resonant, bow-tie optical parametric oscillator.

The original design for this cavity (the mirror mounts, optical layout, mounting block etc.) originates from the work of Nicolai Grosse for use in a harmonic entanglement experiment [116, 133, 80]. The general design suited our needs because of its modularity, the ability to customise the components and the fact that it was a travelling wave design.

The cavity length is controlled with a lead zirconate-titanate ceramic stack (or PZT). A number of modifications were made to the PZT mount, the crystal holder, the crystal translation stage, and the cavity length to improve upon the original setup. The design allows for easy exchange of non-linear materials, multiple input and output ports, and the ability to alter the mirror separations with ease. The layout of the cavity is shown in Figure 7.2. The design choices taken when constructing the bow-tie cavity were;

- Physical Size - One of the design philosophies was to design the OPO as small as possible after taking all other considerations into account. This was to reduce the bench space required for the device.
- Mechanical Stability - The entire cavity is constructed on a large steel block, shown in Figure 7.1. The steel block at the base of the cavity allows for easy construction and, once completed, shifting of the cavity. It allows the OPO to be a modular device and adds rigidity to the entire device.
- Angle - The folds in the bowtie cavity are designed to have an angle of 12 degrees. This angle is made as small as possible in order to reduce astigmatism. The limit on the reduction of this angle is the cavity size and clipping of mirror mounts by the beam.
- Cavity Length - The cavity length was chosen such that with the smallest angle possible, the mirror mounts would not interfere with the beam paths.

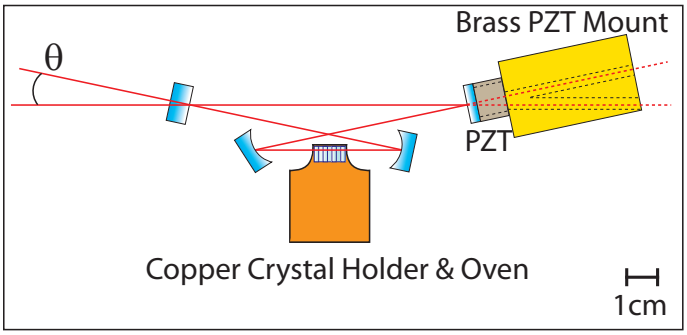

Figure 7.2: To-scale layout of the bow-tie optical parametric oscillator. The bow-tie angle, θ, is 12 degrees and the brass PZT block is cut out to allow for optical access to the back of the mirror attached to the PZT.

Three of the cavity mirrors were provided by Photon LaserOptik; the two curved HR mirrors (with radii of curvature of -38 mm) and the input/output coupler, all half an inch in diameter and 6.35 mm thick. The remaining mirror, from AT Films, was the 99.82 % reflective coherent locking mirror which was half an inch in diameter and 3.2 mm thick to reduce the weight that the PZT had to drive. The PZT is a standard ceramic stack from Piezomechanik, attached using Loctite E-30CL epoxy due to its large Young's modulus, onto a brass block. This block is hollowed such that the input and output ports of this mirror are accessible. This was done after finding that coupling through the curved mirrors had proved difficult in previous cavities. The coatings were all designed for an angle of incidence of 6 degrees to account for the 12 degree cavity angle. The cavity parameters are shown in Table 7.1

Cavity Parameter	**Symbol**	**Value**	**Uncert.**	**Units**
Fundamental Wavelength	λ_1	1064	-	nm
Second Harmonic Wavelength	λ_3	532	-	nm

Table 7.1: The properties of the ANU squeezer. The loss values given are the transmission values of loss equivalent high reflectivity mirrors. Uncertainties are given for measured values.

The parameters were chosen to optimise squeezing without sacrificing stability. The locking frequencies were chosen to match the frequencies available at the LIGO Hannford site and as such the linewidths of the cavity were tailored, as much as possible, to work with these frequencies. The following sections detail the optimisation of the non-linear medium within the cavity and the two most important measurements for defining the cavity properties, the threshold, which describes the strength of the non-linear interaction, and the intra-cavity loss.

7.1.1 Optimising the Wedged Crystal

Determining the optimum operating conditions of the non-linear medium within the squeezer is non-trivial. The position of the crystal varies the intra-cavity dispersion as well as the loss due to local defects; the temperature sets the phase matching condition; and finally, the pump power determines the amount of localised heating. Figure 7.3 shows the experimental setup used for optimising the crystal parameters within the OPO.

Figure 7.3 shows that both the fundamental (red) and pump (green) fields enter the cavity through the input coupler after combining on a dichroic mirror. The cavity length can be scanned using the PZT attached to one of the cavity mirrors and a second PZT can be driven to scan the relative phase between the fundamental and pump fields. The crystal is located on a translation mount and temperature actuation is available through utilisation of a Peltier device. Photo-detectors are used to detect the transmitted and reflected components of both laser fields. The reflected fields are separated by a second dichroic mirror.

- 1) The bottom half of 1) in Figure 7.4 shows that the crystal was set up such that the fields travelled through it at one edge to provide a position reference. The pump power was then set to the expected final operating pump power so that localised

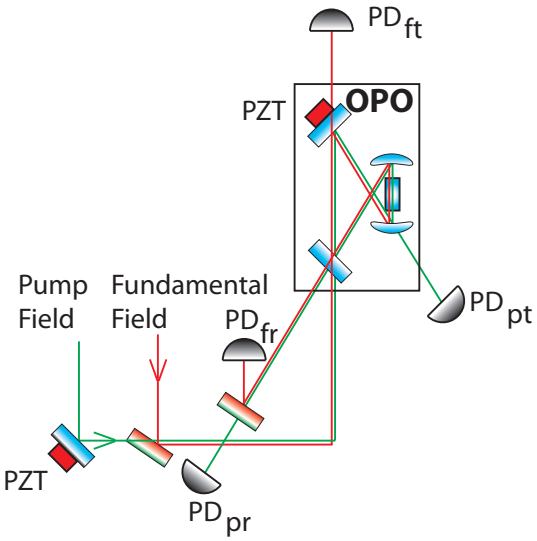

Figure 7.3: Schematic of the experimental setup used to optimise the crystal parameters within the OPO. PZT - piezo-electric transducer, PD_{ft} - transmitted fundamental field photo-detector, PD_{fr} - reflected fundamental field photo-detector, PD_{pt} - transmitted pump field photo-detector, PD_{pr} - reflected pump field photo-detector.

heating due to absorption from the pump was factored into the optimisation. A theoretical value for the threshold, allowing one to estimate the expected operating pump power, can be found using the technique described by Boyd and Kleinmann [121] or alternatively, one can estimate values from previous experiments by using information such as that shown in table 7.1. The top half of 1) illustrates the pump (green) and fundamental (red) fields detected on PD_{pt} and PD_{ft} photo-detectors respectively, as the cavity length was scanned. At this point, the temperature of the crystal had been set to the phase matching temperature specified by the manufacturer, of approximately 35 degrees Celsius. At this temperature, the two fields resonated at different cavity lengths.

- 2) To tune the dispersion such that the cavity was co-resonant for both circulating fields, the crystal was displaced relative to the circulating fields as shown in the bottom half of 2) in Figure 7.4. The crystal was translated until the transmitted fields, as monitored on PD_{pt} and PD_{pt}, showed that both fields were resonating at the same cavity length.

- 3) The co-resonance condition found by following the previous steps provides only a rough estimate for co-resonance. This is mainly due to the fact that co-resonance has been found as the cavity was being scanned and therefore the pump field, which causes localised heating and thereby introduces dispersion, does not have enough time to reach an equilibrium within the cavity. Additionally, it is not strictly co-resonance that one need to concern themselves with. To optimise the amount of squeezing, the non-linear interaction strength is the parameter that must be optimised. To optimise this, and to remove dynamical effects, the non-linear gain was then measured. This involved locking the cavity length, reducing the fundamental field power, and scanning the phase of the pump field using the second PZT. These

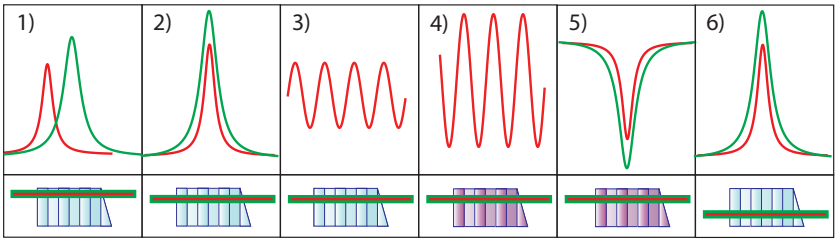

Figure 7.4: Schematic of the procedure used to optimise the temperature and position of the non-linear crystal. The top row illustrates the modelled signals (not to-scale) from various photo-detectors for the fundamental (red) and pump (green) fields (the magnitude of these signals is arbitrary and the x-axis is time). The bottom row shows the position of the laser beam through the crystal inside the cavity. Different colours for the crystal represent that the crystal temperature has changed. Full description in text.

steps are described in further detail in § 7.1.2. The signal on PD_{ft} then shows the non-linear gain of the fundamental field as the relative phase between the fundamental and pump fields was scanned.

- 4) To optimise the non-linear gain, the temperature of the crystal was then adjusted until the largest amount of gain was seen. The non-linear gain is recorded (as described in § 7.1.2.

- 5) Although the maximum non-linear interaction had then been determined, another parameter must also be addressed, loss within the crystal. The loss can change by very large amounts as the crystal is translated due to local defects in the crystal. Therefore the loss at this crystal position was measured, by unlocking and then scanning the cavity length and analysing the reflected field signals detected by PD_{pr} and PD_{fr}. The process is quite involved and so a detailed description is left for § 7.1.3.

- 6) The locally optimised non-linear interaction strength and the intra-cavity loss were then known for some position within the crystal. However, the crystal wedge was designed such that there were at least 3 locations where the beams could enter the crystal, at the phase matching temperature, and be co-resonant. The entire process was then repeated for these other locations, found by tuning the crystal to the phase matching temperature and translating the crystal to where the two fields were seen to co-resonate again. The entire process was then repeated, eventually resulting in a known crystal displacement with the lowest loss and highest non-linear interaction strength. The system was then brought back to this operating regime.

7.1.2 Measuring Threshold

The setup for measuring the non-linear gain of the OPA system is shown in Figure 7.5.

First, the pump field is blocked such that it does not enter the cavity, and the temperature of the non-linear crystal is set to approximately 20 degrees above the phase matching temperature (specified at approximately 35 degrees Celsius). The fundamental field enters the cavity, resonates and some portion is then transmitted through the cavity. This transmitted field reflects off a dichroic mirror, and is then detected on the photo-detector.

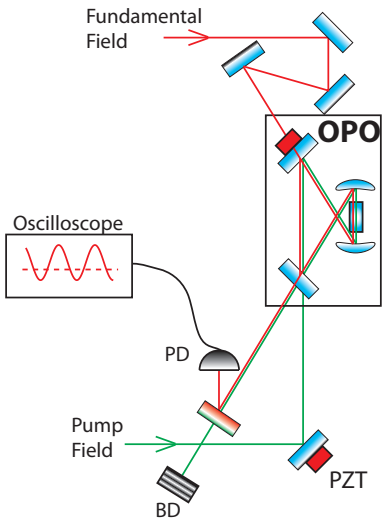

Figure 7.5: The setup for measuring the parametric gain. PD - Photo-Detector, BD - Beam Dump, PZT - Piezo-Electric Transducer.

This signal is measured on an oscilloscope and sets a reference level for the amount of transmitted cavity light in the absence of non-linear gain. Next, both the fundamental and second harmonic fields are made to enter the cavity and the temperature of the non-linear crystal is tuned to near phase matching. By scanning the phase of the pump field, using the piezo, the system is driven through amplification and de-amplification of the fundamental field (See § 5.5). The output field, consisting of light at both wavelengths, is then incident on a dichroic mirror, separating the two fields. The intensity of the fundamental field is once again detected on an oscilloscope. The resulting signal is a sinusoid showing the non-linear gain on the fundamental field. The amount of amplification and de-amplification is maximised by tuning the temperature of the crystal. By taking the ratio of the maximum and minimum voltage values of this sinusoid, with the initial reference value, one can determine the non-linear gain in both the amplification and de-amplification regimes respectively. By taking these measurements for many different pump powers, the threshold can be determined by using the theory introduced in § 5.5. The results for the ANU squeezer are shown in Figure 7.6.

The incident pump power was multiplied by the mode matching of this field to the cavity in order to get a more accurate figure on the amount of light that will actually enter the cavity and undergo cavity enhancement. The proportion of light that does not match the cavity mode simply reflects off the coupling mirror. The best fit to this data resulted in a threshold power of 118 mW for the amplification regime and a threshold of 85 mW for the de-amplification regime. The discrepancy is likely due to the fact that de-amplification is much harder to measure accurately. The signal to noise ratio is smaller because of the signal size and thus noise sources can add systematic offsets if not properly accounted for. With this in mind it was assumed that the amplification regime provided the best estimate and concluded that the squeezer had a threshold of approximately 118.0 ± 0.1 mW. Using this threshold power and the mirror properties in Table 7.1, Equation 5.36 can then be solved for the non-linear coupling term, g, to determine a value for the non-linear coupling term of $1891 \pm 9\,\mathrm{s}^{-\frac{1}{2}}$.

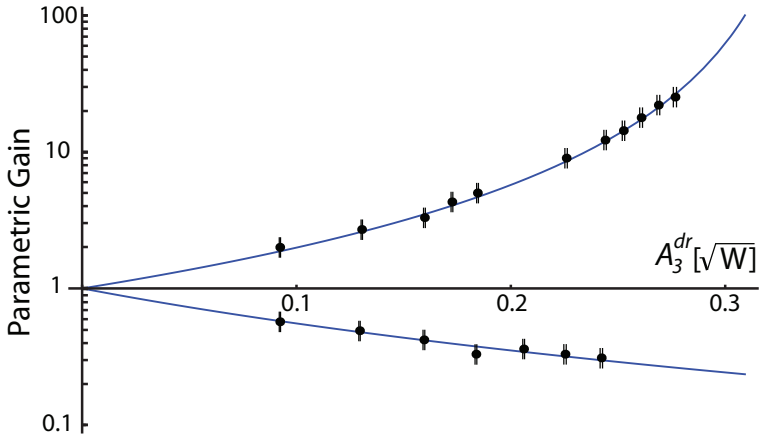

Figure 7.6: Parametric gain as a function of pump amplitude for the ANU squeezer. The points are the data and the blue curve is the best fit to Equation 5.52.

7.1.3 Measuring Intra-Cavity Loss

It has been emphasised many times that the total losses in the cavity, arising from sources such as scatter, absorption and non-unity mirror reflectivities, limit the amount of squeezing that can be produced. To get a reasonable understanding of the experiment, it is therefore necessary to characterise the intra-cavity losses as accurately as possible.

The simplest method to get an estimate for the intra-cavity losses is to measure the transmission of the individual components within the cavity, the mirrors and the crystal, in a single-pass setup. Whilst this will give a rough estimate on the losses, this method cannot provide information on scatter or absorption and the single-pass experiment cannot mimic the exact conditions in the cavity. Local defects, in particular within the non-linear medium, but also from defects in the mirror coatings, are spatially dependent and thus depend upon the beam radius as it interacts with the various loss sources, as well as the positioning of these beams on the mirrors and the positioning through the crystal. The cavity samples these loss sources many times before exiting the cavity so a method of measuring loss that utilises this fact can provide a more accurate measure than single-pass techniques.

Perhaps the most common method for determining intra-cavity losses is to measure the finesse of the cavity. Equation 5.17 shows that the finesse is dependant upon both the coupler reflectivity and the intra-cavity losses. The first step is to determine the properties of the coupler, specifically the power reflectivity. Measuring the transmissivity of an individual mirror, such as the coupler, is simple provided that the mirror is not highly reflective. This is a relative measurement (between input and output powers) and as such, any systematic error from the power meter is subtracted. If the reflectivity of the coupler were much higher, as is the case for the cavity HR mirrors, then the power reflectivity must be inferred from the transmission. By doing this, one must assume that loss from scatter and absorption is negligible, which is often valid, but as the reflectivity of the mirror increases, these effects become more important.

Now that the reflectivity of the input coupler is known, we can infer the losses of the OPO. Note that we infer the total losses of the intra-cavity system, and also that the process by which the loss occurs (such as scatter or absorption) is of no importance because

they all have the same effect on the intra-cavity field. We assume a single-ended cavity, feed a field at the fundamental frequency into the input/output coupler and investigate the reflected light as the cavity resonance frequency is scanned. Figure 7.7 shows the power of the reflected field for various intra-cavity losses, using Equation 5.14.

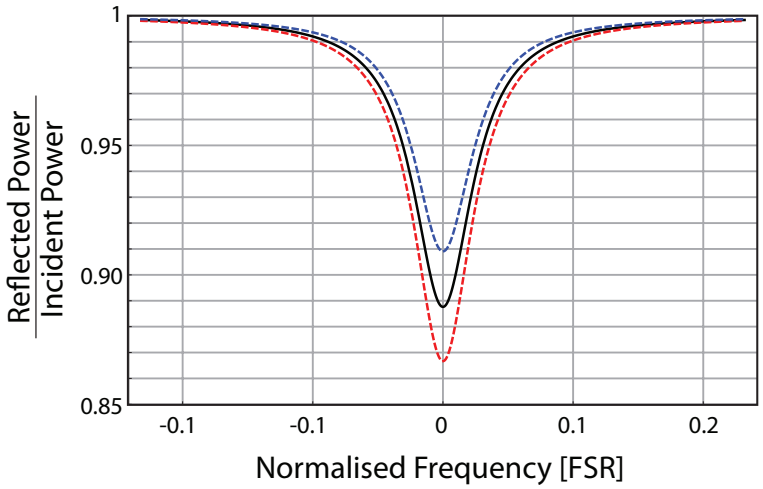

Figure 7.7: Theoretical fundamental field power response ratio of a singly-ended OPO (off phase matching). The cavity resonance conditions is scanned and the response is shown for 3 values of the total intra-cavity loss; 0.5% as the solid black line (finesse of 34.8), 0.4% as the dotted blue line (finesse of 34.6), and 0.6% as the dotted red line (finesse of 35.0).

Figure 7.7 reveals that the finesse is a poor measure of the loss. It is evident that the linewidth of the cavity response varies minutely as the intra-cavity loss changes. The reason for this is evident in how the finesse is defined, see Equation 5.17. By measuring the finesse, we are trying to measure a change in reflectivity of 0.1% on top of a reflectivity of 85% from the input/output coupler.

Additionally, resonance is typically scanned by driving a PZT. This needs to be done over an entire free spectral range in order to evaluate the finesse 5.2.3. The response of these PZTs is not linear, particularly not over a large scanning range [134]. So not only is the signal small, but the non-linear response of the PZT results in a completely unreliable measurement.

Figure 7.7 shows that the power of the reflected field on resonance is a much more sensitive measure of the intra-cavity loss. Working from Equations 5.14 we can determine the reflected power on resonance as a function of the cavity decay rates. We drop the operator notation as we are only interested in the classical behaviour of the fields and write

$$\begin{aligned} \frac{P_1^{ref}}{P_1^{dr}} &= \frac{A_1^{ref*} A_1^{ref}}{A_1^{dr*} A_1^{dr}} \\ &= \left(\frac{2\kappa_1^{in/out} - \kappa_1}{\kappa_1} \right)^2 \\ &= \left(\frac{\kappa_1^{in/out} - \kappa_1^{loss}}{\kappa_1^{in/out} + \kappa_1^{loss}} \right)^2 . \end{aligned} \tag{7.1}$$

where we have assumed that the driving power, P_1^{dr} is equal to the amount of reflected power when the cavity is off resonance. This is a valid assumption for small intra-cavity decay rates and when the cavity is far from resonance. The P_1^{ref} term, refers to the amount of power that is reflected from the cavity when it is on resonance.

The result is an equation that resembles the form of the fringe visibility, Equation 3.8.1, which is very sensitive to the loss term, $\kappa_1^{in/out}$. Determining the loss from the reflected power is very sensitive because the drop on reflection is completely due to the intra-cavity loss. In the absence of any intra-cavity loss, the reflected field equals the input field and no dip in reflection is seen. The limitation to determining the intra-cavity loss from this method is how well one can know the reflectivity of the input/output coupler. However, as noted previously, this mirror typically has a moderately low reflectivity and thus the error introduced by being unable to account for scatter and absorption is minimal.

The final note on measuring the intra-cavity loss using the reflected dip in power on resonance is the effect that imperfect mode-matching has. Imperfect mode-matching into the OPO can result in a low estimate for the loss because of the fact that any mode-mismatched light will enter the detection photodiode and provide a DC offset. The situation is shown in Figure 7.8, where the reflected power from the input/output coupler of the ANU cavity was measured as the cavity length was scanned.

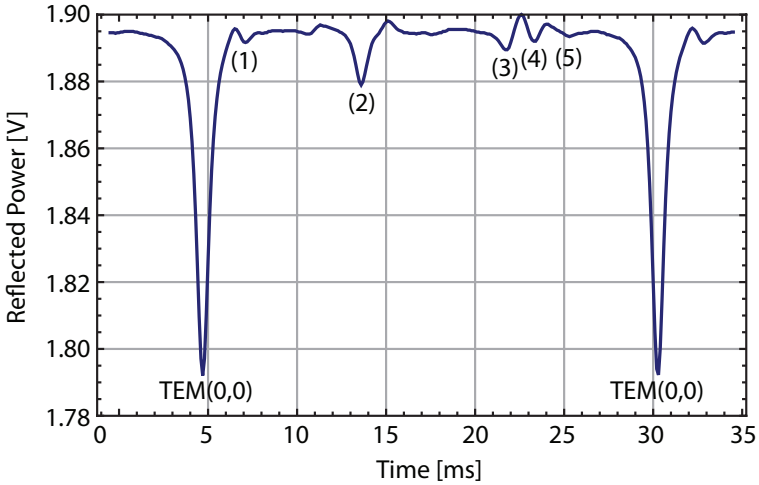

Figure 7.8: Reflected power from the OPO, in Volts, as the OPO length was scanned using a PZT. The higher order modes, modes (1)-(5), do not resonate when the cavity is locked to the TEM(0,0) mode.

We can quantify how well the light field is matched to the resonance of the cavity by defining the mode-matching value, MM, as

$$MM = \frac{MM_{(0,0)}}{MM_{(0,0)} + \sum MM_{(x,y)}}, \tag{7.2}$$

where $MM_{(0,0)}$ is the amount of light in the desired mode, in this case the (0,0) transverse electromagnetic mode, TEM$(0,0)$, and $\sum MM_{(x,y)}$ is the summation of the power in all the remaining modes. All values are measured in voltages and are relative to the maximum

reflected value. For Figure 7.8 the mode matching is written as

$$\frac{TEM(0,0)}{TEM(0,0)+((1)+(2)+(3)+(4)+(5))} = 0.784 \pm 0.003. \tag{7.3}$$

Let's assume that the cavity were off resonance, which is to say that we assume all modes $MM_{(x,y)}$ and $TEM(0,0)$ are off resonance. In this case, all of the light is reflected towards the detector. The power measured is therefore the total power of this field. When the cavity is on resonance, the reflected field consists of the reflected TEM(0,0) mode, *plus* the other modes that are not resonant at this particular cavity length. These other modes, in both cases, will result in a DC offset that needs to be subtracted. We can therefore rewrite Equation 7.1 for the case where the modematching is not perfect as

$$\frac{P_1^{ref} - \sum MM_{(x,y)}}{P_1^{dr} - \sum MM_{(x,y)}} = \frac{\left(\kappa_1^{in/out} - \kappa_1^{loss}\right)^2 - \sum MM_{(x,y)}}{\left(\kappa_1^{in/out} + \kappa_1^{loss}\right)^2 - \sum MM_{(x,y)}}. \tag{7.4}$$

This results in a loss value of 0.0026 ± 0.0001 per round-trip. Using this loss value and the coupling mirror transmission shown in Table 7.1, results in an escape efficiency of 0.985 ± 0.001.

For comparison, we can determine the estimated round-trip loss by multiplying all known loss sources from inside the cavity, the measured mirror transmission, and the expected AR coating and PPKTP absorption losses. The AR coatings on the non-linear crystal are specified at a transmission of 99.99% or higher, the PPKTP absorption was found by Wang [109] to be 0.02%/cm, and the two curved HR mirrors had a measured transmission of approximately 0.5%. The transmission of the coherent locking mirror was measured to be 0.9982 ± 0.0002. The resulting loss equivalent mirror power reflectivity is

$$\underbrace{0.9999 * 0.9999}_{2*ARCoatings} * \underbrace{0.9998}_{PPKTPAbsorption} * \underbrace{0.9995 * 0.9995}_{2*CurvedHR} * \underbrace{0.9985}_{Coh.Lock.HR} = 0.9971 \pm 0.0005. \tag{7.5}$$

Equation 7.5 shows that the resulting loss equivalent mirror is 99.71 %. Using the values for the coupling mirror and cavity length from Table 7.1, this results in an escape efficiency of 0.983 ± 0.003. As discussed, this value is not as reliable as found by measuring the ratio of the reflected power on and off resonance but the two methods do agree.

7.2 The ANU experiment

The optical layout and electronic schematic for the ANU squeezer are shown in Figures 7.9 and 7.10 respectively. The majority of the main laser power (Innolight Mephisto) is directed towards the SHG (SHG lock), with the remaining light passing through the modecleaner cavity (MC lock) and providing the light for the LO field at the homodyne detector. A beamsplitter in the LO path taps off some light to be used as a seed for measuring visibility and parametric gain. The SHG passes through a Mach-Zender setup (MZ lock) in order to stabilise the pump power before entering the OPO. The Mach-Zender was only locked when squeezing measurements spanning over many hours were desired. The reflected pump field is detected at the OPO Ref 532 photo-detector and used to control the OPO cavity length via the Pound-Drever-Hall locking technique (OPO lock). The auxiliary laser, phase locked to and frequency shifted from the main laser by

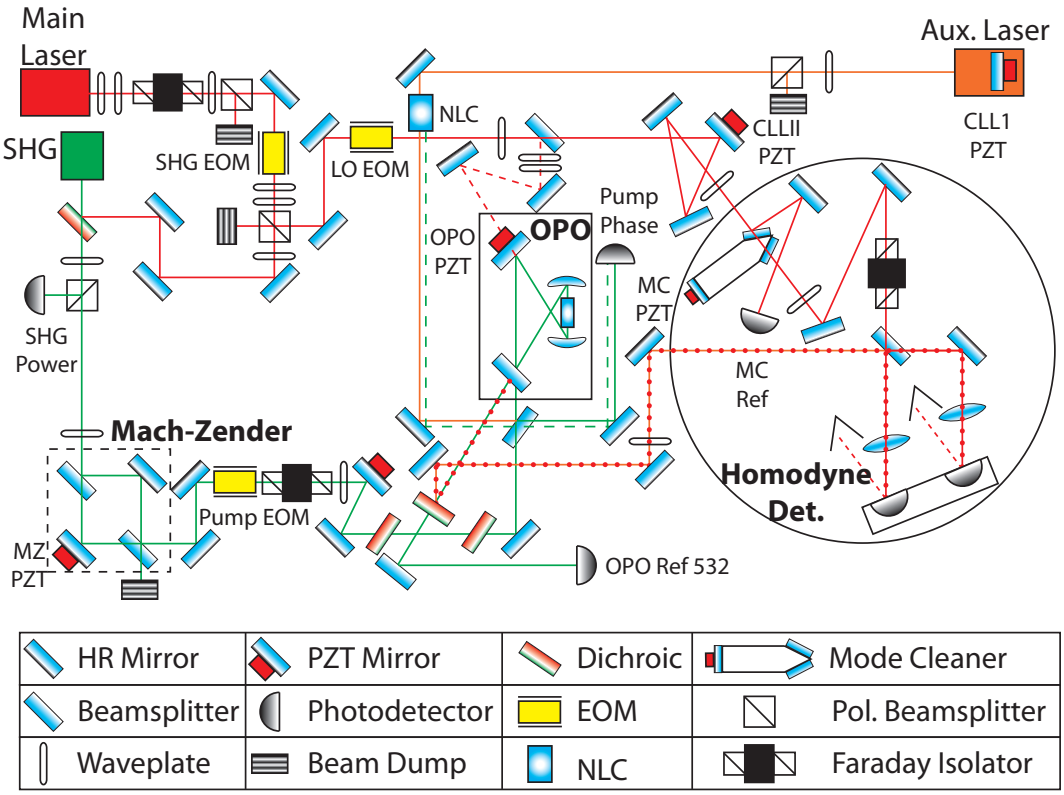

Figure 7.9: The layout of the ANU experiment. All of the optical elements apart from mode-matching lenses have been included. Red, green and orange fields are the fundamental, pump, and frequency offset auxiliary laser fields respectively. The dashed green beam is the auxiliary laser (Aux. Laser) second harmonic field, obtained after traversing a single pass through a non-linear crystal (NLC). The dotted red beam is the squeezed field. EOM is electro-optic modulator, dichroic indicates a dichroic mirror, and Pol. Beamsplitter represents a polarising beamsplitter.

29.8 MHz, makes a single pass through a PPKTP nonlinear crystal, generating a small amount of second harmonic. The second harmonic from the auxiliary laser beats, at 59.6 MHz, with some of the main laser second harmonic at the pump phase detector and is used to lock the phase of the pump field to the phase of the auxiliary laser (CLLI lock). The remaining power from the auxiliary laser enters the OPO, where it senses the nonlinear interaction and a second sideband field is generated, at -29.8 MHz. The beat between these two sidebands and the LO, at 29.8 MHz, is then used to derive an error signal to lock the phase of the LO to the phase of the auxiliary laser (CLLII lock).

The electronic loops for the ANU squeezer are shown in Figure 7.10. The second harmonic generation cavity length (SHG), Mach-Zender phase (MZ), optical parametric oscillator cavity length (OPO), the coherent locking loop phases (CLLI and CLLII), and the local oscillator mode cleaner cavity (MC) loops are all illustrated. The first half of the coherent locking loop, CLLI, locks the phase of the pump to the phase of the auxilliary laser, and the second half, CLLII, locks the phase of the local oscillator to the phase of the auxiliary laser. In the Mach-Zender loop, MZ, the SR560 preamplifier is set with a 6 dB per octave low pass filter at 3 Hz with a gain of 1. In the CLLII loop, the SR560 is set with a 6 dB per octave low pass filter at 100 Hz with a gain of 5. The servos, high voltage

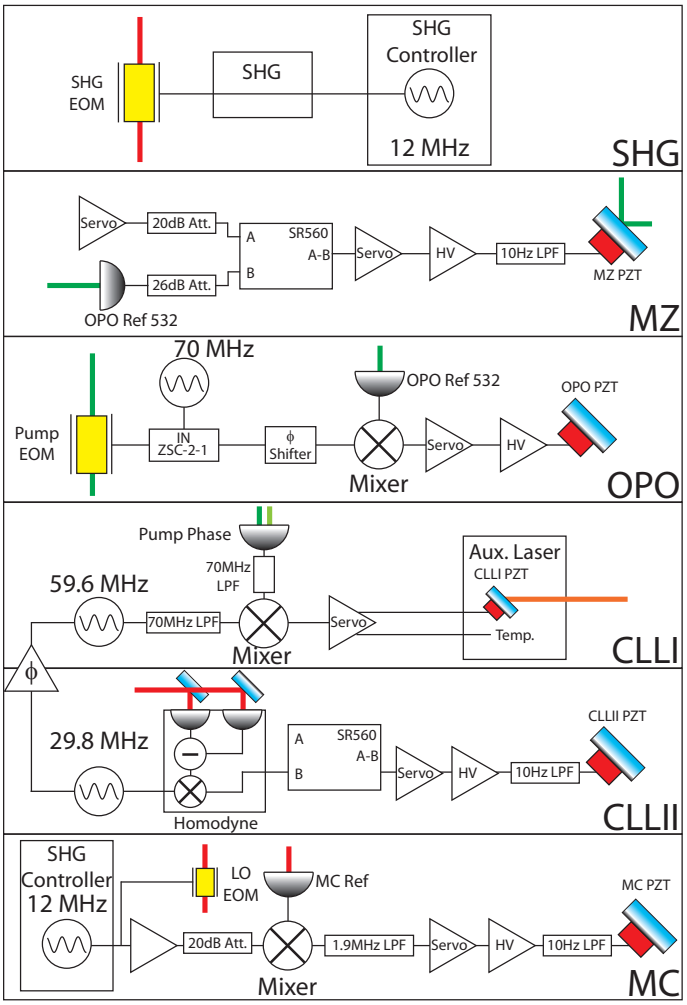

Figure 7.10: The electronics of the ANU experiment, showing the locking loops used. EOM - electro-optic modulator, HV - high voltage amplifier, SR560 - Stanford research systems preamplifier, LPF - low pass filter. Further explanation in text.

amplifiers (HV), and the phase shifter were all constructed in-house. The phase between the 29.8 MHz and 59.6 MHz frequency sources of the coherent locking loops are locked by a function within the frequency generators.

7.3 Squeezed State Control

It was shown by McKenzie *et al.* in 2004 that in order to produce squeezing in the audio detection band and below it was necessary to vacuum seed the OPO in order to remove various noise couplings [63]. This necessity is made apparent in Appendix 1, where the cavity equations of motion have been used to illustrate the relevant noise couplings. However, the presence of a bright seed allows for the use of standard modulation locking techniques in order to control the phase of the squeezing field [116]. Without a bright seed field centred about the squeezing, control of the squeezed state becomes a challenging task. In order to control the vacuum squeezing produced in the first audio-band squeezing

measurements, McKenzie used a technique known as quantum noise locking [135]. This technique was shown to work and was capable of controlling vacuum squeezed states. However, it was found that, when locking a bright squeezed state, the performance of the lock was worse than a reference technique, that of standard dither locking. The stability of the lock was shown to be limited by both the amount of squeezing and the squeezing bandwidth [135]. Unfortunately, these two parameters are not easily improved, and the amount by which they can be improved is limited. It was concluded that quantum noise locking was a useful technique but that its performance was limited.

7.4 Coherent Control

In 2006 Vahlbruch *et al.* introduced a new method for locking a vacuum squeezed state. It was a coherent control technique and is now commonly simply called *coherent locking* [66]. This locking technique derives its error signals from a bright field that enters the squeezer, but is detuned from the resonant condition of the cavity, which is at half of the pump frequency. This field can then provide information about the non-linear process within the cavity, and hence the phase of the squeezed vacuum field, without seeding the squeezing. The scheme is illustrated in Figure 7.11.

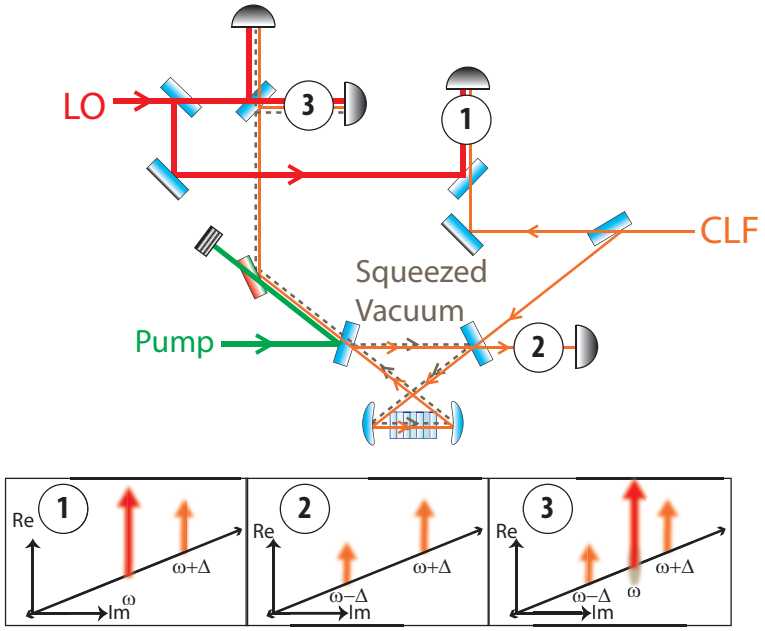

Figure 7.11: The coherent locking scheme. The fields important to the various locking loops are highlighted at locations 1,2,3. Full description of the fields and locking loops can be found in the text.

The final goal of the locking scheme is to lock the phase of the squeezing to the phase of the local oscillator. This occurs in many steps. At location 1 the auxiliary laser field, a single coherent sideband field (CSF), shifted from the fundamental frequency by an amount Δ, beats with a field from the main laser. This signal is used to offset phase lock the two lasers by the frequency Δ. This auxiliary laser is frequency offset so that the field can enter the OPO and undergo non-linear gain without seeding the process at the main laser

frequency. Inside the OPO, the CSF experiences the non-linear interaction, resulting in a generated sideband field (GSF) (See § 7.4.1). The beat between the CSF and GSF fields, at a frequency of 2Δ, is detected at location 2 and is used to lock the phase of the pump to the phase of the auxiliary laser. It will be shown in § 7.4.1 that the phase of the GSF depends upon the phase of the pump field, providing the necessary phase information from the pump field for this loop. At location 3, the CSF, GSF and co-propagating squeezing have interfered with the LO at the homodyne detector beamsplitter. The beat at the frequency Δ betweeen the CSF, GSF and LO is used to lock the phase of the LO field to the auxiliary laser. The pump field which exits the OPO is transmitted through a dichroic mirror and dumped such that it does not reach the homodyne detector.

In summary, the coherent locking scheme has one loop to lock the phase of the auxiliary laser to the main laser. It then has a second loop to lock the phase of the pump field to the phase of the auxiliary laser and a final loop to lock the phase of the LO to the phase of the auxiliary laser. This chain of loops results in the phase of the LO being locked to the phase of the pump field. In Chapter 5 it was identified that the phase of the pump field defines the angle of the squeezing. Therefore, the phase of the LO is locked to the angle of the squeezing, as desired.

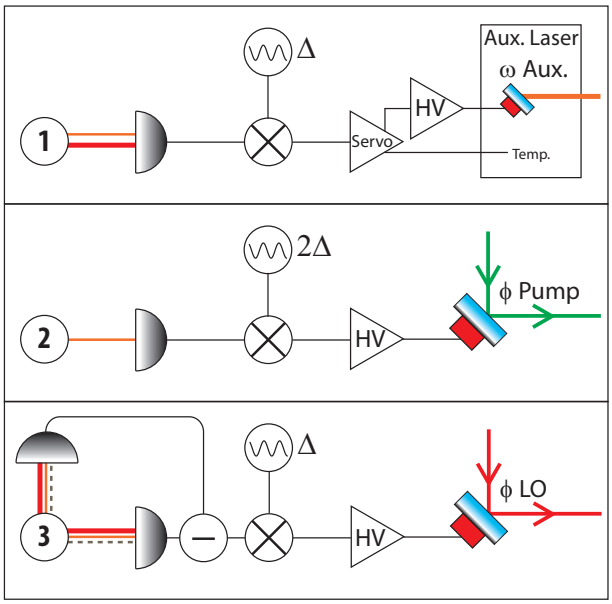

Figure 7.12: Simplified schematic of the locking loops that make up the coherent locking scheme. Fields 2 and 3 are the same as those illustrated in Figure 7.11. The two function generators at Δ and 2Δ are locked to one another to ensure phase stability between the two locking loops.

7.4.1 Coherent Control Model

We note that the coherent locking system is essentially a non-degenerate OPA, a system that we can model using the cavity equations of motion (Equations 5.32). We aim to model the classical behaviour of the CSF and GSF fields present in the coherent locking scheme. We begin by stating the classical equations of motion for the NDOPA and follow

similar methods as undertaken by [136, 137, 138]

$$\begin{aligned}
\dot{a}_1 &= i\Delta_1 a_1 - \kappa_1 a_1 + g a_3 a_2^\dagger + \sqrt{2\kappa_1^{in}} A_1^{dr} \\
\dot{a}_2 &= i\Delta_2 a_2 - \kappa_2 a_2 + g a_3 a_1^\dagger + \sqrt{2\kappa_2^{in}} A_2^{dr} \\
\dot{a}_3 &= i\Delta_3 a_3 - \kappa_3 a_3 - g a_1 a_2 + \sqrt{2\kappa_3^{in}} A_3^{dr}.
\end{aligned} \tag{7.6}$$

In this case, terms with a subscript 1 represent the properties relating to the CSF, subscript 2 relates to the GSF field and subscript 3 is, as before, the pump field. The first simplification we will make is that the decay rates for the two locking fields, the CSF and the GSF, are equal. This is reasonable provided that the cavity is locked at the squeezing frequency (half of the pump field) because the two fields are symmetric about the fundamental frequency. We will also assume that the pump field is resonant. The detuning terms for the CSF and GSF fields *cannot* be set to zero as in the case of the OPA because these terms describe the detuning of the coherent locking field from half the pump frequency. The CSF field entering the cavity under standard operating conditions is incredibly small, so it is valid to assume that the pump field is not depleted. Finally, the GSF is not driven by an external field and hence we set $A_2^{dr} = 0$. Solving for the steady state of the system allows us to write

$$\begin{aligned}
(\kappa_1 + i\Delta_1)\alpha_1 &= g\frac{\sqrt{2\kappa_3^{in}}\hat{A}_3^{dr}}{\kappa_3 + i\Delta_3}\alpha_2^* + \sqrt{2\kappa_1^{in}}\hat{A}_1^{dr} \\
(\kappa_2 + i\Delta_2)\alpha_2 &= g\frac{\sqrt{2\kappa_3^{in}}\hat{A}_3^{dr}}{\kappa_3 + i\Delta_3}\alpha_1^*.
\end{aligned} \tag{7.7}$$

We wish to allow for any pump phase because this is important to the coherent locking scheme. To achieve this, Equations 7.7 are simultaneously solved for the intra-cavity field terms, α_1 and α_2, and their complex conjugates. This results in

$$\begin{aligned}
\alpha_1 &= \frac{-\sqrt{2\kappa_1^{in}}A_1^{dr}\left(\kappa_2 + i\Delta_2\right)}{\frac{2\kappa_3^{in}g^2A_3^{dr*}A_3^{dr}}{\kappa_3^2} - \left(\kappa_1 + i\Delta_1\right)\left(\kappa_2 + i\Delta_2\right)} \\
\alpha_2 &= \frac{-2g\sqrt{\kappa_1^{in}\kappa_3^{out}}A_1^{dr}A_3^{dr}\left(\kappa_2 + i\Delta_2\right)}{\kappa_3\left(\frac{2\kappa_3^{in}g^2A_3^{dr*}A_3^{dr}}{\kappa_3^2} - \left(\kappa_1 + i\Delta_1\right)\left(\kappa_2 + i\Delta_2\right)\right)},
\end{aligned} \tag{7.8}$$

where the relationship between the detuning of the CSF and GSF fields is such that $\Delta_1 = -\Delta_2$.

Using the input/output relations (Equation 5.9), we can determine the output fields and from this the power of the fields exiting the system (using Equation 5.5). Figure 7.11 shows the setup for the coherent locking field.

The chosen parameters match those for the ANU cavity, given in Table 7.1. It is important to note that for the coherent locking scheme, the input coupler is now the HR mirror that the CLF enters the cavity through, with $R = 0.9982$, and the output coupler is, as before, the mirror where the squeezing and the coherent locking field exit the cavity and travel towards the homodyne detector, with $R = 0.839$. The input coupler was chosen to have a reduced reflectivity, when compared to the other HR mirrors, in order to slightly

increase the component of the GSF field at location 2. The reflectivity was chosen such that the additional intra-cavity loss, resulting in a lower escape efficiency, would be small compared to the total intra-cavity loss. The reflected and transmitted fields can thus be written

$$A_1^{ref} = \sqrt{2\kappa_1^{in}}\alpha_1 - A_1^{dr} \tag{7.9}$$

$$A_1^{trans} = \sqrt{2\kappa_1^{out}}\alpha_1 \tag{7.10}$$

$$A_2^{ref} = \sqrt{2\kappa_2^{in}}\alpha_1 \tag{7.11}$$

$$A_2^{trans} = \sqrt{2\kappa_2^{out}}\alpha_1, \tag{7.12}$$

from which the powers of the fields can be determined using Equations 5.5. Under most circumstances, we can assume $\kappa_1^{in} = \kappa_2^{in}$ and $\kappa_1^{out} = \kappa_2^{out}$, by requiring that $\Delta_1 = -\Delta 2$.

We are now in a position where we can investigate the properties of the fields present in the coherent locking scheme. Figure 7.13 shows the power and phase properties of the transmitted and reflected CSF and GSF fields as a function of pump power and phase. The figure illustrates many important features of the coherent locking scheme. With no pump power, there is no generated sideband field. This is expected as there is no non-linear interaction to transfer photons to this field. As the pump power is increased, the non-linear gain of the system increases and photons are added to the CSF and GSF fields. The gain in the figure is limited because of the large detuning of the fields. It is necessary to ensure that the powers in the CSF and GSF do not become too large, otherwise noise on these fields will be detected by the homodyne detector, adversely affecting the squeezed state measurement.

As the phase of the pump field is varied, the phase of the CSF does not change but the phase of the GSF varies linearly for both the reflected and transmitted fields. This is a very important feature for the coherent locking scheme. The phase of the GSF is linearly related to the phase of the pump and this is what facilitates the locking of the phase of the auxiliary laser to the phase of the pump field.

The power seen in the reflected CSF and GSF fields highlights the limitation to this coherent locking scheme as it was constructed in this experiment. The reflected field consists of two components, the promptly reflected field and a component that escapes the cavity. The issue is that due to the fact that we are coupling in via an HR mirror, the promptly reflected component is much larger than the small amount that escapes the cavity. This is very clear in Figure 7.13, where the reflected CSF has a power of 99 μW and the reflected GSF has a power of 0.8 nW. The beat between these fields is small due to the very minor contribution from the GSF. The small amount of intra-cavity field leaking through this HR mirror results in a lock with a suboptimal signal to noise ratio and limited bandwidth.

It was experimentally seen that when the power of the auxiliary laser (or CSF field) was increased above hundreds of micro-Watts the squeezing degraded. The mechanism by which this happens is believed to be due to direct detection of the noise from the locking field on the very sensitive homodyne detector but is not fully understood. The effect this has, however, is to set a limit on the strength of the coherent locking field that can enter the cavity. In particular, this sets a limit on the amount of GSF field that exits the cavity, limiting the size of the beatnote used for the various locking loops.

One might ask whether the locking loop which locks the phase of the pump to the

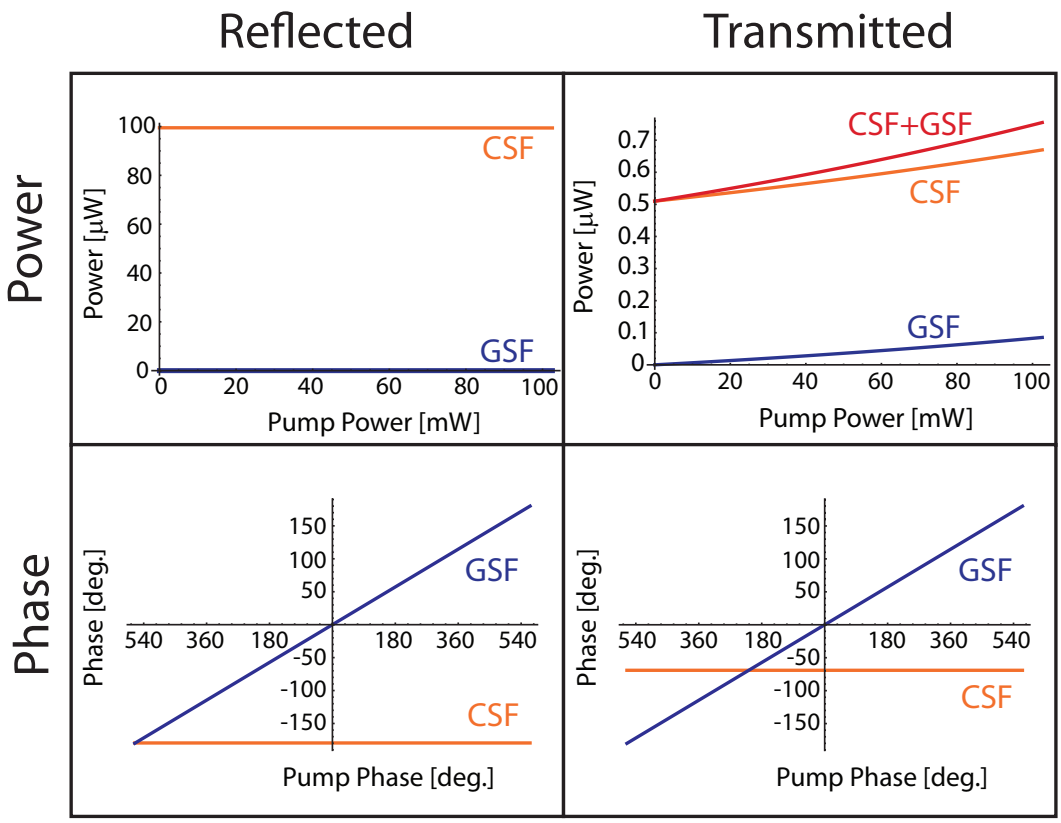

Figure 7.13: The powers of the transmitted and reflected CSF and GSF fields as the pump is increased up to OPO threshold and the phase of the CSF and GSF fields as the phase of the pump field is varied. The system is modelled on the ANU squeezer and as such all parameters are chosen to match those given in Table 7.1; cavity length $L = 0.273m$, non-linear interaction strength, $g = 1891$, reflectivity of the input/output coupler at the pump and fundamental wavelengths, $R_3^{in/out} = 0.722$ and $R_1^{in/out} = 0.839$, respectively, and intra-cavity loss at fundamental and pump, 0.26% and 4.6%, respectively. The coherent locking field power was set to 100 μW with a detuning of $\Delta_1 = 2\pi \times 29.8\,\text{MHz}$. For the phase diagrams, a pump power of 90 mW is assumed.

phase of the auxiliary laser, location 2 in Figure 7.11, could instead be derived from the field that exits the front coupler, where transmission is orders of magnitude larger than those for the HR mirrors. However, this field also carries the squeezed light and as such detection of this field before the homodyne detector cannot be made without degrading the squeezing. It might then be possible to derive the error signal for this lock at the homodyne detector. The homodyne detector is already used to lock the LO phase to the coherent locking fields but it could also be used to lock the CSF to the pump phase provided that the extra path length from the squeezer to the homodyne detector were stable. This should theoretically produce a much stronger lock because of the increased field strength exiting through the front coupler. The issue that arises, however, is that the homodyne detector must now detect in the gravitational-wave audio-band, at Δ_1 and at $2\Delta_1$. This is technically challenging to do without affecting the performance of the detection circuit in measuring the squeezed state and of the locks themselves. In particular, second harmonics of the lock at Δ_1 may affect the stability of the second lock at $2\Delta_1$.

The coherent locking scheme was the original scheme used to control the angle of the

squeezing in the ANU squeezer. With this scheme, the unity gain frequency of the loop that locked the phase of the auxiliary laser to the pump phase was approximately 20 Hz and the bandwidth of the loop that locked the LO phase to the CLF was 40 kHz. The very poor bandwidth of the fist loop was the limiting factor in our control scheme and so it was desirable to determine if a new method could be devised in order to improve the stability of our squeezed state control.

7.4.2 Modified Coherent Locking

The concept of the modified coherent locking scheme was that instead of locking the phase of the CLF to the pump phase by sensing the non-linear interaction, the phase between these two fields could be locked by first up-converting some small portion of the auxiliary laser field and then beating the pump field with this second harmonic CSF field. This would also lock the phase of the auxiliary laser to the phase of the main laser in the same locking loop, removing one of the locking loops from the original coherent locking scheme.

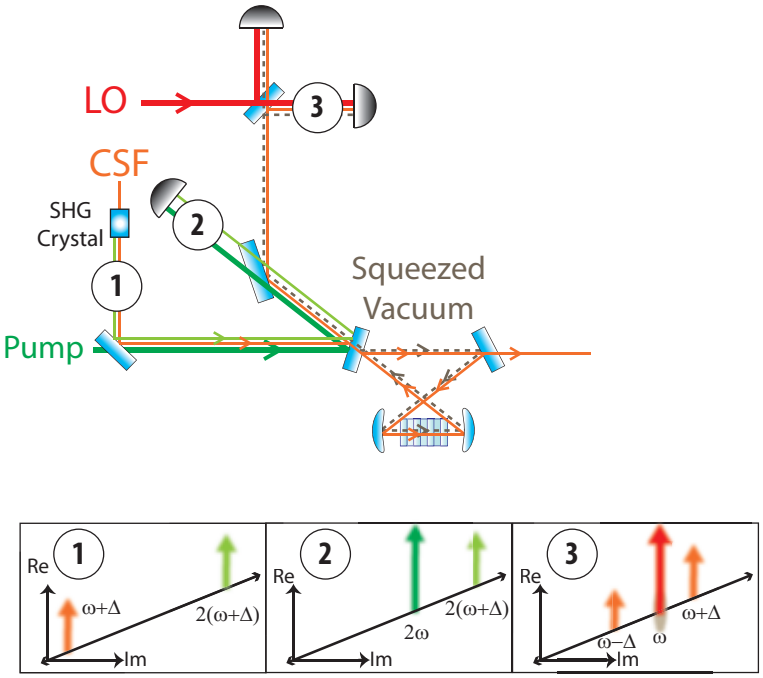

Figure 7.14: The modified coherent locking scheme. The important fields are highlighted at locations 1,2,3. A full description of the fields and locking loops can be found in the text.

The experimental setup for the modified coherent locking scheme is shown in Figure 7.14. At location 1 the coherent sideband field (CSF), shifted from the fundamental frequency by an amount Δ, and its second harmonic are present. The second harmonic is generated using a single-pass non-linear medium. At location 2 the green light reflected from the OPO and transmitted through a dichroic beamsplitter is detected. The beat, at a frequency of 2Δ, between the up-converted CSF and the pump field is used to offset phase lock the frequency of the auxiliary laser to the main laser using a standard offset phase lock [139]. At location 3 the fields are unchanged from the original coherent locking scheme, the CSF, GSF, squeezing and LO fields are all present at this location.

By moving to this modified coherent locking scheme, the first locking loop can now be optimised by varying parameters that do not affect the squeezing. In particular, the power in the frequency doubled CLF field can be tailored for the locking loop. The already strong second half of the lock, the loop that locks the phase of the LO to the phase of the auxiliary laser, remains unchanged. The electronic loop of the modified coherent lock, which locks the phase of the auxiliary laser to the phase of the pump, is shown in Figure 7.15.

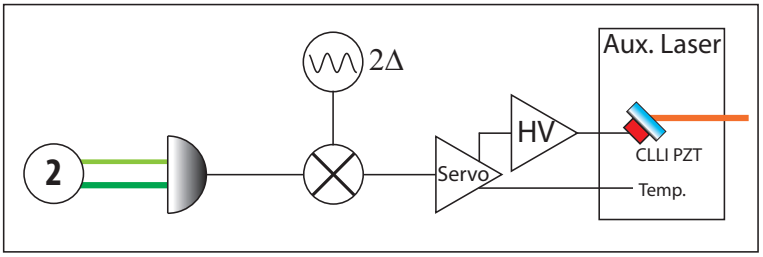

Figure 7.15: The modified coherent locking electronics scheme. The beat between the pump and up-converted auxiliary laser fields is used to derive an error signal. This error signal locks the phase of the the auxiliary laser field to the phase of the pump field. Note that this loop also locks the frequency of the auxiliary laser to the frequency of the main laser, with an offset of Δ.

With this modified coherent locking scheme, the bandwidth of the loop locking the auxiliary laser phase to the pump phase was 2.5 kHz. The larger bandwidth results in better suppression of the phase fluctuations on the squeezed field, reducing phase jitter. This lock is more flexible due to two reasons; the amount of frequency doubled CSF can be varied and; the fundamental CSF field power is only used for the stronger lock at the homodyne detector, allowing for reduction of the the power in the CSF is so desired. The CSF power used in the experiment for this locking loop was not changed from the original coherent locking scheme, retaining its bandwidth of 40 kHz.

Both of these coherent locking schemes share an inherent weakness. This is that the coherent locking schemes do not strictly force the lock to the angle of squeezing. It merely ensures that the phase of the local oscillator in the homodyne detection scheme is locked to the phase of the pump. In both the original and modified coherent locking schemes, if the temperature of the non-linear medium changes in a way that cannot be compensated for, as is the case with localised thermal heating due to drifts in pump power, then the cavity is no longer perfectly resonant for both the pump and squeezed fields. This condition results in a shift between the angle of the squeezed light and the local oscillator. Nonetheless, even with this limitation, stability has been shown over many hours after recognising local heating due to pump field fluctuations were a major source of noise, first identified and overcome through stabilisation of the pump field power by Khalaidovski [140]. Stable squeezing, controlled using the coherent locking scheme,in this paper was shown to have a duty cycle of 99 % over 20 hours.

Chapter 8

Detection of Squeezed States

This chapter introduces the challenge of the detection of the states described thus far. The first measurements of squeezing in the audio-frequency band were limited by excess noise at low frequencies [63]. A "roll-up" in the frequency spectrum was seen towards lower frequencies. This noise was evident on both the shot noise and squeezing measurements [63, 66]. This led to the interesting situation where it could not be determined whether the squeezing itself was degrading at low frequencies, or whether it was simply a limitation of the measurement device. It was later shown that it was indeed possible to measure white shot noise at frequencies down to below one hertz [141]. Beam jitter, electronics, local oscillator noise coupling [64], non-stationary events in the balanced homodyne detector output [65], and parasitic interference [141, 142] have all been shown to contribute to the excess noise at low frequencies. In this chapter we present our findings on low-frequency noise sources and the steps by which the various sources were identified and mitigated. This chapter is based largely on the work presented in a paper recently written on this topic [87].

8.1 Balanced Homodyne Detection Noise Couplings

We investigate the noise coupling by modelling the photocurrents in the balanced homodyne detector in the same way as introduced in § 3.8. The model is set up as shown in Figure 8.1. A bright local oscillator, $\hat{A} = \alpha + \delta\hat{a}$, and the weak signal beam, $\hat{B} = \delta\hat{b}$, of interest interfere on a beamsplitter of power splitting ratio, $\eta_{\rm bs}$, that is close to, but not precisely, 50 %. We assume that the signal field has no coherent amplitude, and is thus a vacuum or squeezed vacuum state. The two photo-detectors have differing quantum efficiencies, $\eta_1(x, y)$ and $\eta_2(x, y)$, that vary in the transverse plane. A loss term, η_l, is added to one arm of the balanced homodyne detector to simulate loss from sources such as dust (location 2). We define the δ_V terms as the vacuum fluctuation contributions entering due to the the losses from the various loss sources, the inefficient photodiodes, δV_1 and δV_2, and the loss introduced in one of the balanced homodyne detector arms, δV_0.

The fields incident on the two photo-detectors, $F_{1,2}$, are written

$$\hat{F}_1 = \sqrt{\eta_1}\left(\sqrt{1-\eta_l}\left(\sqrt{\eta_{\rm bs}}\hat{A} + \sqrt{1-\eta_{\rm bs}}\hat{B}\right) + \sqrt{\eta_l}\delta\hat{V}_0\right) + \sqrt{1-\eta_1}\delta\hat{V}_1, \quad (8.1)$$

$$\hat{F}_2 = \sqrt{\eta_2}\left(\sqrt{\eta_{\rm bs}}\hat{B} - \sqrt{1-\eta_{\rm bs}}\hat{A}\right) + \sqrt{1-\eta_2}\delta\hat{V}_2, \quad (8.2)$$

where the explicit spatial dependence of the photodiode efficiencies have been removed for succinctness. The ideal photocurrent produced by photodiode 1 is then proportional to $\hat{F}_1^\dagger\hat{F}_1$ and similarly for the photocurrent in photodiode 2. The two photocurrents can

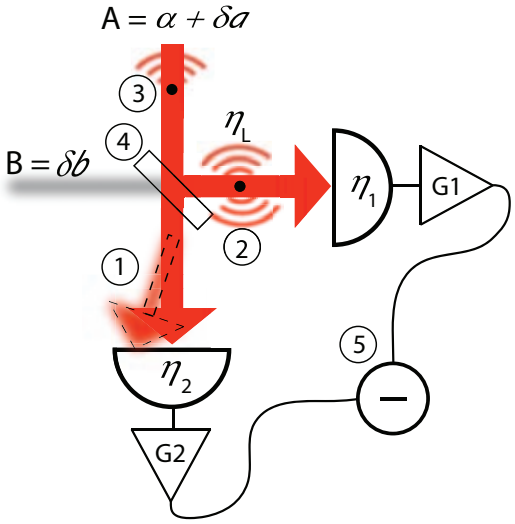

Figure 8.1: Conceptual view of the major issues arising in low-frequency measurements with a balanced homodyne detector setup; 1 - beam pointing, 2 - scatter resulting in loss and/or mode shape disortion, 3 - scatter leading to parasitic interference, 4 - the splitting ratio of the beamsplitter, 5 - the subtraction of the photocurrents. All other terms are described in the text.

thus be written

$$\begin{aligned} i_{HD1} &= \eta_1\eta_{bs}(1-\eta_l)\alpha^2 + \eta_1\eta_{bs}(1-\eta_l)\alpha\delta\hat{X}_a^+ + \\ &\quad \eta_1\sqrt{\eta_{bs}}\sqrt{1-\eta_{bs}}\sqrt{1-\eta_l}\alpha\delta\hat{X}_b^+ + \sqrt{\eta_1}\sqrt{\eta_{bs}}\sqrt{1-\eta_1}\sqrt{1-\eta_l}\alpha\delta\hat{X}_{V1}^+ + \\ &\quad \eta_1\sqrt{\eta_{bs}}\sqrt{1-\eta_l}\sqrt{\eta_l}\alpha\delta X_{V0}^+ \qquad (8.3) \\ i_{HD2} &= \eta_2\sqrt{1-\eta_{bs}}\alpha^2 + \eta_2(1-\eta_{bs})\alpha\delta\hat{X}_a^+ - \eta_2\sqrt{\eta_{bs}}\sqrt{1-\eta_{bs}}\alpha\delta\hat{X}_b^+ - \\ &\quad \sqrt{\eta_2}\sqrt{1-\eta_{bs}}\sqrt{1-\eta_2}\alpha\delta\hat{X}_{V2}^+, \qquad (8.4) \end{aligned}$$

where the $\delta\hat{X}_a^+ = \delta\hat{a}^\dagger + \delta\hat{a}$ terms are the amplitude quadrature fluctuation operators for the field fluctuation term $\delta\hat{a}$ and similarly for $\delta\hat{X}_b^+$. It is the subtraction of these two photocurrents, limited by experimental imperfections, that gives the output of the balanced homodyne detector. Many of the coupling mechanisms for the various noise sources can be seen in these equations and will be discussed in the following sections.

8.2 Electronic Issues

In an attempt to organise the various noise sources, the issues have been divided into those of an electronic nature, and those of an optical nature. However, the distinction is not always clear because many of these issues have a source in one of these origins but couple in via some mechanism in the other. We begin by discussing the issues of an electronic nature that limit the low-frequency measurement of squeezed states.

8.2.1 Balanced Homodyne Photo-Detector Electronics Designs

Two differing electronic designs for balanced homodyne photo-detectors were investigated. Their simplified schematics are shown in Figure 8.2. The first is a twin photo-detector,

variable gain design. In this design, the measured photocurrents are immediately amplified through a trans-impedance stage on separate electronic boards and an electronic subtractor then takes the difference between these two signals [63]. The gain between the two detectors can be varied to allow the subtraction of the photocurrents to be optimised electronically, allowing for the compensation of uneven optical powers and differences in the photodiode responses. This allows for the compensation of unequal $\eta_1(x, y)$ and $\eta_2(x, y)$ terms as well as an imperfect η_{bs} term from § 8.1. This design, henceforth known as the *variable gain* design, is given in detail in [108], and the first measurements of audio-band squeezing were made using this balanced homodyne detector design.

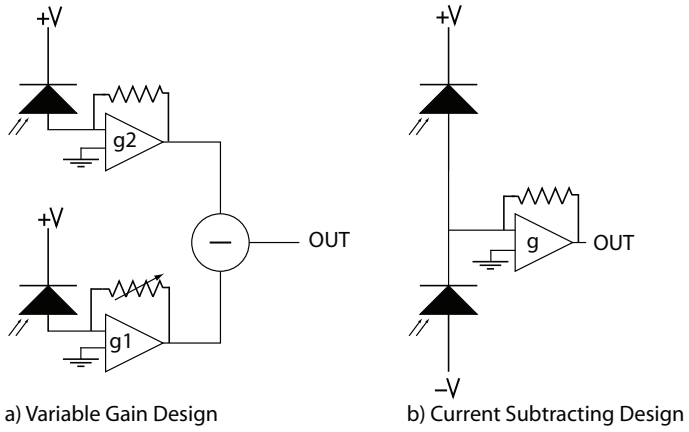

Figure 8.2: The two balanced homodyne detector schemes: a) The variable gain design. The photocurrents from the two photodiodes undergo separate transimpedance gain stage, g1 and g2, and the two output signals are then subtracted. b) The current subtracting design. The two photocurrents are subtracted before undergoing any electronic gain, g.

The second design is a single electronic board design, also shown in Figure 8.2. In this design the photocurrents of both photodiodes are immediately subtracted from each other before undergoing any amplification. There is no longer a variable electronic gain and thus, balancing of the subtraction must be done optically, through manipulation of the η_{bs} term. This is typically achieved by rotating the polarisation of the local oscillator and/or signal field. A homodyne detector utilising this design, henceforth known as the *current subtracting* design, is given in detail in [143]. A detector utilising this design was constructed at the Max Planck Institute for Gravitational Physics in Hannover, Germany and was provided to the ANU for use in the ANU squeezing experiment, to be later used in the LIGO squeezed light injection. This detector had already been shown to measure squeezing down to below 10 Hz [141] and was used in most of the homodyne detector measurements presented in this thesis. The current subtracting design has reduced classical noise due to the fact that all of the electronic components after the photodiodes are common.

The current subtracting design also eliminates a second noise source, flicker noise. This is not the case, however, for the variable gain design and as such it is necessary to address the issue. Flicker noise is a noise source found in resistors that is proportional to the amount of current passing through the resistor [144]. Flicker noise results in a pink noise spectrum, or a 1/f roll-up towards low frequencies. The source of flicker noise is not well known, but it can be mitigated using wire wound or metal film type resistors [145]. Figure

8.3 shows shot noise measurements for the variable gain design constructed with standard carbon film and with low flicker noise metal electrode leadless face (MELF) type resistors. An experiment was devised where shot noise was measured in three separate cases. The first two cases involved two identical homodyne photodetectors, the same as that presented in [108], set up to work as a variable gain homodyne detector. One measurement was taken with carbon film resistors and the other with MELF resistors. In the third case, one of these photodetectors was modified by adding a second photodiode and having current subtraction between these two photodiodes occur before the first gain stage, as shown in Figure 8.2. This was done on a board using standard carbon film resistors to show that the current subtracting design mitigates flicker noise. The results of these tests are shown in Figure 8.3.

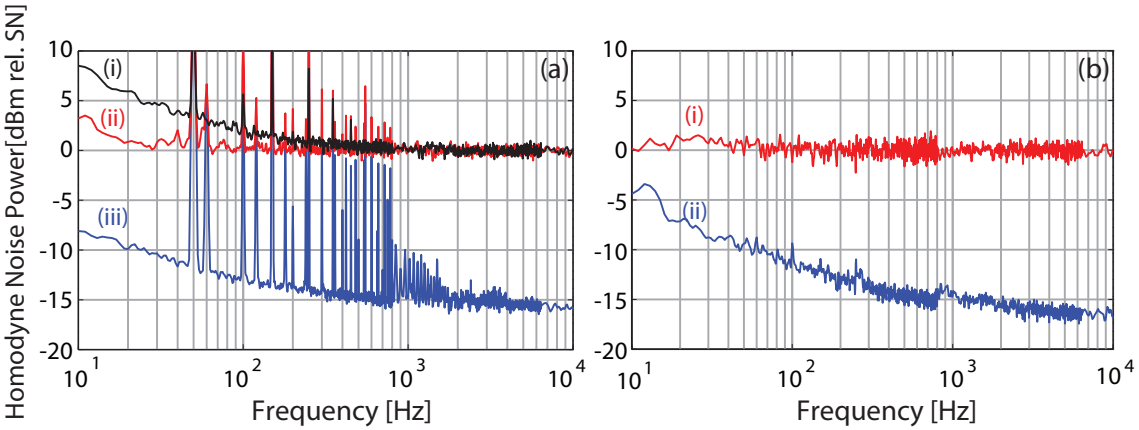

Figure 8.3: Figure (a) shows the dark noise, (iii), and two shot noise traces, (i) and (ii), for the variable gain balanced homodyne detector design with a local oscillator power of approximately 1.9 mW. In trace (i), standard carbon film resistors are used and the shot noise is seen to deviate strongly at lower frequencies. Replacing these resistors with low flicker noise resistors results in the near flat shot noise measurement seen in trace (ii). The deviation seen near 10 Hz is believed to be caused by parasitic interference, as it was seen to have a time dependence (See § 8.3.4). Figure 3(b) shows the normalised dark noise (ii) and shot noise (i) for the current subtracting design, constructed by adding a photodiode to one of the photodetectors used in the variable gain homodyne detector. As expected, even with standard carbon film resistors, flat shot noise was measured to 10 Hz. All traces are pieced together from 3 FFT windows: 0-800 Hz, 0-6.4 kHz, 0-102.4 kHz with 800 FFT lines, resulting in resolution bandwidths of 1 Hz, 8 Hz, and 128 Hz respectively. 200 RMS averages were taken for all traces. The noise spikes seen in (a) are due to mains harmonics that could not be removed.

The homodyne detector board design used to produce the traces in Figure 8.3 was the same as that used in the first measurement of squeezing in the audio-band [63]. Flicker noise had not yet been identified as a limiting noise source and as such, the measurements, taken with a variable gain board, had a very similar roll-up to that illustrated in Figure 8.3 (a) trace (i). Flicker noise was almost certainly the major noise contributor in this early experiment. As shown in Figure 8.3, the use of low flicker noise components is enough to reduce the flicker noise to a level that no longer affects the measurements at the frequencies we are interested in.

8.2.2 Dark Noise

Dark noise, the electronic noise of the detection system when no light is incident on the photodiodes, can also limit the measurement of shot noise and even more so squeezing. This is typically worse at lower frequencies where electronics tend to have increased noise. The problem is a technical one but it is worth briefly mentioning. Depending upon the operating conditions, the current and voltage noise in the op-amps, and less so the the dark current of the photodiode, are the sources of dark noise. Correct selection of readily available components ensures that the dark noise does not limit the measurement. The dark noise is typically measured relative to the shot noise level. The required clearance between the two is dependent upon the amount of squeezing one wishes to measure. Typical detectors can be made and bought with the shot noise approximately 10 dB above the dark noise for normal operating conditions, but more advanced designs have the shot noise around 20 dB or greater above the dark noise [143]. The clearance between shot noise and dark noise can be increased in the balanced homodyne detector by increasing the power of the LO field, thereby increasing the amount of measured shot noise. The limitations to this however, are the amount of power that the photodiode can receive before damage occurs and the fact that a greater LO field strength leads to a larger amount of classical noise. This increases the amount of subtraction the balanced homodyne detector needs to achieve in order to operate in the quantum noise limited regime.

Dark noise degrades shot noise and squeezing measurements because the noise of the electronics adds to the measured shot noise or squeezing and makes them appear noisier than they actually are. For the purpose of estimating the amount of squeezing incident on the detector, one can correct for dark noise by simply subtracting it from all other traces. For some signal, S, we can write its dark noise corrected value, S_{DNcor}, in dBm as

$$S_{\mathrm{DNCor}}[\mathrm{dBm}] = 10\log_{10}(10^{S/10} - 10^{\mathrm{DN}/10}), \tag{8.5}$$

where S[dBm] is the measured signal strength in dBm, and DN is the measured dark noise, in dBm.

8.3 Optical Issues

Many optical issues also need to be addressed in order to achieve flat shot noise across the audio-frequency spectrum. These optical issues and their solutions were investigated on a simple tabletop experiment, shown in Figure 8.4. The output of an ND:YAG 1064nm laser, after passing through a Faraday isolator, was directed into a steel chamber through an anti-reflection (AR) coated window. Within the chamber, the light underwent spatial filtering with a triangular ring mode-cleaner cavity or modecleaner with a linewidth of approximately 4.7 MHz. The modecleaner was locked using the Pound-Drever-Hall technique [146]. The light travels through a half-wave plate and is then incident on the beamsplitter which directs the light towards a current subtracting balanced homodyne detector [143]. The half-wave plate is used to tune the beamsplitter power splitting ratio, η_{bs}.

8.3.1 Optical Balancing

Balancing the optical splitting ratio of the beamsplitter is crucial to the performance of the balanced homodyne detector. A high common mode rejection ratio (CMRR), the

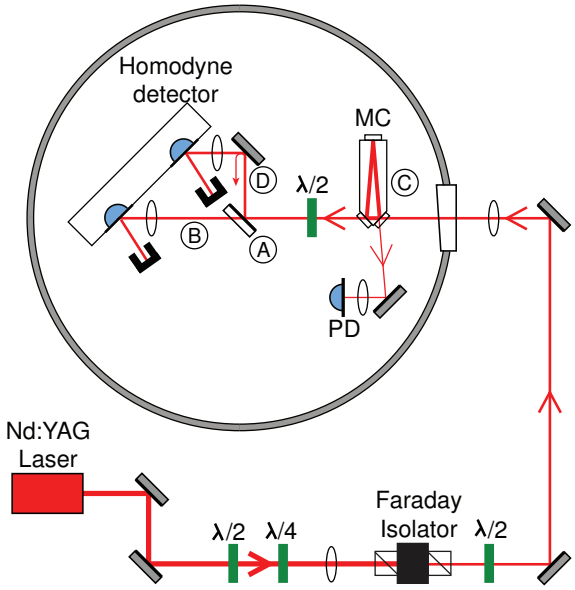

Figure 8.4: The optical layout of the experiment designed to detect low-frequency noise sources in the balanced homodyne detector setup. A high-speed photo-detector (PD) was used to lock the modecleaner cavity (MC). The core components are enclosed in a steel chamber with an AR coated window. The circled labels refer to the locations of issues discussed in following sections; (A) 8.3.1 - Optical Balancing; (B) 8.3.2 - Scattering Loss (C); 8.3.3 - Beam Pointing (D); 8.3.4 - Parasitic Interference.

measure of the ability of the balanced homodyne detector to reject signals common to both photodiodes, is necessary such that classical noise present on *both* fields entering the beamsplitter, the local oscillator and the signal field, is subtracted to a level well below the shot noise level by the balanced homodyne detector. This issue is highlighted in Equation 8.3. It is seen that with optimisation of the $\eta_{1,2}(x, y)$ and η_{bs} terms, the subtraction of these two photocurrents can completely remove all terms proportional to δX_a^+, which is the noise on the local oscillator field. This is a necessary condition for the balanced homodyne detector setup to ensure that one is accurately measuring the signal field, absent unwanted classical noise sources.

The importance of balancing the beam splitting ratio becomes even more critical when the signal field itself carries noise which needs to be subtracted, such as in the coherent locking scheme [66]. The optical balancing is firstly tuned with the splitting ratio of the beamsplitter, primarily through tuning of the angle. The coatings on the beamsplitters typically do not allow for a perfect splitting ratio, and as such, the final balancing is done through adjustment of the polarisation of the input fields using a half-wave plate. Alternatively, if a variable gain design were used, then this adjustment could be made through varying the gain. Optimising for the local oscillator arm, a stable CMRR of up to 80 dB was consistently achieved. Figure 8.5 shows that this level of subtraction should be enough to adequately to suppress the classical laser noise from the local oscillator across the entire spectrum. With this setup, a CMRR of 50 dB was obtained for the signal field. This is sufficient because the power in the signal field is many orders of magnitude less than the local oscillator.

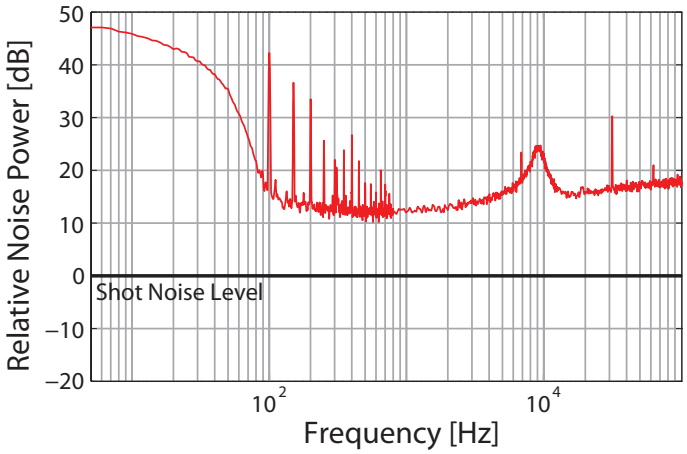

Figure 8.5: Relative intensity noise of the local oscillator field incident on the balanced homodyne detector. At low frequencies, local oscillator intensity noise is more than 40dB greater than shot noise. The trace is pieced together from 3 FFT frequency ranges: 0-800 Hz with 50 root mean square averages, 0-6.4 kHz and 0-102.4 kHz both with 100 averages. All traces taken with 800 FFT lines, resulting in resolution bandwidths of 1 Hz, 8 Hz and 128 Hz respectively.

8.3.2 Scattering Loss

We define scattering loss as an event occurring in the beam path which causes the scattered light to exit the beam path and be lost to the system. Scattering events before the beamsplitter will not affect the splitting ratio, but can couple noise in through changes in mode shape (this is further discussed in § 8.3.3). However, problems can arise if the loss originates in one of the balanced homodyne detector arms after the beamsplitter. This loss, η_l, is illustrated in Figure 8.1 and in Equations 8.3. Dust particles, originating from many sources such as clothing and skin, passing through the beam due to air currents or gravity, will result in a non-zero loss term and momentarily reduce the magnitude of the photocurrent, i_{HD1}. This momentary change in the photocurrent occurs at frequencies characteristic of the speed of the particle and will unbalance the homodyne detector setup. This will result in a reduction of the CMRR, the transient value of which may not be adequate to cancel the classical intensity noise of the laser.

If the dust particle in the beam path reduces the power in one of the beams by one percent, the subtraction is reduced from 80 dB to 40 dB. Figure 8.5 shows that this reduction in CMRR is enough to couple classical intensity noise into the output of the balanced homodyne detector. In addition, intensity noise at frequencies characteristic of the time taken for the dust particle to traverse the beam, will couple directly to the output. Prior work has shown that settling of dust does in fact improve the noise statistics of shot noise measured using a balanced homodyne detector [65].

The effect of loss due to scattering in the homodyne detector arm was investigated by first setting the optical power on each photodiode to 7V. With light on both photodiodes, the DC voltage was subtracted to less than 1 mV. An air puffer was then used to disturb the dust that had settled on various optics mounts. During this process, the subtracted output of the detector was monitored on an oscilloscope. With this configuration, substantial spikes in the subtracted output were observed for a few seconds after dust was excited with the puffer at a location after the beamsplitter.

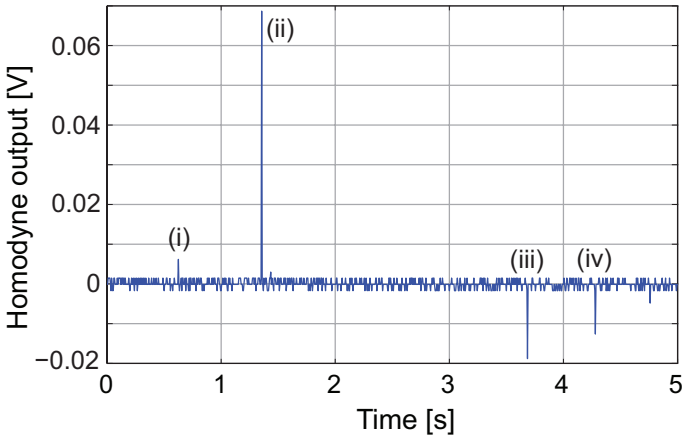

Figure 8.6: The DC output of the balanced homodyne detector as a function of time. At time t=0 a puffer was used to excite dust on a lens mount in the beam path. The spikes in the output, (i)-(iv), are individual dust events affecting the balancing of the homodyne detector.

Figure 8.6 shows the voltage measured on the balanced homodyne detector over time after one such excitation. Four spikes were observed, the largest causing a 0.07 V, or 1 %, change in the voltages between the two photodiodes. The typical voltage seen from these disturbances was approximately 0.01 V. These spikes would occur over a few seconds following the excitation.

We also excited dust activity before the beamsplitter to see what effect this has on the balanced homodyne detector. As expected, no spikes in the subtracted signal were observed because the dust-induced loss is now common to both arms. Isolation against scattering loss post homodyne detector beamsplitter is therefore crucial. The best way to stop dust is to ensure the cleanliness of the environment. Clean rooms, suitable clothing and enclosures all aid in reducing the amount of dust present in an experiment. However, there always will be some dust present in air, therefore eliminating the air currents that carry the dust through the beam paths, such as with an enclosure, is the next step. The steel tank placed around the detection optics in our experiment both reduced the dust present and the air currents. Once the tank was in place and sealed, the spikes in the DC output of the balanced homodyne detector were no longer seen.

8.3.3 Beam Pointing and Mode Shape

A fundamental limitation to the photocurrent subtraction of the balanced homodyne detector is provided by the spatially non-uniform response of the two photodiodes in the detection scheme. This is represented by photodiode quantum efficiencies that are a function of position, $\eta_{1,2}(x, y)$. An investigation into the response of typical photodiodes has shown that there are differences in the quantum efficiency across the photodiode surface and also indicated that small "dead regions" are common [147, 148]. This inhomogeneity allows for beam pointing and mode shape changes to couple into the measurement as a noise source.

Beam pointing, also known as beam jitter, is a change in the trajectory of the beam, which results in a translation of the intensity profile on the photodiode surface. Beam pointing originates from forces acting on optical components, such as acoustic vibrations

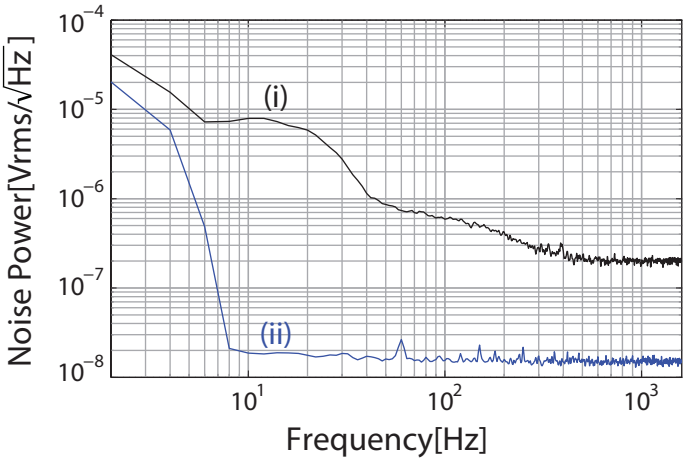

Figure 8.7: Balanced homodyne detector output traces illustrating a beam pointing event. Trace (ii) is the regular shot noise level and trace (i) is the output of the balanced homodyne detector during a typical blow-out event. The experimental setup is that shown in Figure 8.4, with the lid of the steel tank removed. Blow-outs such as that seen in trace (i) occurred every few seconds, with flat traces seen for most of the remaining time. All traces are measured with a span of 0-1.6 kHz with 800 FFT lines, resulting in a resolution bandwidth of 2 Hz. 100 root mean square averages were taken for both traces.

and air currents, or from changes in air density in the beam path resulting in varying refractive indices - the Schlieren effect [75]. If the transverse profile or positioning of the beam changes (see § 8.3.3), then the photocurrent from the photodiode will vary due to the spatial dependence of the diode efficiencies. Writing the spatial dependency on the quantum efficiency in radial coordinates, $\eta(r,\theta)$, the intensity measured by the photodiode is the integral over the entire diode surface, assumed to be circular, of the quantum efficiency multiplied by the intensity profile, and can be written

$$\int_0^{d/2}\int_0^{2\pi} I(r,\theta)\eta(r,\theta)\,d\theta\,dr, \tag{8.6}$$

where d is the diameter of the photodiode surface and $I(r,\theta)$ is the intensity profile of the incident field in radial coordinates.

This will directly modulate the photocurrent of the detectors and will be uncommon to both signals due to the differing responses of the photodiodes, hence it cannot be subtracted. The frequency dependence of this noise will be determined by the specifics of the photodiode inhomogeneities and the speed of the beam translation. The frequency characteristics are illustrated in [64] and show that the noise becomes larger at lower frequencies. The effect of beam pointing can be seen by disturbing the air near to the beam path, anywhere on the table. Many large blow-outs in the spectrum at frequencies up to about 1 kHz can be seen in the output spectrum when this disturbance is introduced. One of these events is shown in Figure 8.7.

These effects can be reduced by designing the experiment to be robust to pointing fluctuations by using short, shielded beam paths, and mechanically stable optics mounts. This effect can also be reduced by enlarging the spot size on the photodiode surface in

order to better average these inhomogeneities, whilst ensuring that all of the light is still detected. To completely solve the issue, a mode-cleaning optical cavity was placed in the balanced homodyne detector setup [141]. Beam pointing can be thought of as the coupling of some fraction of the original beam power into different spatial modes. The cavity is designed such that these modes are non-degenerate, and as such, the higher order modes do not resonate and are reflected from the cavity's input coupler. By this mechanism, pointing noise is converted into intensity noise. This intensity noise has occurred *before* the beamsplitter and is now common to both arms of the homodyne detector, allowing large CMRR of the balanced homodyne detector to remove this intensity modulation.

The modecleaner cavity also filters changes in mode shape, which may occur due to dust passing through the beam. Changes in the mode shape will also couple into intensity noise through the photodiode inhomogeneity. As with beam pointing, the modecleaner cavity will convert mode shape fluctuations into intensity fluctuations which can then be subtracted.

Once the mode cleaner was introduced, it was seen that air disturbances before the modecleaner did not result in low-frequency blow-outs. The experiment is still sensitive to pointing noise which occurs downstream of the modecleaner. By placing the modecleaner inside the homodyne detector system's steel tank, the steel tank then stabilised air currents and reduce dust in this section of the experiment, solving the issues of beam pointing and varying mode shape.

8.3.4 Parasitic Interference

Parasitic interference, also commonly known as a parasitic interferometer, was recognised as the limiting factor in the first measurements of flat shot noise across the entire audio-band [141]. Parasitic interference occurs when some light is scattered from the original beam path, through dust or surface imperfections, reflects off an object such as a mirror mount or another optical element, and re-enters the original beam path. Interference will occur between the original field and the scattered field at the point where these two fields overlap. Any change in the path length of the scattered field, caused by vibrations in the object that the scattered light is reflecting off or by the Schlieren effect will modulate the intensity of the light. If this modulation occurs after the beamsplitter then, much like beam pointing, it cannot be subtracted. Since the balanced homodyne detector is capable of measuring vacuum fluctuations, small fractions of a single photon on average per bandwidth Hz are clearly visible.

It is possible for the scattered light to exit the beam path completely upon scattering and it is possible for the scattered light to reverse direction but travel within the original beam path. If the scattered light exits the beam path, then careful placement of beam dumps will be enough to ensure that parasitic interference does not occur. However, if the scattered light does not exit the beam path, then it is more difficult to correct. This situation is shown schematically in Figure 8.8 for different scattering locations. The scattering is assumed to originate from either arm of the balanced homodyne detector and could occur at the photodiode or from one of the focussing lenses, illustrated in the Figure 8.8 as location 'S'. This *backscattered light* will traverse down the path of the main beam in the opposite direction. When the backscattered field scatters for a second time, it may again scatter into the beam path and then travel in the forward direction, resulting in interference between what we call the *forward scattered* field and the local oscillator field. The spurious interference converts motion of optics and air currents in the scattered

beam path into intensity noise. Figure 8.8 shows the possible locations where scattering can occur. We discuss the effect that parasitic interference, originating from different locations, will have on the shot noise.

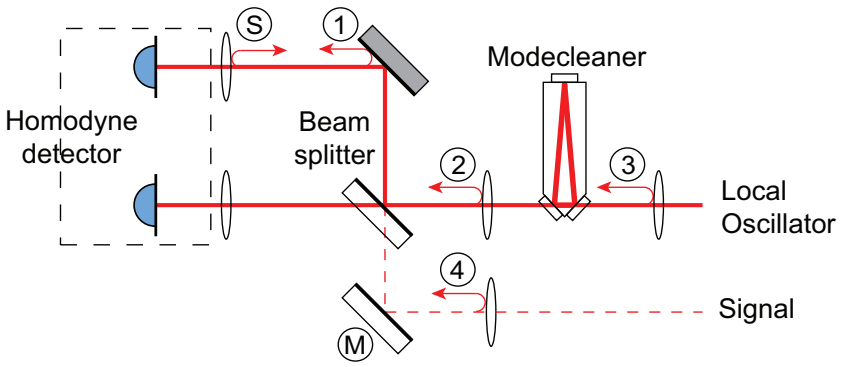

Figure 8.8: Scatter in the balanced homodyne detector leading to parasitic interference. The backscattering occurs in one of the detector arms, chosen here to be location S, and the scattered light travels along the beam path in the opposite direction. Forward scattering can then occur off a second surface, locations 1-4. The location of the forward scattering determines the effect on the balanced homodyne detector output, described in the text.

First we note that interferometric effects which occur between the beamsplitter and the laser source will result in intensity noise that is common to both arms of the balanced homodyne detector, which will be suppressed by the CMRR. This is the case for the forward scattering locations 2 and 3. Additionally, location 3 may be afforded some filtering effect by the modecleaner cavity. Parasitic interference in the experiment was detected here, and although it was not seen to negatively affect homodyne detector measurement (due to the CMRR being high enough to subtract these fluctuations) the ANU squeezer eventually had a Faraday isolator located near position 2 to remove interference at this location and ensure the CMRR was as high above the required level as possible. The forward scattering seen at location 1 will set up a parasitic interference in one arm of the balanced homodyne detector. The intensity noise on the optical field due to this parasitic interference is incident on only one photodiode, and hence cannot be subtracted. If the magnitude of this noise is large enough compared to the shot noise, then it will be seen in the output spectrum. The final location is forward scattering from location 4, in the path where the signal field enters the balanced homodyne detector setup. Scattering from this location will have a substantial impact since the balanced homodyne detector system is designed to be maximally sensitive to any light that enters through the signal port. Scattering in this path will interfere at the beamsplitter with the local oscillator field and the resulting intensity fluctuations will be anti-correlated in the two arms of the balanced homodyne detector, resulting in anti-correlated noise in each of the two photodiodes.

To determine whether parasitic interference was a limiting source of noise in our setup, shot noise spectra were taken with a beam dump in the signal port at location 4 in Figure 8.8 and with the signal port open but with no laser fields present in this path, shown in Figure 8.9. The beam dump was placed such that there were no optical components between it and the beamsplitter.

The difference between the shot noise for the two cases illustrated in Figure 8.9, with and without a beam dump in the signal path, is strong evidence for the presence of parasitic

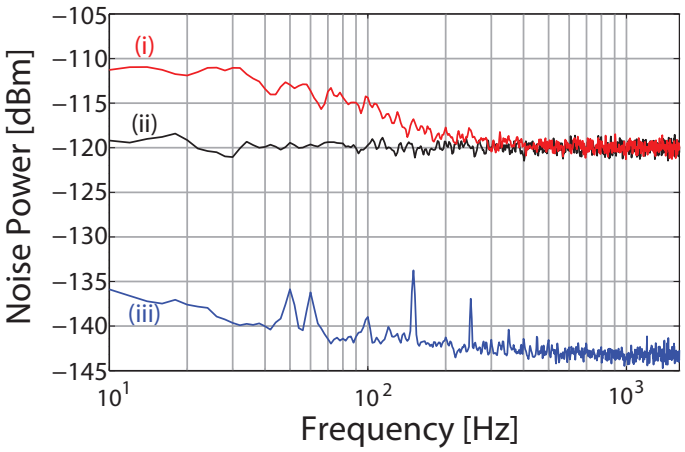

Figure 8.9: Parasitic interference from the signal port of the balanced homodyne detector. Only the local oscillator field was present. Trace (i) is the homodyne detector output with the signal port open, trace (ii) is the balanced homodyne detector output with the beam dump in place and trace (iii) is the dark noise of the balanced homodyne detector.

interference. A more conclusive method for determining the presence of scattered light is presented in § 8.3.5. Flat shot noise is seen when the beam dump is in place but excess noise is seen when it is absent. A Faraday isolator with approximately 22dB of isolation was inserted in place of the beam dump but the excess noise did not noticeably change, indicating that perhaps greater isolation is required or that scatter off the Faraday isolator itself was enough to cause these effects. The beam dump was moved up the signal path to try and determine if there was a single point where most of the forward scattering was occurring but it seemed to be a cumulative effect from several locations in this path.

8.3.5 Detecting the Presence of Parasitic Interference

Using a method known as opto-mechanical frequency shifting, or cyclic averaging, it is possible to determine with certainty whether a low-frequency roll-up is due to the presence of scattered light or otherwise [149]. This technique has been used in many situations to remove the noise from scattered light out of the detection band of interest [150, 151, 152]. The mirror M in Figure 8.8 is actuated with a PZT that is driven with a triangle wave. Now consider what happens to light that is scattered from position S, backwards to position 4, where a scattering plate has been introduced, and then forwards to the balanced homodyne detection. The PZT is set up such that it sweeps the phase of the scattered light through an integer number of cycles, time-averaging the scattered light to zero. The signal due to the motion of the scatter sources now appears at the dither frequency of the PZT and its harmonics. A simple classical model illustrates this effect. We start with an electric field, E, and write

$$E = A + Ce^{i\phi_s}, \tag{8.7}$$

where A represents the local oscillator field and we have chosen a reference frame such that we do not require a phase term for this field. The amplitude of the scattered light, C with phase ϕ_s, will interfere with the local oscillator field. The phase of the scattered

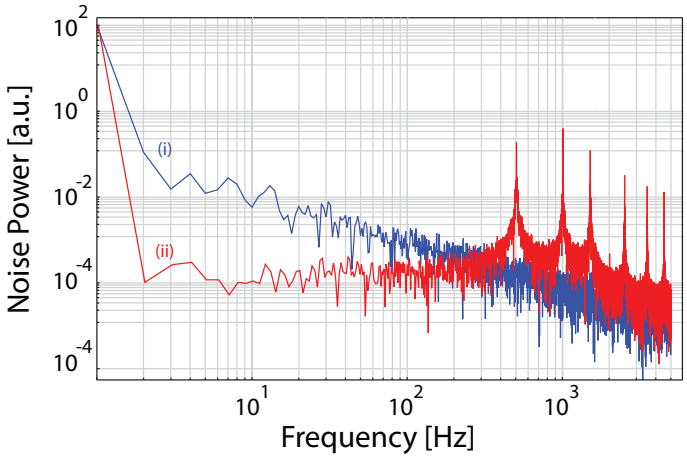

Figure 8.10: Simulated results of the cyclic averaging technique. Trace (i) shows the intensity noise of the LO field with some scattering present, resulting in a low-frequency roll-up. Trace (ii) shows that the low-frequency noise can be shifted up to the dither frequency and harmonics above it by driving a PZT in the scattering path with a triangle wave. Parameters are; local oscillator amplitude, $A = 1$, scattered light amplitude, $C = 0.01$, dithering frequency, $f = 500\,Hz$, and a standard deviation of the scattered phase of 0.01.

light is written

$$\phi_s = \sum R, \tag{8.8}$$

where $\sum R$ is the cumulative sum of normally distributed random noise about zero, with the standard deviation of this noise defining the degree of phase modulation due to air currents or mirror motion. The spectrum of such a field is shown in Figure 8.10.

In order to shift the intensity noise due to scattering out of the band of interest requires one to modulate the scattered field with a triangle wave. This provides a linear sweep on individual ramps, a necessary feature. The amplitude of this modulation is set such that one sweep of the dither progresses the phase an integer number of fringes. We can thus write for the dithered field

$$E_{\text{dither}} = A + Ce^{i\phi_d}, \tag{8.9}$$

where ϕ_d is the scattered phase plus the phase due to the dither. The phase of the field including the dithering is written

$$\phi_d = \phi_s + nD(f), \tag{8.10}$$

where n is the number of fringes wrapped by the dither and $D(f)$ is a triangle wave dither with some frequency, f. The spectra of the dithered scattered field is shown in Figure 8.10.

Figure 8.10 shows the spectra for the local oscillator field with scattered light present, trace (i), and with a PZT, dithered with a triangle wave present in the scattering path, trace (ii). The figure shows that even with scattering present, by dithering the scattered light we should be able to recover flat shot noise below the dithering frequency.

The experiment was then constructed as shown in Figure 8.8, with the mirror M being driven by a triangle wave. The amplitude of the dither was varied until the noise below the dithering frequency was at a minimum, this is the point at which the dither is shifting the phase by an integer number of fringes.

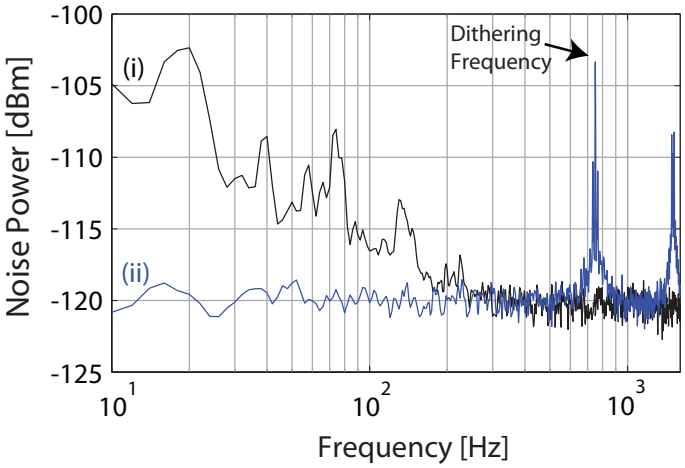

Figure 8.11: The cyclic averaging technique applied to the balanced homodyne detector with a scatter source placed in the signal path. Trace (i) shows the measured shot noise when a scatterer was placed in location 4 in Figure 8.8. With this scatterer in place, the PZT placed between this scatterer and the detector's beamsplitter was dithered at a frequency of 750 Hz. The amplitude of the dither was adjusted until all of the low-frequency noise was seen to shift up to the dither frequency and its harmonic as seen in trace (ii).

Figure 8.11 shows that the opto-mechanical frequency shifting-method has indeed confirmed the presence of scattered light in our setup. The scattered light noise has been mixed up to the dithering frequency and the shot noise is now flat below this frequency. This method has also provided additional information. The fact that the dithering results in flat shot noise has provided information on the location of the scattering and it signifies that the forward scatter originates in this beam path. If one were to move the position of the PZT in this beam path progressively further away from the balanced homodyne detector at some point it might be seen that the signal at the dither frequency decreased. This would indicate that scattering has not undergone the phase shifts introduced by the PZT and hence scattering has occurred nearer to the balanced homodyne detector than the current location of the PZT.

Parasitic interference can be overcome in 3 ways; by reducing the amount of scattering through the use of components with minimal surface roughness, by dumping the scattered photons through careful placement of beam dumps, and by reducing the phase fluctuations in the scattered fields through reduction of vibrations in the experimental setup. The use of super-polished optics and an enclosure around the entire experiment aids greatly in all of these endeavours.

8.3.6 Phase Jitter

The final detection issue is phase jitter. The effect that this has on the squeezing has been recognised previously by Takeno *et al.* [97]. Phase fluctuations on the vacuum squeezed

field result in a rotation of the squeezed field relative to the local oscillator field. The phase control loop designed to control the squeezing angle, such as coherent locking, will provide some finite suppression of this rotation but some rotation will still occur. This rotation results in a suboptimal detection angle for the homodyne detector setup, resulting in the measurement of a noise projection that does not align with the squeezed quadrature. This is shown in Figure 8.12.

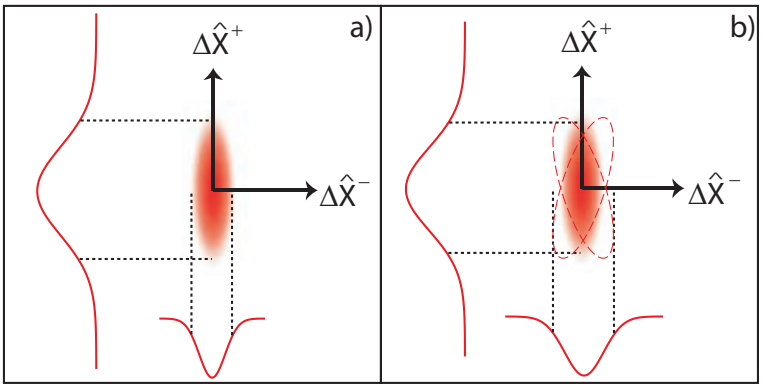

Figure 8.12: The effect of phase jitter on the measurement of a vacuum squeezed state. In case a) the phase is steady and measurement of either the amplitude or phase quadrature squeezed state, which is the projection onto one the quadrature axes, yields its properties. In case b), where the phase is fluctuating, and hence the squeezing ellipse is rotating, the projection of the state onto the two axes is averaged, resulting in different results to those found in the absence of jitter. In particular, the projection of the squeezing onto its axis, in this case the phase quadrature, increases. In the presence of phase jitter, the measured squeezing does not reflect the statistics of the original state.

Assuming some root mean square (RMS) fluctuations of the angle, determining the effect this has on the measured squeezing and anti-squeezing, $V^{\pm'}$, can be found via [97]

$$V^{\pm'} \approx V^{\pm}\mathrm{Cos}^2\theta + V^{\mp}\mathrm{Sin}^2\theta, \tag{8.11}$$

where $V^{\pm}$ is the squeezing/anti-squeezing level in the absence of phase jitter and θ is the rms phase fluctuations of the state. The larger the anti-squeezing, the greater the effect that phase fluctuations have. This is due to the fact that when rotated at the same angle, the projection of a longer ellipse will be proportionally larger for that rotation. This means that as the system is driven closer to threshold, and the anti-squeezing increases, it become increasingly important to stably control the phase of the squeezing relative to the local oscillator. The effect on measured squeezing due to phase fluctuations for an OPO with the ANU squeezer parameters is shown in Figure 8.13.

Figure 8.13 shows the degradation of measured squeezing for various rms phase jitter values. The squeezed state produced by this system mimics that we would expect from our ANU squeezer as the parameters have been chosen to match the ANU squeezer properties. We note that as the system gets closer to threshold, the rms phase jitter has a greater effect due to the increased anti-squeezing. The main source of phase jitter is changes in the refractive index of free space due to air currents, the Schlieren effect [75]. Hence the best way of reducing phase jitter is by reducing these air currents. The steel isolation tank placed around the detection part of the experiment helps in this regard but it is also

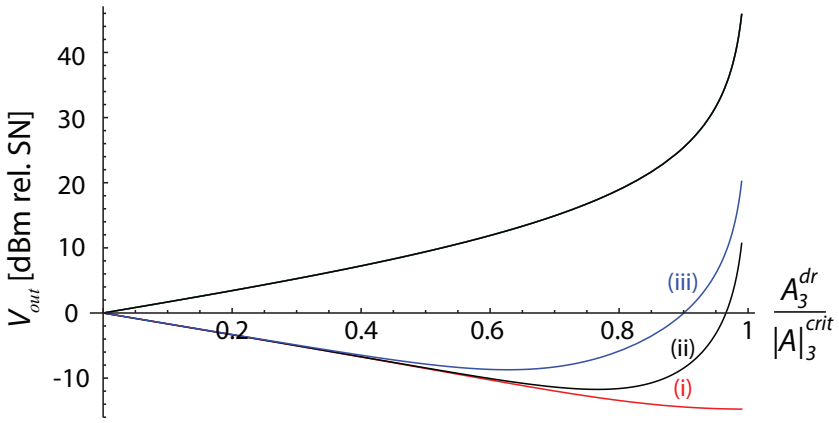

Figure 8.13: The variance at the output of an OPO as the system is driven towards threshold power, A_3^{crit}. The variance of the squeezing and anti-squeezing is shown for the same system with varying phase jitter of 0 degrees, trace (i), 1 degree, trace (ii) and 3 degrees, trace (iii). Parameters are; optical path length $L = 0.279\,\mathrm{m}$, non-linear interaction strength, $g = 1891$, reflectivity of the input/output coupler at the pump and fundamental wavelengths, $R^b_{co} = 0.722$ and $R^b_{co} = 0.839$, respectively, and intra-cavity loss at fundamental and pump, 0.26% and 4.6%, respectively.

necessary to place the rest of the experiment in an airtight (or close to airtight) enclosure in order to isolate the experiment from the typical air currents in the lab, as shown in Figure 8.15. Furthermore, optimisation of the locking loops, in particular increasing the gain at low frequencies, can aid in reducing the rms phase jitter of these states.

8.4 Squeezing from the ANU Squeezer

Now that the technical limitations to measuring shot noise and squeezing in the low-frequency regime are understood, we can move onto measuring these states of light. In this section, we will investigate the history of squeezing results from the ANU squeezer. In this way, we can directly see the effect that various changes to the setup has had. Shown in Figure 8.14 is the squeezing produced by the ANU squeezer over the course of two and a half years.

8.4.1 March 2009 Squeezing

The experiment at this time was in its early stages and many of the high quality components were not yet integrated into the table. Of particular importance is that the homodyne detector from the Max Planck Institute for Gravitational Physics had not yet arrived and in its place a voltage subtracting homodyne detector was used to measure all results. Low flicker noise resistors had not yet replaced the noisy carbon film resistors that were present from its original design. As such, low-frequency flicker noise accounted for much of the roll-up seen in the squeezing trace below about 2 kHz and also resulted in a shot noise measurement that was not flat across the entire spectrum (See § 8.2).

The squeezing magnitude was poor because a PPKTP crystal from Raicol with cheap in-house AR coatings was used. The loss on this crystal, using the method described in § 7.1.3 was found to be around 1.4 % per round trip at the fundamental frequency. This

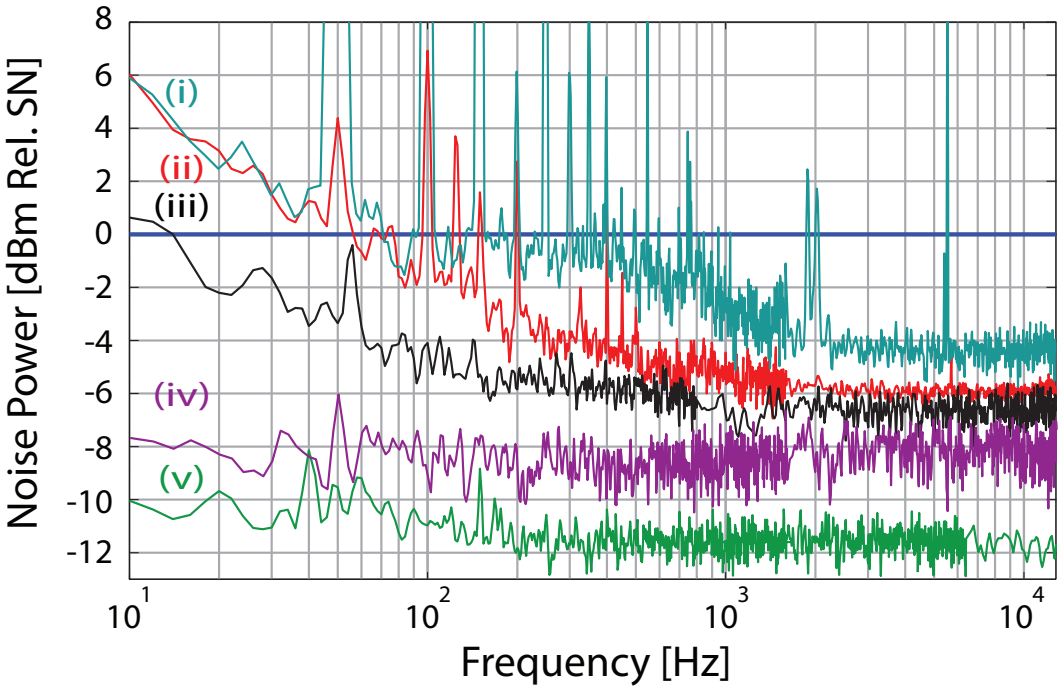

Figure 8.14: A snapshot of squeezing in the ANU squeezer over the years. (i) is the squeezing produced in March 2009 with a squeezing plateau (the lowest squeezing measured over some span) of 4.4 dB, (ii) is the squeezing produced in May 2009 that has a squeezing plateau of 6.0 dB, (iii) is the squeezing produced in January 2010 that has a squeezing plateau of 6.7 dB, (iv) is the squeezing produced in April 2011 that has a squeezing plateau of 8.6 dB and trace (v) is the squeezing produced in November 2011 with a plateau of 11.6 dB. Traces (i)-(iv) are constructed from two spans of 0-1.6 kHz (RBW = 2 Hz) and 0-12.8 kHz (RBW = 16 Hz). Trace (v) is constructed from three spans of 0-1.6 kHz (RBW = 2 Hz), 0-6.4 kHz (RBW = 8 Hz) and 0-102.4 kHz (RBW = 128 Hz). All traces have at least 100 averages except for traces (i) and (iv) which have 50. Dark noise has not been subtracted from any of the data. The dark noise clearance of traces (i) and (ii) was approximately 6 dB and the dark noise clearance of the remaining traces was greater than 10 dB as illustrated in Figure 8.16.

large loss value is enough to explain much of the very poor squeezing seen at this time, the theoretical effect of which can is discussed in § 5.6.

8.4.2 May 2009 Squeezing

The new components had still not arrived but much work had gone into increasing the stability of the locks. In particular, it was seen that noise was coupled into the squeezing at low frequencies via the coherent locking field. Low incident power levels, of 10s of micro-Watts hitting the CLF coupling mirror, were required in order to reduce this coupling to a level where the coherent field was not seen to degrade the squeezing (Theoretically investigated in § 7.4). Ground loops in these locks and the homodyne detector were also worked on, by having the detectors run from their own power supply which was plugged in at different locations until an optimum was found, such that the mains coupling into the measurements was drastically reduced. The phase lock between the primary and CLF lasers was also optimised by varying optical powers and electronic gains. These

improvements resulted in much less low-frequency noise coupling, reducing the roll-up seen at low frequencies, and the increased stability of the locking reduced in an improvement in squeezing magnitude due to a reduction in phase jitter. At this stage, the homodyne detector performance was still limited primarily by the flicker noise. The shot noise at this stage still exhibited a low-frequency roll-up.

8.4.3 January 2010 Squeezing

Many changes were made at this time. A new OPO was constructed that had a higher beam height to replicate the needs of the LIGO squeezing injection. Following advice from Roman Schnabel, new PPKTP crystals that were provided by Raicol, superpolished by Photon LaserOptik GMBH (with a micro-roughness < 0.2rms) and coated by LaserOptik GMBH (with reflectivity $< 0.1\%$ at 1064 nm and $< 0.5\%$ at 532 nm) were ordered. One of these crystals was placed in the new cavity and the intra-cavity loss due to the crystal dropped to the value shown in Table 7.1 of 0.26%.

Much work had been done on a separate experiment to determine the sources of the roll-up seen in the shot noise at low frequencies as discussed previously in this Chapter. The experiment was very successful, and flat shot noise was achieved to below 10 Hz. Flicker noise (§ 8.2), beam jitter (§ 8.3.3), dust and parasitic interference (§ 8.3.4) were found to be the major contributors to low-frequency noise, agreeing with previous findings from prior experiments. At this stage, a new homodyne detector, designed and supplied by Henning Vahlbruch from the Max Planck Institute for Gravitational Physics [143] was swapped in for the previous homodyne detector.

With the introduction of a modecleaner cavity in the LO path, and an isolation tank around the detection components of the setup, the shot noise was finally measured flat down to below 10 Hz. Parasitic interference was present in the squeezing spectrum but was not seen in the shot noise spectrum due to the beam path of the squeezing being blocked when measuring the squeezing.

8.4.4 April 2011 Squeezing

In order to measure flat squeezing then required comprehensive work on the reduction of parasitic interference locations which were initially believed, and later confirmed, to be a major source of noise (See § 8.3.4). It was also postulated that phase jitter may be playing a role in degradation of squeezing, however, it was difficult to confirm this postulate the second harmonic generator would often not produce enough power to reach threshold, where the phase jitter can be measured (See § 8.3.6). A semi-air-tight enclosure was built around the optical table in order to simultaneously reduce phase noise, beam jitter and protect the entire experiment from dust. The enclosure is shown in Figure 8.15.

At this stage, one of the ETX500 diodes in the homodyne detector had failed and was replaced. The efficiency of a number of these diodes were compared to one another and the one with the highest quantum efficiency was chosen. Between diodes from the same batch, only minor variance in efficiency was found, but a recently ordered batch of diodes showed an efficiency of approximately 10 % less than the ones in the older batch (ordered at least 1 year prior). The reduction of parasitic interference, and the box around the table, resulted in the first measurements of flat squeezing. Unfortunately, phase jitter on the beam was not measured at this time so it is difficult to say how much of the improvement in squeezing was due to the new diode, which could not be compared with the broken one, and how much was due to reduced phase jitter, as there was not enough power to get

Figure 8.15: The box encasing the ANU experiment. The primary purpose is to reduce air currents, which in turn reduces noise coupling of beam pointing and phase jitter. It also protects the experiment from dust.

close enough to threshold to characterise it sufficiently. In any case the enclosure certainly aided in stabilising the locks and reducing phase jitter.

8.4.5 November 2011 Squeezing

The final improvement to the experiment was the replacement of Epitaxx ETX500 photodiodes with high quantum efficiency (quoted at $> 99\%$) photodiodes from Laser Components GmbH. These photodiodes were measured to have a quantum efficiency which was approximately 4 % greater than that of the ETX500's. This was determined by constructing a small experiment in which a laser beam was incident on a beamsplitter, with one output field directed towards a detector where the diodes were switched in and out of the same electronic circuit, and the second output field directed towards a reference detector. As expected, this reduction in loss resulted in the detection of much more squeezing with greater purity. The full measurement of this squeezing is shown in Figure 8.16, illustrating the purity, flat shot noise, and dark noise clearance. The optical parametric oscillator was operated with 90 mW of input power (76 % of threshold). The expected propagation loss on the squeezed state is approximately 0.7 % and the balanced homodyne detector had a visibility of 99.4±0.2 %. The squeezing is seen to degrade slightly below 200 Hz due to the presence of parasitic interference that could not be removed. Small factors, such as the slightly altered detector alignment after the diodes were replaced, can have a large effect on the parasitic interference in the experiment and after this change there was difficulty in reducing interference such that it did not degrade the squeezing measurement.

Figure 8.16 shows that with a local oscillator power of approximately 1.9 mW, the shot noise of our detector is greater than 20 dB above the electronic noise. The anti-squeezing is 17.5±0.4 dB above the shot noise and is flat. Below 200 Hz, 10 dB of squeezing is seen and above this frequency 11.6±0.4 dB of squeezing is observed. The measurement shows that noise due to parasitic interference was suppressed down to a level approximately 10 dB below the shot noise. Correcting for dark noise (see § 8.5), the squeezing level becomes 11.9±0.4 dB.

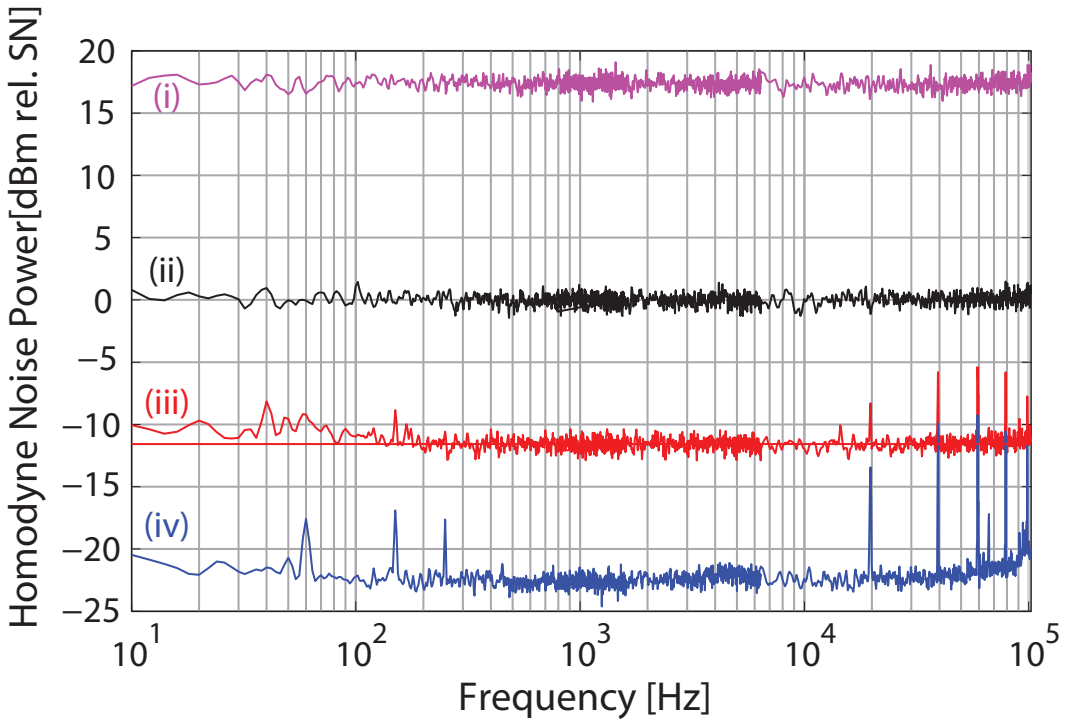

Figure 8.16: Measured squeezing from the ANU squeezer using quantum noise limited balanced homodyne detection showing the anti-squeezing (i), shot noise (ii), squeezing (iii), and dark noise (iv). A red line at -11.6 dB has been added to show the average of the squeezing from 1.6 kHz to 6.4 kHz. All traces are pieced together from 3 FFT windows: 0-1.6 kHz, 0-6.4 kHz, 0-102.4 kHz with 800 FFT lines, resulting in resolution bandwidths of 2 Hz, 8 Hz, and 128 Hz respectively. 100 RMS averages were taken for all traces. Dark noise has not been subtracted from the data.

8.4.6 Correcting for Detection Losses

Using the measured squeezing and anti-squeezing levels, we can infer the total loss on the state by assuming production of a pure state and determining the losses that result in the measured data. This value provides an estimate to the amount of squeezing injected into an interferometer, as the detection scheme is bypassed when the squeezed state is directed towards the interferometer. We can write for the measured squeezing, Sqz[dBm], and measured anti-squeezing, Asqz[dBm],

$$\begin{aligned} \text{Sqz[dBm]} &= 10 * \text{Log}_{10}\left[10^{\text{Sqz}_0/10}\eta_{tot} + (1-\eta_{tot})\right] \\ \text{Asqz[dBm]} &= 10 * \text{Log}_{10}\left[\frac{1}{10^{\text{Sqz}_0/10}}\eta_{tot} + (1-\eta_{tot})\right]. \end{aligned} \tag{8.12}$$

We then simultaneously solve these equations for the total detection efficiency, η_{tot}, and pure intra-cavity squeezing, Sqz_0. This equation accounts only for propagation losses and does not account for other detection issues such as phase jitter. The measured squeezing, Sqz[dBm], should be corrected for dark noise and the initial squeezing is the theoretical value of the squeezing before exiting the cavity. Multiplying Sqz_0 by the escape efficiency results in the amount of squeezing exiting the OPO. Using the measured values from

Figure 8.16, a total loss on the squeezed state of 0.048±0.004 is found, which agrees well with the expected losses. After accounting for the escape efficiency of 0.985 ± 0.001, the amount of squeezing exiting the cavity is found to be approximately 15.0±0.1 dB.

Chapter 9

The LIGO Injection

In this section the LIGO injection experiment is introduced. This project was a large international effort most notably involving the LIGO Scientific Collaboration, the ANU, the Max Planck Institute for Gravitational Physics, Caltech and MIT. The main focus of the input from the ANU was to supply a suitable squeezer, and as such, detail is directed towards the performance and properties of the squeezed light source. This squeezed light source was designed and constructed by Sheon Chua, Conor Mow-Lowry, Sheila Dwyer and I at the ANU. My personal responsibilities were in the design of the cavity geometry, modelling of the non-linear interactions, and investigation of noise sources in the balanced homodyne detection scheme.

The results of the LIGO injection experiment are then revealed. The injection experiment involved many people from all of the aforementioned institutions and will be detailed in the paper soon to be released on this work [153]. My contribution to this experiment was to firstly produce, as part of the group at the ANU, a travelling-wave squeezer that met strict performance benchmarks. Once this was achieved at the ANU, I then spent 6 months at MIT with Sheila Dwyer under the supervision of Prof. N. Mavalvala and Dr. D. Sigg building and characterising a replica of the ANU system. Finally, I spent approximately 2 months aiding in the integration of this squeezer with LIGO in Washington state. During this time I aided in integrating and characterising the squeezer, integrating the control electronics and taking the first measurements of the squeezing enhanced interferometer.

Further information on noise sources, scattered light measurements and interferometer performance with squeezed light injection will be given in more detail by Sheon Chua and Sheila Dwyer in their theses as well as future LIGO working notes and additional papers that are currently under construction.

9.0.7 LIGO Injection Aims

Squeezed light has already been shown to reduce the shot noise in interferometers, including the GEO600 device [68]. The aim of the LIGO H1 injection was not to demonstrate that squeezing could reduce shot noise, instead the goals were to investigate noise, scattered light and integration issues in the more sensitive LIGO interferometer. In particular, the sensitivity of LIGO at frequencies below about 500 Hz allows for investigation of these phenomena at low frequencies, inaccessible in previous experiments. With LIGO H1, it could be ensured that the reduction of shot noise through the injection of squeezed light did not degrade the performance of the device at lower frequencies. It was also decided that it would be beneficial to test a travelling wave bow-tie OPO geometry to complement the findings from GEO600, where a linear OPO geometry was used [100, 120]. The

experimental setup for the injection of squeezed states into H1 is shown in Figure 9.1.

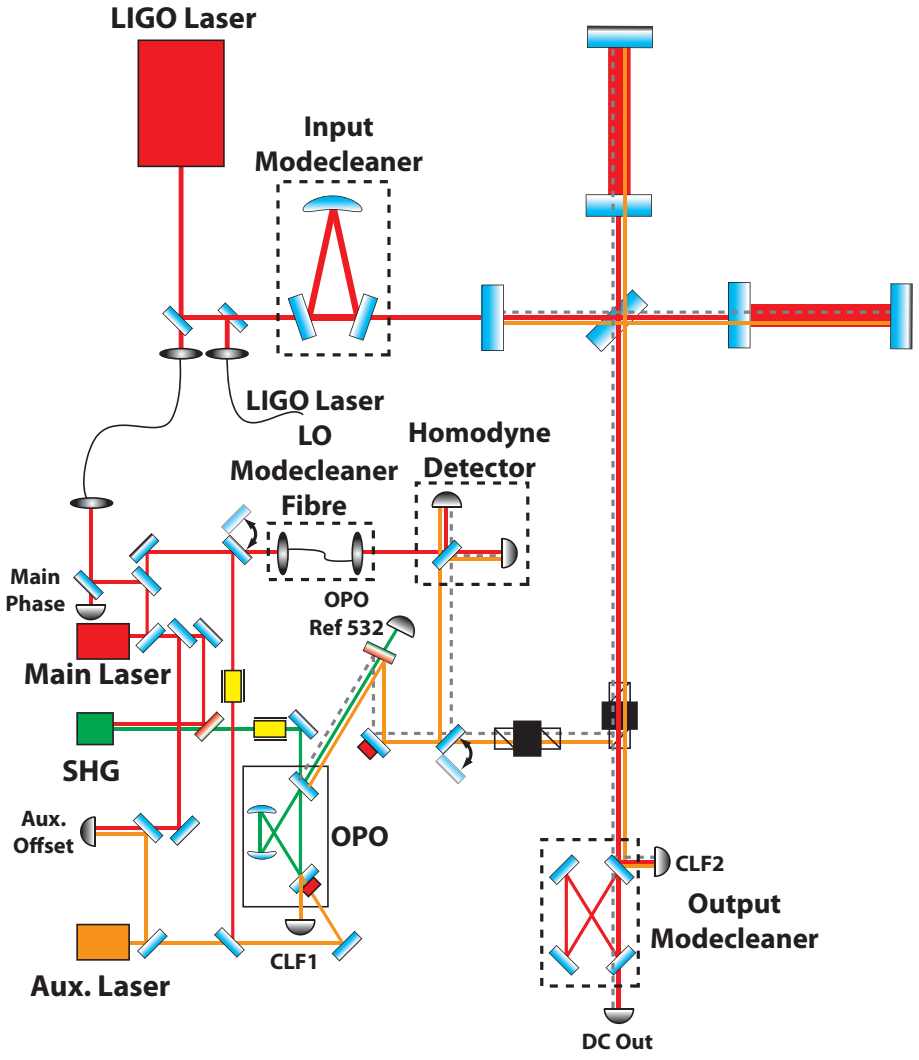

Figure 9.1: Schematic of the squeezed light injection experiment into H1 at LIGO. Pump field is in green, main laser and LIGO laser are both in red, the auxiliary laser is in orange and the squeezing is denoted by a dashed grey line. Full description in text.

The LIGO injection scheme involves three laser sources. The LIGO laser [154], the main squeezing laser (a decommissioned LIGO laser source operating without the amplifier [155]), and an auxiliary laser (Lightwave) for coherent control of the vacuum squeezed state. The phase of the main laser is locked to the phase of the LIGO laser by directing a tap-off from the LIGO laser into a fibre and beating this with a small amount of light from the main laser. Most of the main laser power is directed towards an SHG cavity, where the 1064 nm light is frequency doubled to 532 nm. The SHG cavity was provided by the Max Planck Institute for Gravitational Physics using the same design as that described in [143]. The pump field is incident on the coupling mirror of the OPO. The 532 nm field is then transmitted through a dichroic mirror while the squeezing and auxiliary beams are directed towards either the homdodyne detector or the LIGO interferometer. The transmitted 532 nm light is detected in order to derive a PDH locking signal for the cavity

length. The light from the main laser which is not used for SHG can be passed through a fibre optic cable and used as the local oscillator for the balanced homodyne detector. The fibre optic cable works in much the same way as the modecleaning cavity introduced in Chapter 8 to reduce beam pointing noise. Alternatively, a tap-off from the LIGO laser, directed through a second 100 m long fibre, could be used as the local oscillator for the homodyne detector by swapping the fibre connections at the end of modecleaner fibre setup, this fibre is marked as the LIGO laser LO. The LO from the LIGO laser could ideally be used to characterise the phase lock between the main laser and the LIGO laser when measuring squeezing, although the fibre noise in this LO plays a significant role. With the use of a flipper mirror the main laser field, instead of being used as the LO, can be directed towards the coherent locking coupling mirror in order to seed the OPO for gain and visibility measurements. A tap-off is also used to lock the frequency offset of the auxiliary laser to the main laser.

The auxiliary laser, which is frequency offset locked to the main laser, enters the OPO cavity through the coherent locking mirror. Within the cavity, it senses the non-linear interaction and a sideband field is generated. The reflected auxiliary laser and some small portion of the intra-cavity field is then detected at CLF1 and used to derive the first half of the coherent locking scheme. The auxiliary field and the generated sideband field also transmit through the OPO input coupler, along with the squeezed field, propagating through one Faraday isolator and reflecting off a second isolator, entering the interferometer. When it returns from the interferometer, the coherent locking field reflects off the output mode cleaner and is detected at CLF2. This field is used to derive the locking signal for the second half of the coherent locking. The squeezing passes through the output mode cleaner and is detected at the DC output of the interferometer. This detector is where the gravitational wave signals are also detected. The presence of squeezed light at this detector reduces the shot noise, thus increasing the sensitivity of the interferometer.

9.1 LIGO Squeezer Properties

The LIGO cavity was constructed taking into account the experience provided by the ANU prototype. The major differences were the purchase of higher quality cavity mirrors and the reflectivity of both the pump and squeezed fields on the input/output coupler. It was decided that the high escape efficiency of the ANU squeezer was not necessary for the LIGO cavity, seeing as losses inside the interferometer would limit the enhancement of the squeezing anyway, and as such the reflectivity of the input coupler at the fundamental was increased slightly. Whilst this decreases the escape efficiency, it also decreases the threshold power, reducing photothermal effects and increasing the thermal stability of the OPO slightly. Unfortunately, the modified coherent locking scheme was not developed in time to implement it in this experiment.

9.1.1 Mirror Properties

For reference, the properties of some of the intra-cavity mirrors and coatings bought from Advanced Thin Films are shown in Table 9.1. These mirrors were coated using the Ion Beam Sputtering (IBS) method and are of higher quality than those used in the ANU experiment.

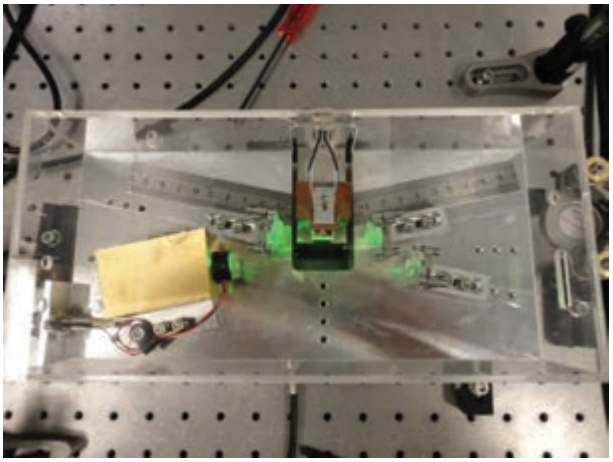

Figure 9.2: The LIGO squeezer, an almost exact replica of the ANU squeezer design.

Mirror Parameter	Value	Units
532 nm HR Reflectivity	>99.99%	-
1064 nm HR Reflectivity	>99.9%	-
532 nm AR Reflectivity	<0.2%	-
1064 nm AR Reflectivity	<0.1%	-
1064 HR Coating Absorption	<0.001%	-
RoC	-38	mm
Substrate Surface Roughness (Curved Surface)	<0.1	nm

Table 9.1: Specified mirror properties for the curved HR OPO mirrors from the manufacturer. The back of the mirrors are AR coated to allow for the injection of fields through these mirrors. All coatings are for an angle of incidence of 6 degrees.

9.1.2 Threshold

The threshold power of the system was measured using the same method as introduced in § 7.1.2. The mode matching of the pump field to the cavity was 74.5 %. The best fit to this data results in a threshold of 75.0±0.1 mW for the amplification regime and a threshold of 74±0.1 mW for the de-amplification regime. Using this information, we can determine the non-linear interaction strength, g, using Equation 5.36. We find that the non-linear interaction strength is 1880 $\pm 9\, s^{-\frac{1}{2}}$, which is very similar to the value found for the ANU squeezer. We expect this to be the case owing to the fact that the geometry of the two squeezers is nearly identical.

9.1.3 Losses

Using the same method as that shown for the ANU squeezer (see § 7.1.3), the reflected power of a seed directed into the front coupler was found to be 84.8 % after correcting for mode matching and dark noise. This results in an intra-cavity loss of 0.0056 ± 0.0001 for the squeezed field. The loss of this cavity was also measured by constructing the cavity without the crystal. The reflected power from the cavity without the crystal loss was 88.8 % after correcting for mode matching and dark noise, resulting in an intra-cavity loss of 0.0041 ± 0.0001. From these values, we can infer that the total crystal loss, consisting

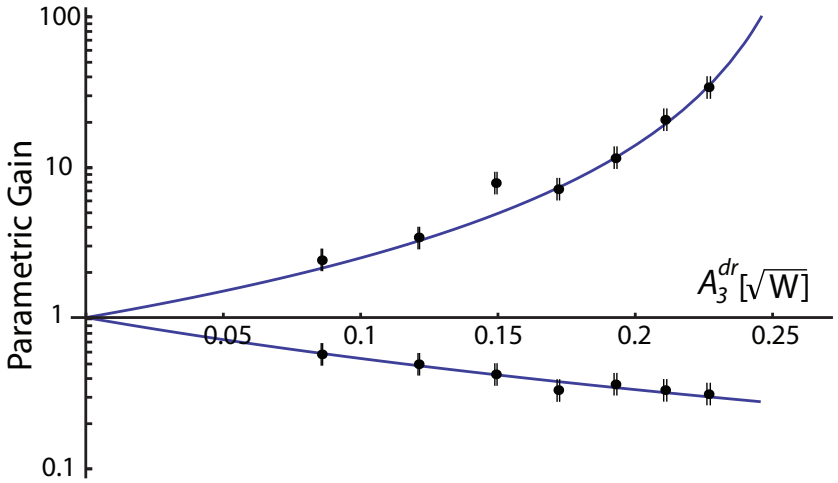

Figure 9.3: Parametric gain as a function of pump amplitude for the LIGO squeezer. The points are the data and the blue curve is the best fit to Equation 5.52.

of the two AR coatings and the absorption, is 0.0015 ± 0.0002. These losses, coupled with the reflectivity of the coupling mirror, of 0.868 ± 0.009, result in an escape efficiency of the cavity of 0.961 ± 0.002. The uncertainty is dominated by the uncertainty in the measurement of the coupling mirror reflectivity by the power meter.

The same process was repeated for the pump field. The reflected power of the pump directed into the front coupler was found to be 61.8 % after correcting for mode matching and dark noise. This implies an intra-cavity loss of 0.039 ± 0.001 for the pump field. The reflected power of the cavity without the crystal loss was 72.7 % after correcting for mode matching and dark noise. This results in an intra-cavity loss of 0.026 ± 0.001. From these values, we can infer that the total crystal loss for the pump, consisting of the two AR coatings and the absorption, is 0.013 ± 0.002.

9.1.4 Cavity Parameters

Table 9.2 shows the parameters of the LIGO squeezed light source. The main difference between this cavity and the prototype ANU cavity is the increase in reflectivity of the input/output coupler at the fundamental wavelength. As expected, this reduced the threshold of the LIGO cavity to 75 mW but also decreased the escape efficiency to 96.1 %.

9.1.5 Squeezing

The squeezing produced by the LIGO squeezed light source is illustrated in Figure 9.4. The squeezer was operated with 850 μW of local oscillator and 50 mW of pump light. The homodyne detector is the same as that used in the ANU squeezing experiment, with ETX500 diodes, and the dark noise lies greater than 20 dB below shot noise.

Figure 9.4 shows that the squeezing plateaus at 5.6 ± 0.4 dB below the shot noise above 1 kHz and the anti-squeezing is 8.8 ± 0.2 dB above shot noise. Using the methods detailed in §8.4.6, the total detection efficiency is found to be 81.4 %. This implies that there is 8.4 ± 0.1 dB of squeezing exiting the cavity. Much of this loss can be attributed to the ETX photodiodes, which we expect to have a quantum efficiency anywhere from 86 % to

Cavity Parameter	Symbol	Value	Uncert.	Units
Fundamental Wavelength	λ_1	1064	-	nm
Second Harmonic Wavelength	λ_3	532	-	nm
Input/Output Coupler Fundamental Reflectivity	$R_1^{in/out}$	0.868	0.009	-
Input/Output Coupler Pump Reflectivity	$R_3^{in/out}$	0.696	0.002	-

Non-linear Coupling Strength	g	1880	9	$s^{-\frac{1}{2}}$
Curved Mirror Radius of Curvature	RoC	-38	-	mm

Table 9.2: Properties of the LIGO squeezer. The loss values given are the transmission values of loss equivalent high reflectivity mirrors. Uncertainties are given for measured values.

96 % (See § 8.4.5). The degradation in squeezing below about 1 kHz is believed to be due to parasitic interference, however, due to time constraints on the project there was not enough time to hunt down the noise sources at these frequencies.

9.2 LIGO Enhancement

Figure 9.5 shows the LIGO strain sensitivity both with, blue trace (ii), and without, red trace (i), squeezed light enhancement. The sensitivity of LIGO has been increased by up to 2 dB in the shot noise limited regime. As expected, the amount of sensitivity improvement diminishes at lower frequencies. Importantly, the sensitivity of the device is not seen to decrease in the low-frequency regime, below about 200 Hz. This is an important result. It shows that scatter, electronic noise couplings and any other noise coupling mechanism has not degraded LIGO's performance at low frequencies. It also indicates that the increase in radiation pressure, the dominating quantum noise source at these frequencies, due to the presence of phase quadrature squeezing is still well below other noise sources. This is not expected to be the case for aLIGO, as shown in Figure 2.5.

9.2.1 Injection Losses

The main limitation to the amount of sensitivity improvement in this experiment was the losses on the squeezed state within the interferometer. One of the major sources of loss were the Faraday isolators in the path of the squeezed field. Each of the Faraday isolators, shown in Figure 9.1, introduced a 6 % loss upon transmission. The Faraday isolator in the LIGO output path is also traversed twice by the squeezed field, doubling this loss.

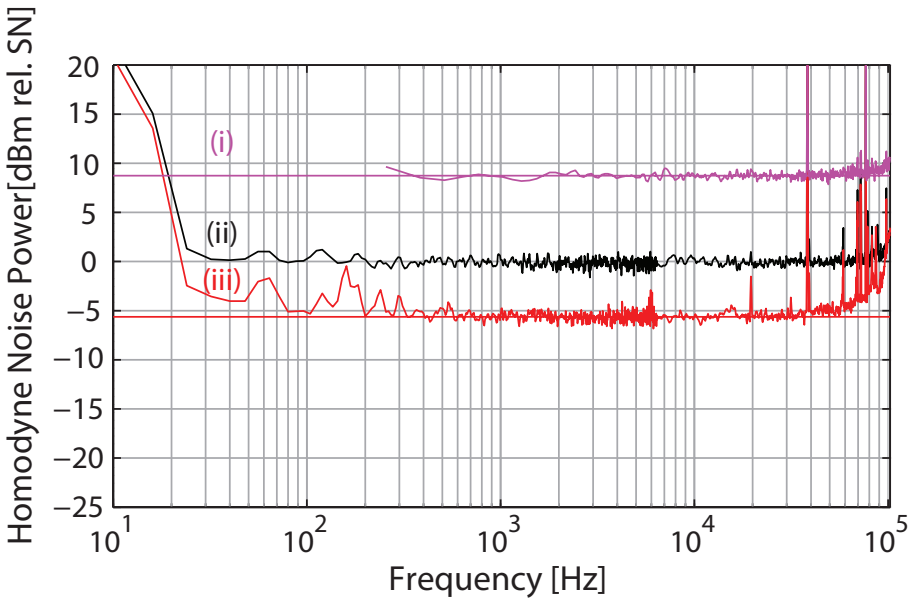

Figure 9.4: Measured squeezing from the LIGO squeezer using a quantum noise limited balanced homodyne detector showing the anti-squeezing (i), shot noise (ii), and squeezing (iii). A red line at -5.6 dB has been added to show the average of the squeezing from 1 kHz to 6 kHz. The shot noise and squeezing traces are pieced together from 2 FFT windows: 0-6.4 kHz, and 0-102.4 kHz with 800 FFT lines, resulting in resolution bandwidths of 8 Hz and 128 Hz respectively. The additional noise seen below 30 Hz is due to DC noise entering the measurements due to the large resolution bandwidths. The anti-squeezing trace has a 0-102.4 kHz bandwidth with 800 FFT lines and a bandwidth of 128 Hz. The first few data points have been removed. 100 RMS averages were taken for all traces. Dark noise has not been subtracted from the data.

The propagation efficiency between the squeezing cavity and the output mode cleaner was measured both in chamber with a power meter at various locations and using the power calibrated CLF2 diode from Figure 9.1 whilst under vacuum. The propagation efficiency determined by both of these measurements agreed and was found to be approximately 80 %.

The element producing the most loss was the output mode cleaner. The transmission through this cavity was measured for a well matched mode and was found to be 82 %. Mode matching to this cavity is difficult because it is near impossible to mode match with the interferometer at full power, therefore it is done at low power and then the power is increased to operational levels. Thermal effects, particularly thermal lensing, from the increased circulating laser power will alter the mode matching when moving from low power to standard operating conditions. The mode matching was measured in a low power configuration to be 74 %. These losses result in a total loss on the squeezed state of approximately 48 %. As shown in Figure 3.8, the most squeezing we could ever hope to measure with a 50 % loss is 3 dB. A more complete summary of these results is expected to be available in the near future [156].

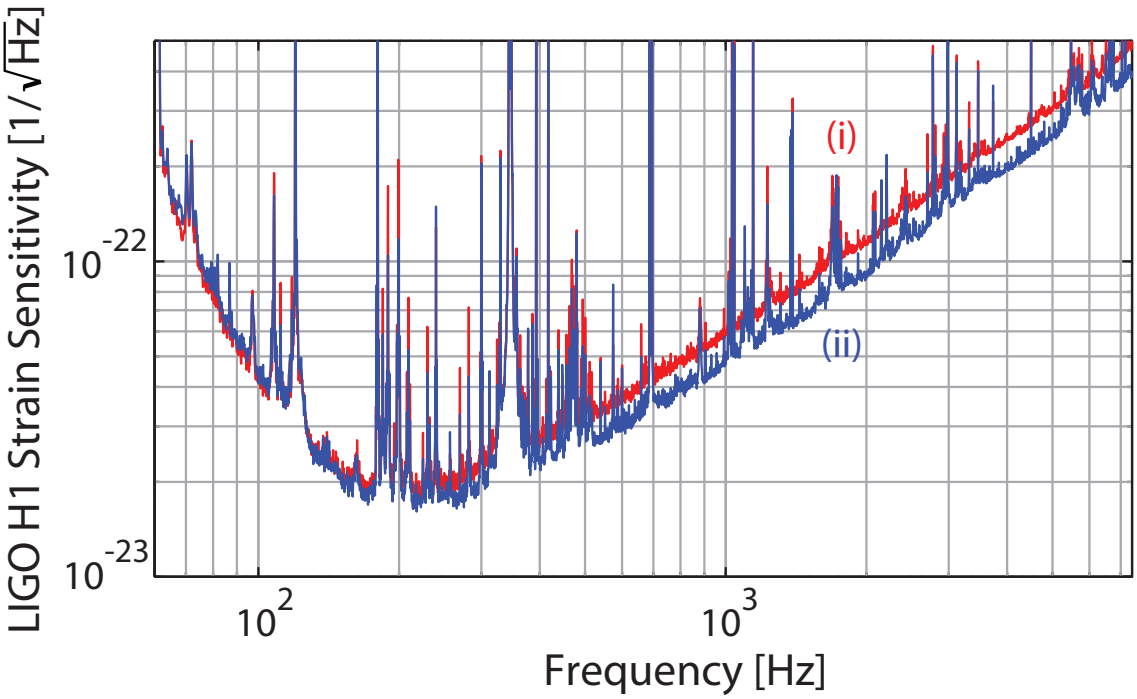

Figure 9.5: LIGO H1 detector squeezing sensitivity without, (i), and with, (ii), squeezing enhancement. Trace (i) shows the typical 6$^{\text{th}}$ science run (S6) operating sensitivity.

9.2.2 Travelling Wave Cavity Backscatter Isolation

It was previously mentioned that each pass through the Faraday isolator resulted in an approximately 6 % loss on the squeezed state. Figure 9.1 shows that the squeezing passes through one Faraday isolator before it enters the beam path of the interferometer's field. This isolator is placed in this location in order to reduce backscatter from the interferometer travelling towards the squeezer. The isolator is critical in ensuring that no scattered light re-enters the interferometer, which would reduce the sensitivity of the device.

In the GEO600 squeezed light experiment, where a linear OPO was used, two Faraday isolators were required in this path to reduce the scattering to an acceptable level [68]. The second Faraday isolator adds additional loss to the squeezed state, reducing the amount of squeezing injected into the interferometer. The travelling wave design used in the LIGO H1 experiment provides isolation to backscattering of greater than 40 dB, which is on par with the isolation offered by a single high-quality large-aperture Faraday isolator [102, 157]. The advantage of the travelling wave cavity is that this isolation is gained without introducing the additional losses of the Faraday isolator. As squeezing becomes a common technique for enhancing the sensitivity of gravitational-wave detectors, effort will be focussed towards decreasing the loss on the squeezed state. As the losses within the interferometer are reduced, the loss due to the Faraday isolators will become increasingly significant.

Chapter 10

Conclusions and Further Work

In this chapter, brief summary of the key results resulting from the ANU squeezer experiment and the H1 LIGO squeezed light injection are provided. From these results, a number of future goals and investigations are identified.

10.1 Summary of Squeezed Light Generation and Control for Gravitational-Wave Detection

- An optical parametric oscillator was designed and constructed as a prototype for the H1 squeezing experiment. The cavity was different to previous designs used in the enhancement of interferometers in that it was a doubly resonant, travelling wave system. Importantly, the travelling wave design was expected to provide a high level of immunity to backscattered light from integration into an interferometer and indeed this was found to be the case. A detailed discussion of the final cavity parameters was presented, and with them the reasoning behind choosing these parameters. Even with the additional intra-cavity loss introduced by the travelling wave design, this squeezer attained record levels of squeezing in the audio band. Down to 200 Hz the squeezing was directly observed at 11.6 dB below shot noise. Parasitic interference degraded the squeezing below this frequency but even so, 10 dB was still directly observed at 10 Hz. The progression of the squeezing results over the life of the experiment was presented and the steps taken to improve these results were discussed.

- A brief investigation of coherent locking was presented. Using the cavity equations of motion, the coherent locking scheme was modelled as a non-degenerate optical parametric oscillator and, using this method, the field amplitudes and phases were determined. It was found that one half of the coherent locking scheme was limiting the stability of the entire system and an alternative solution to this locking loop proposed. This alternative solution required second harmonic generation of the coherent locking field but allowed for the optimisation of this lock without negatively affecting the squeezing, as was found to be the case for the original scheme.

- An investigation into the various noise sources limiting low-frequency balanced homodyne detection was presented. Most of these noise sources had previously been identified but this work discussed all known noise sources and how they relate to each other. A method for detecting and eliminating parasitic interference was presented and the technique was experimentally shown to work as expected. The methods used to overcome the remaining noise sources was presented.

- Finally, a replica of the ANU squeezer was built in the United States and later moved to the LIGO Hannford site. The team at the LIGO site then installed and operated this squeezer in order to enhance the sensitivity of the device to levels never before seen. The noise couplings and integration issues were investigated by the science team at Hanford and will be detailed in later work and the theses of Sheon Chua and Sheila Dwyer.

10.2 Further Work

With the work presented in this thesis, a squeezing goal set around a decade ago has been reached [60, 49]. Squeezing of 10 dB down to frequencies of 10 Hz have been directly observed and should soon become readily reproducible. With the current amount of loss in gravitational-wave detectors, squeezed states of greater magnitude provide very little additional benefit over states such as the one presented here. This illuminates the fact that progression in this field of squeezed states for gravitational-wave detection needs to move towards the investigation of integration and stability, rather than squeezing magnitude. A number of issues that will need to be addressed in the near future are discussed below.

10.2.1 Squeezing Stability

As explained in § 7.4.2, the coherent locking field does not strictly lock to the angle of squeezing. It locks to some arbitrary angle that we choose to align to the angle of the squeezing. It was also discussed that the phase reference can drift, with changes in the temperature of the non-linear medium for example, and this will reduce the amount of squeezing enhancement in the interferometer. Ideally, the squeezer should provide stable squeezing for as long as possible in order to minimise the impact of integration on a fully operational gravitational wave detector. This will require further investigation along the lines of work previously conducted by Khalaidovski [140], possible introduction of a digital control loop to ensure the squeezed light angle does not drift over time, or perhaps the development of a new locking scheme. Further investigation into the coherent locking model presented in this thesis will aid in understanding the direction that needs to be taken.

One possible avenue for improving squeezed state control is to investigate the integration of a phase-matching locking loop into the system [158]. This technique reads out the phase matching condition from within the non-linear medium and if it were somehow integrated, perhaps by use of the frequency shifted auxiliary laser, then it might be able to increase the temperature stability of the system, thus stabilising the angle of the squeezing [140].

10.2.2 Dithering to Remove Parasitic Interference

It was shown in § 8.3.4 that noise due to parasitic interference could be averaged out at lower frequencies and shift the noise up to higher frequencies by dithering the phase of the scattered light. In this case, a mirror was placed in the beam path of the squeezing and therefore dithering of this mirror whilst attempting to measure squeezing would introduce a source of phase jitter, reducing the measured squeezing. By placing a second mirror in the path and feeding-forward the dither to the local oscillator phase, it should be possible to have the squeezing and local oscillator follow each other. This would allow one to

measure the full amount of squeezing, whilst still removing the noise due to the scattered light from the detection band. An investigation into whether this technique would be viable in a gravitational wave detector would be beneficial.

10.2.3 Noise Coupling of the Coherent Locking Field

It was mentioned in § 7.4.1 that as the coherent locking field power was increased, the squeezing was seen to degrade. The reason for this is believed to be due to the presence of intensity noise on the coherent locking field, but further investigation into the matter is required. By understanding how the power of this field leads to degradation in the squeezing, it might be possible to increase the performance of the coherent locking scheme by finding ways in which the generated field can be maximised.

10.2.4 Frequency Dependent Squeezing

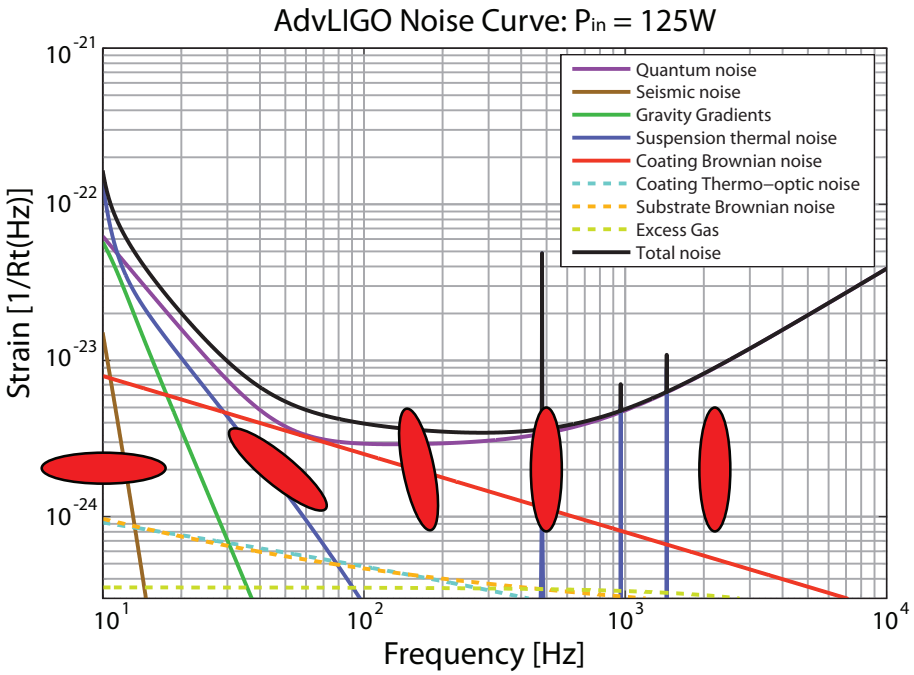

Figure 10.1: The Advanced LIGO expected noise budget showing roughly how frequency dependent squeezing would integrate. The red ellipses indicate the angle of the injected squeezing at the corresponding frequencies, where the phase quadrature is in the x-axis. At high frequencies the squeezed state is squeezed in the phase quadrature, whilst at lower frequencies the squeezing rotates and eventually aligns in the amplitude quadrature. With such a frequency dependent state, the quantum noise can be reduced at all frequencies.

Finally, now that ideal squeezing magnitudes have been achieved, and as the stability and noise couplings are better understood, the next logical step is the production of frequency dependent squeezing. In this work, the squeezing was uniform across all frequencies

and as such, decreasing the shot noise at high frequencies also increases the radiation pressure at low frequencies. Currently, radiation pressure noise is not the limiting noise source at low frequencies and as such increasing its magnitude by introducing phase squeezing has little effect. In the next generation of detectors. however, the radiation pressure noise is expected to be the dominant noise source below many tens of Hertz. Hence, the introduction of a phase squeezed state would improve the high frequency performance, as shown in this thesis, but would also decrease the low-frequency performance of the device.

The exception to this is if frequency dependent squeezed light is utilised, as illustrated in Figure 10.1. Such a state would exhibit amplitude squeezing below some frequency, and would gradually rotate to phase squeezing at higher frequencies. It seems as though this is the next big challenge facing squeezing for gravitational wave detection. It has been shown that filter cavities can rotate the squeezing in the necessary way, but that this will require very large cavities [51]. It needs to either be shown that this technique is practical or another method for rotating the squeezing needs to be developed. A new technique will require a system that can provide dispersion at very low frequencies without introducing substantial loss, and very few, if any, systems currently exist with both of these properties. However, with the squeezing magnitude problem solved, the stability currently being worked on, and the noise coupling currently under investigation from the H1 squeezing experiment and also at GEO600, effort now needs to be directed towards producing these frequency dependent states.

Appendix 1

We begin at Equations 5.39

$$\begin{aligned} i\omega\delta\check{X}_1 &= -\kappa_1\delta\check{X}_1 + g\alpha_1\delta\check{X}_3 + g\alpha_3\delta\check{X}_1^{\dagger} + \sqrt{2\kappa_1^{in}}\delta\check{X}_1^{dr} + \sqrt{2\kappa_1^{out}}\delta\check{X}_1^{vout} + \sqrt{2\kappa_1^{l}}\delta\check{X}_1^{vl} \\ i\omega\delta\check{X}_3 &= -\kappa_3\delta\check{X}_3 - g\alpha_1\delta\check{X}_1 + \sqrt{2\kappa_3^{in}}\delta\check{X}_3^{dr} + \sqrt{2\kappa_3^{out}}\delta\check{X}_3^{vout} + \sqrt{2\kappa_3^{l}}\delta\check{X}_3^{vl}. \end{aligned} \tag{10.1}$$

We solve this set of equations by first rearranging these equations into matrix form

$$\begin{aligned} \begin{pmatrix} \delta\check{X}_1^{dr} \\ \delta\check{X}_3^{dr} \end{pmatrix} &= \begin{pmatrix} \frac{i\omega+\kappa_1-g\alpha_3}{\sqrt{2\kappa_1^{in}}} & \frac{-g\alpha_1}{\sqrt{2\kappa_1^{in}}} \\ \frac{g\alpha_1}{\sqrt{2\kappa_1^{in}}} & \frac{i\omega+\kappa_3}{\sqrt{2\kappa_3^{in}}} \end{pmatrix} \begin{pmatrix} \delta\check{X}_1 \\ \delta\check{X}_3 \end{pmatrix} + \\ & \begin{pmatrix} -\frac{\sqrt{2\kappa_1^{out}}}{\sqrt{2\kappa_1^{in}}}\,\delta\check{X}_1^{vout} - \frac{\sqrt{2\kappa_1^{l}}}{\sqrt{2\kappa_1^{in}}}\,\delta\check{X}_1^{vl} \\ -\frac{\sqrt{2\kappa_3^{out}}}{\sqrt{2\kappa_3^{in}}}\,\delta\check{X}_3^{vout} - \frac{\sqrt{2\kappa_3^{l}}}{\sqrt{2\kappa_3^{in}}}\,\delta\check{X}_3^{vl} \end{pmatrix}. \end{aligned} \tag{10.2}$$

The next step is to solve for the intra-cavity fields, resulting in

$$\begin{aligned} \begin{pmatrix} \delta\check{X}_1 \\ \delta\check{X}_3 \end{pmatrix} &= \begin{pmatrix} \frac{\sqrt{2\kappa_1^{in}}(\kappa_3+i\omega)}{\alpha_1\alpha_1 g^2-(g\alpha_3-\kappa_1-i\omega)(\kappa_3+i\omega)} & \frac{\sqrt{2\kappa_3^{in}}\,g\alpha_1}{\alpha_1\alpha_1 g^2-(g\alpha_3-\kappa_1-i\omega)(\kappa_3+i\omega)} \\ -\frac{\sqrt{2\kappa_1^{in}}\,g\alpha_1}{\alpha_1\alpha_1 g^2-(g\alpha_3-\kappa_1-i\omega)(\kappa_3+i\omega)} & \frac{\sqrt{2\kappa_3^{in}}(g\alpha_3-\kappa_1-i\omega)}{-\alpha_1\alpha_1 g^2+(g\alpha_3-\kappa_1-i\omega)(\kappa_3+i\omega)} \end{pmatrix}. \\ & \begin{pmatrix} \delta\check{X}_1^{dr} + \frac{\sqrt{2\kappa_1^{out}}}{\sqrt{2\kappa_1^{in}}}\,\delta\check{X}_1^{vout} + \frac{\sqrt{2\kappa_1^{l}}}{\sqrt{2\kappa_1^{in}}}\,\delta\check{X}_1^{vl} \\ \delta\check{X}_3^{dr} + \frac{\sqrt{2\kappa_3^{out}}}{\sqrt{2\kappa_3^{in}}}\,\delta\check{X}_3^{vout} - \frac{\sqrt{2\kappa_3^{l}}}{\sqrt{2\kappa_3^{in}}}\,\delta\check{X}_3^{vl} \end{pmatrix}. \end{aligned} \tag{10.3}$$

We now have a solution for the intra-cavity fields, allowing us to determine the output fields using the input/output relations from Equation 5.9, which are rewritten as

$$\delta\check{X}^{ref} = \sqrt{2\kappa^{in}}\,\delta\check{X} - \delta\check{X}^{dr} \tag{10.4}$$

$$\delta\check{X}^{trans} = \sqrt{2\kappa^{out}}\,\delta\check{X} - \delta\check{X}^{vout}. \tag{10.5}$$

At this point we no longer need to investigate the properties of the pump field and so we will only calculate the output field properties of the squeezed field, resulting in

$$\begin{aligned} \delta\check{X}_1^{out} &= \begin{pmatrix} \frac{2\sqrt{\kappa_1^{in}\kappa_1^{out}}(\kappa_3+i\omega)}{\alpha_1\alpha_1 g^2-(g\alpha_3-\kappa_1-i\omega)(\kappa_3+i\omega)} \\ \frac{2\sqrt{\kappa_3^{in}\kappa_1^{out}}\,g\alpha_1}{\alpha_1\alpha_1 g^2-(g\alpha_3-\kappa_1-i\omega)(\kappa_3+i\omega)} \end{pmatrix}. \\ & \begin{pmatrix} \delta\check{X}_1^{dr} + \left(\frac{\sqrt{2\kappa_1^{out}}}{\sqrt{2\kappa_1^{in}}} - (\alpha_1\alpha_1 g^2 - (g\alpha_3-\kappa_1-i\omega)(\kappa_3+i\omega))\right)\delta\check{X}_1^{vout} + K \\ \delta\check{X}_3^{dr} + \frac{\sqrt{2\kappa_3^{out}}}{\sqrt{2\kappa_3^{in}}}\,\delta\check{X}_3^{vout} - \frac{\sqrt{2\kappa_3^{l}}}{\sqrt{2\kappa_3^{in}}}\,\delta\check{X}_3^{vl} \end{pmatrix}, \end{aligned}$$

where K is given by $\mathrm{K} = \frac{\sqrt{2\kappa_1^{l}}}{\sqrt{2\kappa_1^{in}}}\,\delta\check{X}_1^{vl}$.

At this point, these equations can be used to investigate how noise from the two driving fields, the pump and seed fields, couples into the output squeezed state. Up until now, the coherent amplitude of the seed field has not been removed in order to illustrate a point. From Equation 10.6 we see that the two elements in the first matrix can be regarded as coupling constants for the elements in the second matrix. Of note is that the first element of the second matrix consists entirely of noise terms from the seed field, and the second element of this matrix consists entirely of noise terms from the pump field. One can write

$$\delta\check{X}_1^{out} = \begin{pmatrix} C1 & \alpha_1 C2 \end{pmatrix} . \begin{pmatrix} \delta 1 \\ \delta 3 \end{pmatrix},$$

where;

$$\begin{aligned}
C1 &= \frac{2\sqrt{\kappa_1^{in}\kappa_1^{out}}(\kappa_3 + i\omega)}{\alpha_1\alpha_1 g^2 - (g\alpha_3 - \kappa_1 - i\omega)(\kappa_3 + i\omega)}, \\
C2 &= \frac{2\sqrt{\kappa_3^{in}\kappa_1^{out}}\, g}{\alpha_1\alpha_1 g^2 - (g\alpha_3 - \kappa_1 - i\omega)(\kappa_3 + i\omega)}, \\
\delta 1 &= \delta\check{X}_1^{dr} + \left(\frac{\sqrt{2\kappa_1^{out}}}{\sqrt{2\kappa_1^{in}}} - (\alpha_1\alpha_1 g^2 - (g\alpha_3 - \kappa_1 - i\omega)(\kappa_3 + i\omega)) \right) \delta\check{X}_1^{vout} + K, \\
\delta 2 &= \delta\check{X}_3^{dr} + \frac{\sqrt{2\kappa_3^{out}}}{\sqrt{2\kappa_3^{in}}}\, \delta\check{X}_3^{vout} - \frac{\sqrt{2\kappa_3^{l}}}{\sqrt{2\kappa_3^{in}}}\, \delta\check{X}_3^{vl}.
\end{aligned}$$

$C1$ can be considered as the coupling constant for the sum of all noise terms originating from fields at the fundamental frequency, $\delta 1$, and in much the same way, $C2$ can be considered as the coupling constant for all noise terms at the pump frequency $\delta 3$. The explicit dependence of the coupling of the noise terms at the pump frequency on α_1 has been highlighted. It becomes clear that the noise of the pump field is completely decoupled from the noise of the output squeezed field when the seed field has no coherent amplitude, as in the case of the OPO. It was this insight that led to the first measurements of squeezing in the audio band [63]. The details of this noise coupling are discussed in detail by McKenzie [108].

The final step is to calculate the spectrum of the amplitude quadrature noise operator. Using Equation 3.7 we can write for the variance of the output field at the fundamental frequency, V_1^{out},

$$V_1^{out} = < \delta\check{X}_1^{out\dagger} \delta\check{X}_1^{out} > . \tag{10.6}$$

This is simple to calculate due to the fact that the average of the first order noise terms is zero. Due to this fact, the average of the multiplication of uncorrelated noise terms will also result in an answer of zero. Also, the variances of all of the vacuum terms are replaced with their value of unity. At this point the coherent amplitude of the seed field is set to zero. This results in a variance for the amplitude quadrature of the squeezed field of

$$V_{out}^{+} = 1 + \frac{4g\kappa_1^{out}\alpha_3}{(\kappa_1 - g\alpha_3)^2 + \omega^2},$$

where the the subscript 1 has been dropped because it is clear that the equation is for the variance of the squeezed field. The superscript has been reintroduced to specify that this equation is for the amplitude quadrature variance. The result shown in Equation 10.7 is equivalent to the solution found for the case of an OPA under the assumption that the pump field can be treated classically (see [83]). This is because, as we have just shown, the noise from the pump field does not couple to the output state in the absence of a bright seed field. The fact that noise does not couple from this field means that we can treat it classically to simplify the situation.

The phase quadrature variance can be calculated by following the same methods presented here. However, it is possible to derive the phase quadrature variance from the variance of the amplitude quadrature. It can be shown that in the case of the OPA, where a bright seed is present, phase squeezing corresponds to amplification of the seed field, and amplitude squeezing corresponds to de-amplification of the seed field. The system can be moved from amplification to de-amplification by rotating the phase of the pump field by 180 degrees. This is equivalent to changing the sign of all the terms containing the coherent amplitude of the pump field, resulting in a variance for the phase quadrature of

$$V_{out}^{-} = 1 - \frac{4g\kappa_1^{out}\alpha_3}{(\kappa_1 + g\alpha_3)^2 + \omega^2}.$$

Electromagnetic Generators and Detectors of Gravitational Waves *

L. P. Grishchuk
Department of Physics and Astronomy, Cardiff University, Cardiff CF24 3YB, United Kingdom
and Sternberg Astronomical Institute, Moscow University, Moscow 119899, Russia
E-mail: grishchuk@astro.cf.ac.uk

The renewed serious interest to possible practical applications of gravitational waves is encouraging. Building on previous work, I am arguing that the strong variable electromagnetic fields are appropriate systems for the generation and detection of high-frequency gravitational waves (HFGW). The advantages of electromagnetic systems are clearly seen in the proposed complete laboratory experiment, where one has to ensure the efficiency of, both, the process of generation and the process of detection of HFGW. Within the family of electromagnetic systems, one still has a great variety of possible geometrical configurations, classical and quantum states of the electromagnetic field, detection strategies, etc. According to evaluations performed 30 years ago, the gap between the HFGW laboratory signal and its level of detectability is at least 4 orders of magnitude. Hopefully, new technologies of today can remove this gap and can make the laboratory experiment feasible. The laboratory experiment is bound to be expensive, but one should remember that a part of the cost is likely to be reimbursed from the Nobel prize money ! Electromagnetic systems seem also appropriate for the detection of high-frequency end of the spectrum of relic gravitational waves. Although the current effort to observe the stochastic background of relic gravitational waves is focused on the opposite, very low-frequency, end of the spectrum, it would be extremely valuable for fundamental science to detect, or put sensible upper limits on, the high-frequency relic gravitational waves. I will briefly discuss the origin of relic gravitational waves, the expected level of their high-frequency signal, and the existing estimates of its detectability.

I. INTRODUCTION

The engineers and enterpreneures are rightly seeing in gravitational waves (g.w.) a new opportunity, even though, at this moment of time, this opportunity does not look like having a chance of becoming practical in foreseeable future. However, we have many examples of wrong prognoses. It is known that when the discoverer of the nucleus, Lord Rutherford, was asked about the possible practical applications of nuclear energy, he answered "never". It is very likely that the gravitational radiation will eventually become useful, say, for purposes of communication. But in any case, it is difficult to imagine that we will go along without attempting to demonstrate in laboratory conditions the possibility of controllable generation and detection of gravitational waves. The laboratory experiment is a necessary first step to possible practical applications of g.w., and it is this first step that will be mostly discussed in this contribution.

Gravitational waves are less mysterious than one can gather from popular accounts. The relativistic Einstein's gravity is usually described in geometrical terms, as curvature of space-time. Correspondingly, gravitational waves are often described as "oscillations of space-time itself". This characterisation is quite puzzling and distressing for a practically-minded person. It makes defunct the usual physical intuition based on electromagnetic waves and other propagating physical fields. It makes one to suspect that there may be something artificial and unreal in the "waves of space-time itself". But this characterisation is only a matter of unfortunate language. Geometrical concepts are useful for some purposes, but they are greatly misleading for others. One should remember that although the Einstein gravity can be described in geometrical terms, it is also a normal physical field. The gravitational field is universal in all its interactions with itself and other fields and matter, and this is what makes the geometrical formulation of relativistic gravity possible, but the geometrical formulation is not necessary and is not obligatory. In fact, it would be a nightmare to try to discuss the laboratory gravitational-wave experiment in terms of differential geometry and "oscillating space-time", rather than in the engineering terms of the emitted and absorbed physical radiation.

The relativistic gravitational field is governed by the non-linear wave equations - the Einstein equations. However, in many situations one can neglect the non-linearities of the gravitational field. In particular, very often one can neglect the interaction of gravitational waves with other gravitational fields and with themselves. In this case, we

*Invited talk at the first conference on High-Frequency Gravitational Waves, May 2003, The MITRE Corporation, McLean, Virginia, USA

come to the notion of linearized gravity and weak gravitational waves. Certainly, in any laboratory experiment we will be dealing with extremely weak gravitational waves. Weak g.w. are very far from being mysterious; they may even appear quite boring and disappointing. Indeed, there is not so much difference with electromagnetic waves in terms of their general properties, but gravitational waves interact with matter and other fields much-much less effectively than electromagnetic waves. Gravitational waves carry their energy practically without scattering and absorption. This is why it is so difficult to detect astronomical gravitational waves. But the other side of this difficulty is the tremendous penetrating capability of gravitational waves. This is why they are so important as a tool of astronomical research, and this is why they attract attention as a possible unique means of communication.

The relativistic gravitational field can be described by 10 components of the 4×4 symmetric dimensionless tensor $h^{\mu\nu}$. The components of $h^{\mu\nu}$ are functions of time and spatial coordinates $x^\alpha = (ct, x, y, z)$. The functions $h^{\mu\nu}$ obey the nonlinear wave-like dynamical equations - the Einstein equations. The energy-momentum tensor $t^{\mu\nu}$ of the gravitational field is calculable from the field tensor $h^{\mu\nu}$.

The linearised gravitational waves satisfy the wave equation

$$h^{\mu\nu,\alpha}{}_{,\alpha} + \eta^{\mu\nu} h^{\alpha\beta}{}_{,\alpha,\beta} - h^{\nu\alpha,\mu}{}_{,\alpha} - h^{\mu\alpha,\nu}{}_{,\alpha} = 0, \tag{1}$$

where the ordinary derivative is denoted by a comma and $\eta^{\mu\nu}$ is the metric tensor of the Minkowski space-time:

$$\mathrm{d}\sigma^2 = \eta_{\mu\nu}\mathrm{d}x^\mu \mathrm{d}x^\nu = c^2\mathrm{d}t^2 - \mathrm{d}x^2 - \mathrm{d}y^2 - \mathrm{d}z^2. \tag{2}$$

The first term in Eq. (1) is the familiar d'Alembert (wave) operator:

$$h^{\mu\nu,\alpha}{}_{,\alpha} = \left(\frac{\partial^2}{c^2 \partial t^2} - \frac{\partial^2}{\partial x^2} - \frac{\partial^2}{\partial y^2} - \frac{\partial^2}{\partial z^2} \right) h^{\mu\nu}.$$

A plane-wave solution to Eq. (1) is given by

$$h^{\mu\nu} = a^{\mu\nu} e^{i k_\alpha x^\alpha} + c.c., \tag{3}$$

where $k_\alpha k^\alpha = 0$, reflecting the fact that a g.w. propagates with the speed of light. Because of this condition, the field equations (1) require the 10 components of the constant matrix $a^{\mu\nu}$ to satisfy 4 constraints: $a^{\mu\nu} k_\nu = 0$. Among the remaining 6 components, only 2 degrees of freedom (sometimes called the TT-components $\tilde{a}^{ij}$) are physically important, in the sense that it is only these degrees of freedom that fully determine the observational manifestations of the plane wave and its energy-momentum characteristics. Indeed, it is easy to show that the gravitational energy-momentum tensor

$$t_{\mu\nu} = \frac{c^4}{32\pi G} \left[h^{\alpha\beta}{}_{,\mu} h_{\alpha\beta,\nu} - \frac{1}{2} h_{,\mu} h_{,\nu} \right] \tag{4}$$

depends only on the TT-components of the field and its two independent amplitudes h_+ and $h_\times$:

$$t_{\mu\nu} = \frac{c^4}{32\pi G} k_\mu k_\nu \left[2\tilde{a}^{ij} \tilde{a}^*_{ij} \right] = \frac{c^4}{32\pi G} k_\mu k_\nu \left[h_+^2 + h_\times^2 \right]. \tag{5}$$

In this expression we have dropped (as we normally do in the case of energy-momentum tensor for the electromagnetic waves) the purely oscillatory terms.

The amplitudes $h_+, h_\times$ are determined by the source of the gravitational waves. To find the amplitudes, we should replace the zero in the right hand side of Eq. (1) by the source term $(16\pi G/c^4) T^{\mu\nu}$, where $T^{\mu\nu}$ is the energy-momentum tensor of the source, and seek the retarded solutions to the inhomogeneous wave equation. For example, for a pair of stars in a circular orbit, with masses of the stars M_1, M_2, located at the distance R_0 from us, and after averaging over the orbital period and orientation of the orbital plane, we obtain

$$h = \left(\langle h_+^2 \rangle + \langle h_\times^2 \rangle \right)^{1/2} = \left(\frac{32}{5} \right)^{1/2} \frac{1}{R_0} \frac{G^{5/3}}{c^4} \frac{M_1 M_2}{(M_1 + M_2)^{1/3}} (\pi f)^{2/3}, \tag{6}$$

where the emitted g.w. frequency f (in Hz) is twice the orbital frequency.

Roughly, the characteristic amplitude h from a given source is given by

$$h_{ij} \approx \frac{G}{c^4} \int \frac{T_{ij}(t_{ret})}{r} dV \qquad \text{and} \qquad h \approx \frac{1}{R_0} \frac{GM}{c^2} \left(\frac{v}{c} \right)^2, \tag{7}$$

where M is the total mass of the source and v is the characteristic velocity of the matter bulk motion. This formula is quite universal, and it can also be written in terms of the characteristic variable stresses σ within the source, and the source's volume V:

$$h \approx \frac{1}{R_0}\frac{G}{c^4}\sigma V. \tag{8}$$

As long as the retardation effects inside the source can be neglected, this formula is equally well applicable to the radiating systems of any nature - in cosmos and in laboratory, mechanical and electromagnetic.

II. CURRENT STATUS OF THE ASTRONOMICAL PROGRAM AND ITS COMPARISON WITH A HFGW LABORATORY PROGRAM

The dimensionless number h is a very convenient characterisation of the strenght of a given g.w. and its detectability. Under the action of a gravitational wave, a pair of free masses, initially separated by the distance l, experience relative oscillatory displacements proportional to the incoming wave amplitude h: $\delta l/l \approx h$. Very powerful astronomical sources, currently under intense experimental g.w. searches [1], [2], [3], produce something like $h \approx 10^{-22}$ at Earth. This is an increadibly small number. It enters any conceivable method of detection of gravitational waves and explains why it is so difficult to observe them. For example, in a $4km$-long laser interferometer, such as LIGO, we need to beat all the noises and measure the mirror's displacements at the level of $4 \times 10^{-17} cm$. At the same time, the flux of energy $F = ct^{0i}$ at Earth from the discussed sources is quite impressive by astronomical standards. At the representative frequency $f = 200Hz$, the flux reaches $F \approx 3 \times 10^{-2} erg/sec\ cm^2$. But most of this energy passes through the g.w. detectors without scattering and absorption. This is why, in the gravitational-wave physics, such characteristics as *watts* and *joules* may be misleading. The dimensionless amplitude h is more adequate. But in any case, whatever the units in which the analysis is being carried out, only a joint discussion of the complete system (emitter plus detector) gives the correct evaluation of what is "small" or "big", easy to detect or extremely difficult to detect.

The recently assembled LIGO interferometers are approaching their planned level of sensitivity. It appears that, at the time of writing, there still exists a gap in one order of magnitude, in terms of h, between the actually reached level of sensisitivity and the design sensitivity [1]. One should clearly understand what is likely to happen when the design level of sensitivity of the initial interferometers is finally achieved. Baring the extremely fortunate surprises, we will probably be able to see only the most powerful, but rare, sources, such as coalescing binary stellar-mass black holes. Less powerful, even if more numerous, sources - coalescing binary neutron stars, are unlikely to be seen, because the expected signal-to-noise ratio is somewhat smaller than 1. For a guaranteed detection of astronomical sources, the experimenters will have to improve the sensitivity by one further order of magnitude, as compared with the design sensitivity of the initial instruments. This is the goal of the so-called advanced interferometers, and this goal will probably be reached by 2007. (For more details on the current status of the gravitational wave astronomy see, for example, [2], [3].)

There is little doubt that the astronomical program will completely dominate, and rightly so, any other experimental efforts in the gravitational-wave physics for some time to come. Having said that, one can still wonder whether a laboratory experiment is much more difficult to realise than to build equipment for the observation of cosmic gravitational waves. Of course, the justifications for these efforts are totally different. In gravitational-wave astronomy we directly explore the fascinating Universe, whereas in the laboratory experiment we are likely to confirm a theory (true, very fundamental theory, but anyway tested also by other means), with very remote prospects for practical applications of gravitational radiation. However, the justification for the laboratory experiment is sufficiently convincing. A more difficult question is its feasibility. Here, one will have to admit that the both enterprises are very difficult. Surprisingly, the laboratory program does not appear to be unacceptably more difficult than the cosmic program. If we take as a benchmark the 4 orders of magnitude separating the detecting and generating capabilities in laboratory (see Sec. IV below), it is like having 1 dollar instead of required 10000. But, strictly speaking, in the cosmic program we also have, at the time of writing, only something like 1 dollar instead of required 100 (see above). The difference between the two programs is substantial, but not ridiculously large.

As an additional motivation for the experimental work on HFGW, there are arguments showing that it can be complementary and useful for the astronomical program. First, there exists the fundamentally important cosmological signal - relic gravitational waves. The high-frequency end of the spectrum is the most natural interval for the high-frequency techniques, and first of all for electromagnetic detectors (see Sec V below). Second, part of the high-frequency studies with electromagnetic detectors may eventually be useful for laser interferometers of the next generation. Indeed, it is quite likely that in order to reach the required level of sensitivity we will be forced to implement the sophisticated techniques such as squeezed light and quantum-nondemolition measurements (see, for example, [4]) and this is where the expertise of the HFGW community can be useful.

III. EFFICIENCY OF GRAVITATIONAL-WAVE EMITTERS

Astronomical sources are immensely more powerful than any conceivable sources at Earth, but they are very far away from us, and not under our control. In contrast, in laboratory, one can place the emitter and the detector very close to each other, choose the appropriate materials, implement the coherence and focusing of the emitted radiation, use the advantages of the resonant detection, etc. One usually illustrates the hopelessness of laboratory g.w. experiments by giving an example of the meager gravitational radiation generated by a rotating massive rod. Well, if you are so naive that you plan to rotate a rod, then the enterprise may indeed be hopeless. But surely there must exist something smarter. Let us give a general comparative analysis of possible mechanical and electromagnetic systems [5].

Let us consider an elementary mechanical emitter (m-emitter) and an elementary electromagnetic emitter (e-emitter). By the elementary we mean a source that occupies a volume of order λ_s^3 in the first case and λ_e^3 in the second case; λ_s and λ_e are the wavelengths of the acoustic and electromagnetic waves. A vibrating object and an oscillating electromagnetic wave in a cavity are examples of $m-$ and $e-$ emitters respectively. For the comparison to be fair, the sources are assumed to emit g.w. with one and the same wavelength λ_g and are placed at the same distance R_0 from the observer.

Let A be the amplitude of elastic vibrations in the m-emitter. Then the characteristic amplitude of the stress tensor T_{ij} is $\sigma_m \approx \rho_m v_s^2 (A/\lambda_s)$, where ρ_m is the density of the material and v_s^2 is the square of the sound speed. Since $\nu_g = c/\lambda_g \approx v_s/\lambda_s$, we have $\lambda_s \approx (v_s/c)\lambda_g \ll \lambda_g$ which means that the body of the elementary m-emitter is situated deeply inside the inductive zone of the gravitational radiation and, hence, the retardation effects within the source are negligibly small. For the g.w. amplitude we obtain from Eq. (8):

$$h_m \approx \frac{G}{c^4}\frac{1}{R_0}\sigma_m \lambda_s^3. \tag{9}$$

Let us now consider an elementary e-emitter. The amplitude σ_e of the electromagnetic stress has the order of magnitude of the energy density ϵ_e of the varying electromagnetic field, $\rho_e c^2 = \epsilon_e$, i.e. $\sigma_e \approx \epsilon_e$. Since $\nu_g = c/\lambda_g \approx c/\lambda_e$, the volume of the elementary e-emitter is of the order of λ_g^3, that is, it is still at the limit of applicability of Eq. (8) with the retardation effects ignored. The amplitude of the emitted gravitational wave is

$$h_e \approx \frac{G}{c^4}\frac{1}{R_0}\sigma_e \lambda_g^3. \tag{10}$$

The ratio of (9) and (10) is

$$\frac{h_m}{h_e} \approx \frac{\rho_m}{\rho_e}\left(\frac{v_s}{c}\right)^5 \frac{A}{\lambda_s}. \tag{11}$$

Using the reasonable parameters: $\rho_m \approx 1 g/cm^3$, $\rho_e \approx 10^{-18} g/cm^3$, $v_s/c \approx 10^{-5}$, $A/\lambda_s \approx 10^{-3}$, we find that $h_m/h_e \approx 10^{-10}$. In other words, an elementary e-emitter is much more efficient than an elementary m-emitter. However, the comparison is not entirely fair as the volume of the former, λ_g^3, is much larger than the volume of the later, λ_s^3. In the volume of an elementary e-emitter one can accomodate a large number $N = (\lambda_g/\lambda_s)^3 \approx (c/v_s)^3 \gg 1$ of elementary m-emitters. Under the condition that they all are phased to work coherently, the total g.w. amplitude is the sum of individual amplitudes, and it can be as large as $h_{mc} \approx N h_m$. Then, we finally obtain

$$\frac{h_{mc}}{h_e} \approx \frac{\sigma_m}{\sigma_e}. \tag{12}$$

This formula answers all the principal questions. We see that the most important parameter is the maximal reachable amplitude of the dynamical stresses. Extremely high stresses, at the limit of static breaking point, for very strong materials, is in the range of $\sigma_m \approx 10^9 dyne\ cm^2$. Similar variable stresses can be obtained by producing and maintaining variable electromagnetic fields with characteristic field strength $E \approx H \approx 10^5 gauss$. Then, an elementary e-emitter, having the volume $\lambda_g^3 \approx 10^6 cm^3$, produces a g.w. amplitude $h \approx 10^{-36}$ at the boundary of the wave zone, and emits the total power $W \approx 4 \times 10^{-13} erg/sec$. To raise the amplitude and power, one would have to implement large composite systems.

This analysis illustrates the advantages of the electromagnetic systems. First, the coherence of the source is automatically achieved in a large volume $\sim \lambda_g^3$. The huge number of mechanical emitters placed in the same volume would need to be specially phased in order to achieve the constructive interference of the emitted gravitational radiation. Second, it seems that it is much easier to manufacture a simple electromagnetic emitter (essentially, an oscillating eigen-mode of the electromagnetic field in a cavity) than try to pack together a large number of specially phased mechanical emitters. Third, the efficient generation process suggests the similar (inverse) process of detection. It seems natural to use the electromagnetic systems also as the detection technique.

IV. COMPLETE LABORATORY EXPERIMENT

The important concern for the succcess of the laboratory experiment is to ensure the focusing, as much as possible, of the emitted g.w. power in one place, rather than to let it be dispersed over all directions. This was one of motivations for the specific geometrical configuration suggested in [6]. It is proposed that the emitter is a torus-like electromagnetic resonator with a rectangular cross-section (see Fig. 1). The oscillating electromagnetic field in the resonator produces a standing gravitational wave in the focal region, near the axis of symmetry. The gravitational wave is standing because the emitted cylindrical gravitational wave passes through the axis of symmetry and interferes with itself. The gravitational-wave frequency Ω is twice the frequency of the variable electromagnetic field in the generator, $\Omega = 2\omega$. Another resonator is placed in the focal region and plays the role of the detector. Its resonant frequency is tuned to the frequency of the gravitational wave Ω. Among the advantages of this particular configuration is its geometrical simplicity, which allows one to find exact solutions to the Maxwell equations, both, in the generator and in the detector.

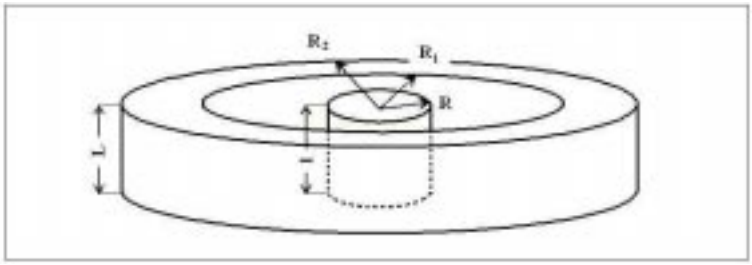

FIG. 1. Scheme of a possible laboratory experiment

Although almost all the calculations [6] have been performed exactly, it is convenient to use the order of magnitude evaluations which follow from the calculations, and which, of course, coincide with the evaluations outlined above. The very important estimate, which we did not discuss yet, is the detectabilty condition.

The analysis shows that the change of energy $\Delta\mathcal{E}$ in the resonator-detector depends on whether the initial electromagnetic field in the detector is realised as a constant (say, magnetic) field, or as a an oscillating resonant electromagnetic eigen-mode. It is assumed that the accumulation of the signal is taking place during the relaxation time $\tau^* = Q/\Omega$, where Q is the quality factor of the resonator-detector. Then, in the first case, $\Delta\mathcal{E} \approx (hQ)^2\mathcal{E}$, where $\mathcal{E} = (H^2/8\pi)V$. And in the second case, $\Delta\mathcal{E} \approx (hQ)\mathcal{E}$, where $\mathcal{E} = (E^2/4\pi)V$. These formulas show that the responses of the detector are different in these two options. But the natural electromagnetic noises are also different. One should impose different criteria in order to determine whether the one and the same g.w. signal is detectable or not. In the first case, one can think that one can distinguish one "photon" (a resonant mode exitation with energy $\mathcal{E} \sim \hbar\Omega$) on the background of a constant (magnetic) field. In the second case, one should typically assume that only the number $\sqrt{N}$ of new "photons" can be distinguished on the background of the already existing N "photons", $N = \mathcal{E}/\hbar\Omega$. Combining each of responses with the corresponding detectability condition, one finds that there is in fact no much difference between these two cases in terms of the measurable amplitude h. The order of magnitude evaluation shows that the detectable h is

$$h_{det} \approx \sqrt{\frac{\hbar\Omega}{\mathcal{E}}}\frac{1}{Q}. \tag{13}$$

The situation can, however, change considerably in favor of the second option, if one succeeds in realising a special (quantum) state of the electromagnetic field in the detector, such that the variance of the number of quanta N is much smaller than $\sqrt{N}$. Then, assuming that the quantum non-demolition measurement can distinguish the energy of, say, a few new quanta on the backgound of a huge (mean) number of quanta in the detector, the detectable g.w. amplitude h_{det} can be significantly lowered. We will first continue our estimates without taking this possibility into account, but will return to it later.

The geometry of the system allows one to choose the following optimal parameters: $L \approx l \approx \lambda$, where $\lambda = 2\pi c/\Omega$, $R \approx 2\lambda/3,\ R_1 \approx 2\lambda,\ R_2 \approx 7\lambda/2$. Then the detectability condition can be written as

$$\lambda^4 E^2 HQ \approx 30\frac{c^4}{G}\sqrt{\hbar c}, \tag{14}$$

where E is the amplitude of the oscillating field in the generator and H is the typical (possibly, constant magnetic) field in the detector. Let us take for illustration $\lambda \approx 10^2 cm,\ E \approx H \approx 3\times 10^5 gauss,\ Q \approx 7\times 10^{13}$. Then, the

left-hand side of Eq. (14) is 4 orders of magnitude smaller than the right-hand side of the same formula. It is this gap of 4 orders of magnitude that we referred to in the Abstract.

One possibility to satisfy Eq. (14) is to simply increase the size of the system, going from $\lambda \approx 10^2 cm$ to $\lambda \approx 10^3 cm$. Another possibility would be to raise the product E^2HQ by the same 4 orders of magnitude. Probably the most elegant and realistic possibility is to try and improve the detectability condition by using the sophisticated quantum states of the electromagnetic field in the detector, that we mentioned earlier. Certainly, the laboratory experiment is going to be difficult, but it seems worth of trying.

V. ELECTROMAGNETIC DETECTORS FOR RELIC GRAVITATIONAL WAVES

In laboratory conditions, and in almost all astrophysical situations, one can completely neglect the non-linearities of gravity, that is, the interaction of gravitational waves with other gravitational fields. However, this is not always the case. The most important example is the interaction of gravitational waves with the strong variable gravitational field of the very early Universe. One can use the engineering intuition in order to understand what is going on here. A gravitational wave can be thought of as a harmonic oscillator, while the smooth variable gravitational field of the surrounding Universe as a gravitational pump field. The g.w. oscillator is parametrically coupled to the gravitational pump field. This specific coupling follows from the non-linear structure of the Einstein equations. This coupling provides a mechanism for the superadiabatic (parametric) amplification of classical waves and for the quantum-mechanical generation of waves from their zero-point quantum oscillations [3]. The word "superadiabatic" emphasizes the fact that this effect takes place over and above whetever happens to the wave during very slow (adiabatic) changes of the pump field. That is, we are interested in the increase of occupation numbers, rather than in the gradual shift of energy levels. The word "parametric" emphasizes the mathematical structure of the wave equation. A parameter of the oscillator, namely its frequency, is being changed by the variable pump field. It is this sufficiently rapid change of frequency of the oscillator that is responsible for the considerable increase of energy of that oscillator.

The parametric amplification of the inevitable zero-point quantum oscillations leads to the generation of a stochastic background of relic gravitational waves. The mechanism itself is based on the fundamental physics only, but the generated signal depends on the pump field. In other words, the amount of relic gravitational waves depend on a concrete cosmological model of the very early Universe. Combining the theory with the available cosmological data, one can evaluate the expected level of high-frequency relic gravitational waves [3]. For example, the root-mean-square (r.m.s.) amplitude is expected to reach $h_{r.m.s.} \approx 10^{-30}$ at $\nu = 10^7 Hz$. The amplitude is smaller at higher frequencies. It may reach $h_{r.m.s.} \approx 10^{-32}$ at $\nu = 10^{11} Hz$, but then it should quickly decrease as a function of higher frequencies. There is no much sense to expect any relic gravitational waves at frequencies higher than that.

We may be lucky (although it does not seem very likely) if the thermal background of gravitational waves survived until now. Then, in the vicinity of $\nu = 10^{11} Hz$ there will be a maximum of the Planck spectrum. The amplitude of the Planck spectrum can be in the region of $h_{r.m.s.} \approx 3 \times 10^{-32}$, but not very much larger than this. The quoted numbers for relic and thermal backgrounds give the feeling of what we can expect of high-frequency cosmic gravitational waves.

What can be said about the detectability of relic gravitational waves ? The first impression is that they may be easier to detect than the gravitational waves produced in laboratory. For example, at $\nu = 10^7 Hz$, the amplitude of relic gravitational waves, $h_{r.m.s.} \approx 10^{-30}$, is several orders of magnitude higher than the realistic amplitude of laboratory gravitational waves (see Sec. IV). Unfortunately, this does not mean that the relic gravitational waves are easier to detect. The crucial difference is in the character of these two signals. The laboratory signal is essentially a deterministic monochromatic wave, which allows one to systematically accumulate the response amplitude. In contrast, relic gravitational waves form a random signal, which allows only an accumulation of energy. When it comes to evaluation of the detectable amplitude of relic gravitational waves [7], formula (13) should be modified. Under the same conditions that formula (13) was derived, but now for the stochastic signal, we obtain

$$h_{det} \approx \sqrt{\frac{\hbar\Omega}{\mathcal{E}}} \frac{1}{\sqrt{Q}}. \tag{15}$$

Applying this formula to a simple electromagnetic detector, we can expect to measure $h_{det} \approx 10^{-26}$ instead of the required level of the cosmic signal $h_{r.m.s.} \approx 10^{-30}$.

This gap is sufficiently wide to discount hopes to bridge this gap by longer observation time, or cross-correlation of several detectors, etc. It appears that the sensitivity of electromagnetic detectors can reach the required level only if the squeezed quantum states of the electromagnetic field in the detector, and quantum non-demolition measurements, are implemented. Aternatively, one can think of large composite systems ("large crystal" [7]), where the individual elements are arranged to work more coherently than simply absorbing gravitational radiation independently one from

other. Although these techniques seem possible in principle, so far, there is no concrete proposals how to implement them in practice. Regrettably, the detection of high-frequency relic gravitational waves will probably be even more challenging problem than their detection in low-frequency and very low-frequency bands. Smart ideas are badly needed.

Abstract. The generation of High-Frequency Gravitational Waves (HFGW) has been identified as the required breakthrough that will lead to new forms of space propulsion. Many techniques have been devised to generate HFGW, but most of them exhibit marginal efficiency, therefore the power emitted in form of gravitational waves (GW) is orders of magnitude lower than the input power. The gravitational wave counterpart of the LASER, termed Gravitational-wave LASER or "GASER" is the quantum approach to the efficient generation of gravitational waves. Electrons, protons, muons, etc, all have charge and mass, if accelerated they usually lose energy through the very fast electric and magnetic channels, this causes a negligible emission through the gravitational channel. Quantum systems can be engineered to forbid electric and magnetic transitions, therefore the gravitational spin-2 transitions can take place. A class of active materials, suitable for making a GASER based on electronic transitions in the solid state, is identified along with their relevant physical properties. Means for creating coherence and population inversion and means to increase the emission probability are described. The expected performances of the device are derived from quantum gravitational theories. Additional properties of the active materials are considered to enforce the theoretical foundation of the device. A proof-of-concept device, operating at about 1 THz, is described. Experiments are proposed as a natural starting point of the research.

INTRODUCTION

Present space propulsion technology, mainly based on rocketry, suffers of serious limitations if the range of operations is extended above earth orbit.

Dynamical and speed limitations are accompanied by safety concerns. Rockets must transport the payload and the propellant used as reaction mass. Rockets require such a large amount of energy to accomplish their tasks that management of the required fuel may expose the passengers to a high risk. The energy requirement for a space transportation system can be reduced if a new technology is developed to employ distant masses as reaction mass. The propellant will be no longer needed and will not take away energy.

Gravitational Wave Propulsion

A remarkable advancement in space propulsion is a form of gravitational wave propulsion (GWP) (Fontana, 2000 and 2003a; Baker, 2000). This is still an untested technique, nevertheless it is based on a straightforward application of the theory of General Relativity (GR), which is trusted by the vast majority of scientists. The new technology is based on High Frequency Gravitational Waves (HFGWs).

A large literature exists on colliding gravitational waves (Szekeres, 1972; Ferrari, 1988a and 1988b), it has been found that the collision or focusing (Alekseev, 1995 and 1996) of gravitational waves produce curvature singularities. These singularities have properties very similar to those of a black-hole, an essential and

fundamentally simple object, which produces a gravitational field. GWP is the application of these theories to space travel.

Generators of GWs could be installed directly onboard or remotely to a spacecraft to induce curvature singularities near the spacecraft. The use of HFGW "… as a source of some additional gravitational field**…**" at a distance was suggested by L. D. Landau and E. M. Lifshitz (1975). According to GR, spacecraft mass interacts with spacetime curvature, therefore the spacecraft will move towards the singularity. In the Newtonian picture, because of the non-linearity of space, the wave at the focus is converted to a Coulomb-like gravitational field. The induced field accelerates the spacecraft and accelerates the reaction mass, this latter can be easily identified with distant masses (Fontana, 2003a). In Newtonian gravity the propagation of the gravitational field is instantaneous; this might not be true, nevertheless it must be accepted when dealing with this approach.

Generators of Gravitational Waves

To create spacetime singularities, powerful and efficient generators of GW are required. The produced GWs must have a wavelength of the order of millimeters or less, because it is necessary to collimate or focus the waves to a small spot to reach the high energy densities that produces non-linearity effects culminating with the creation of spacetime singularities. The wavelength of GWs must be much smaller than the size of the generator which, in turn, must be compatible with the size of a typical spacecraft.

A large literature describes different proposed devices capable of producing HFGWs (Baker , 2004; Pinto, 1988). Generators of high frequency gravitational waves based on quantum effects may offer higher efficiencies because only at the quantum level there is a precise distinction between gravitational and electromagnetic transitions. In addition, quantum generators may benefit from coherence and/or Bose condensation effects, which may strongly increase the emission probability of GW quanta. Quantum generators of HFGWs can potentially be very efficient in converting input power to GWs.

After recognizing that a quantum source can be developed (Halpern, 1964; Ford, 1982), the first serious difficulty in designing a quantum source of HFGW is the identification of a suitable active material.

The first interesting result consists of recognizing that the orthorombic cuprate High Temperature SuperConductor (HTSC) might become an active material in which gravitational transitions may take place (Fontana, 2000). Later a more comprehensive approach to the problem, including the details of the HTSC GASER, was developed and presented by Fontana and Baker (2003b).

According to the historical nomenclature the quantum source of gravitational waves has been named GASER and the quantum of gravitational wave, graviton.

In the article by Fontana and Baker (2003b), the instanton, with its theoretical foundations developed in Gibbons (1993) (Sanchez, 1982 and 1983), has been used to describe the wave-particle associated to a quantum of gravitational radiation. The (gravitational) instanton can be defined as a pseudoparticle solution of the Einstein equations in Euclidean spacetime (signature ++++) with a cosmological constant. The Euclidean signature helps to remove singularities found in the theory with Lorentzian signature (-+++) and has been introduced for the purpose of the analysis. The Euclidean signature is characterized by imaginary-valued time, the Lorentzian signature is characterized by real-valued time. Research programs have also found instantons solutions in our Lorentzian spacetime and, interestingly, some of them can be identified with colliding gravitational waves (Sanchez, 1982).

The well-known "graviton" is not so well defined. It is usually associated to a spin-2 field that has been somehow quantized. Recently it has been discovered that the graviton may have a mass, depending on boundary conditions like large scale, or local, properties of space-time associated to the Λ term, known as the cosmological constant (Novello, 2003), with the result that $m_g^2=-2\Lambda/3$. The possibly changing sign of the Λ term, while going from the vicinity to the source to the free space of our expanding universe, may give unexpected properties to the graviton.

Today, a generally accepted mathematical description of the quantum of GWs does not exist. The lack of experimental access to these objects and their interactions might explain the difficulties in finding an acceptable

model. In addition to space propulsion models, a quantum source of GWs is also the resource that must be developed for further progress towards a better understanding of gravitation and cosmology.

THE HTSC GASER

Different from GW quanta themselves, the mechanisms capable of producing GWs, even from microscopic systems, are better known. The theory describing the emission of gravitational radiation from quantum systems has been developed by Halpern (1964) and Ford (1982). Transitions for which the orbital quantum number L changes by ±2 and for which the total quantum number J changes by 0 or ±2 are gravitational quadrupolar transitions, for which the emission of photons is forbidden and the emission of gravitons is allowed. The selection rules for photons are those for which the orbital quantum number L changes by ±1 and for which the total quantum number J changes by 0 or ±1, etc. For instance, for an atom, gravitational transitions are those between orbitals 3d and one characterized by a lower energy among 3s, 2s and 1s. In typical atomic systems gravitational transitions compete with multiple photon transitions, therefore methods for counteracting photon transitions have to be developed. Detailed analysis comparing the emission of gravitons to the emission of photons has shown that the ratio R of the transition probabilities for matrix elements of equal structures is of the order of 1.6×10^{-36} for the proton (Halpern, 1964) and of the order of 4.8×10^{-43} for the electron. An intermediate value can be found for the muon.

To increase the efficiency, stimulated emission and coherence can improve the apparently negligible emission probability. The device that employs stimulated emission has been named GASER (Halpern, 1964). We adopted (Fontana, 2003b) the same name for the device that employs wavefunction coherence for increasing the emission probability.

According to Fontana and Baker (2003b), the ideal gaser material should provide:

1. A quantum system with two energy levels characterized by a difference in orbital quantum number of 2, in agreement with Halpern and Laurent selection rules.

2. A quantum system possibly composed of densely packed couples of closely interacting electrons.

3. A quantum system in which the two energy levels are respectively populated by objects with exactly the same wavefunction and the same energy in order to have negligible linewidths, thus permitting efficient stimulated emission.

4. A quantum system in which the two energy levels are populated by quantum objects, for which the two wavefunctions are orthogonal in order to prevent photon transitions and tunneling.

5. A quantum system in which population inversion can be achieved to initiate and sustain gaser action.

A candidate material with the enumerated requirements is a cuprate high temperature superconductor (HTSC) with orthorombic crystal structure, being the two quantum systems *s-wave* (l=0) and *d-wave* (l=2) Cooper-pair condensates (Kouznetsov, 1997) (Fontana, 2000).

In Fontana and Baker (2003b), it has been shown, with the help of three quantum gravitational theories, that the emission probability for gravitons is proportional to the square of the number of Cooper-pairs involved. Assuming Cooper-pair density of the order of $10^{20}/cm^3$ or slightly higher (there are $\sim 5 \times 10^{21}/cm^3$ elementary cells in YBCO) the emission probability looks interesting for a volume of the HTSC greater than few cubic centimeters. In addition to that analysis, the recent discovery that Cooper-pair formation in HTSC involves the *4s* to *3d* electron exchange amplitude in Cu atoms (Mishonov, 2003) that shows the electrons of the pairs posses the quantum numbers required for the gravitational transition. The main process allowing direct transitions between *s-wave* and *d-wave* condensates is therefore purely gravitational.

For direct transitions the energy of the emitted particle only depends on the energy gap. Taking into account the measured *s-wave/d-wave* energy gap, the frequency of 1.3THz can be estimated from BSCCO data (Moessle, 1999).

Like the well-known optical laser, a GASER could be pumped by another GW source, this possibility was not yet properly explored and does not solve the problem of producing GWs from a different form of energy. According to Fontana and Baker (2003b), the HTSC GASER can be pumped electrically, with the injection of *s-wave* Cooper-pairs by a Josephson junction between a Low Temperature SuperConductor (LTSC) and the HTSC, respectively connected to the poles of a current generator. LTSCs are characterized by pure *s-wave* pairing. The estimated power emitted in a GW is of the order of 10 W/ cm^2 with a current of 10 kA/cm^2.

FABRICATION OF A PROTOTYPE HTSC GASER

Generally, the fabrication of prototype devices is a complex procedure. It starts with the design of the device, structure and size, goes through the definition of the materials, nature and purity, the definition of the fabrication process, techniques and steps. Finally, the properties of the produced device will be measured to recognize if the results agree with expectation. The procedure is usually repeated many times.

The structure of the proposed HTSC GASER is quite simple; an orthorombic cuprate HTSC mono-crystal should be produced along with a Josephson junction with a LTSC. Both sides of the device should be metalized for connecting the GASER to a current generator. To define the preferable geometry of the HTSC mono-crystal we make some considerations on directivity patterns in wavefunction coherent systems.

Directivity of emission is generally determined by a combination of geometrical properties of the emitter, for instance the shape of the resonant cavity of a LASER. For a wavefunction coherent system in the solid state, composed of microscopic oscillators emitting waves, the directivity function is the product of two components: the directivity function of the single emitter, and the superposition function (interference) of many such emitters. The collective wavefunction is the mechanism that synchronizes the oscillators.

In Halpern (1964) it has been shown that there exists a directivity pattern for transitions emitting gravitons, the directivity here depends on the *d-wave* wavefunction orientation. In HTSC, the macroscopic wavefunction has been observed by interference effects in Josephson junctions. The macroscopic wavefunction is oriented according to the crystallographic orientation of the HTSC crystal. Even if this factor has a minima and maxima, its dependence on the angles is smooth, and it appears to be not critical, nevertheless crystals with different crystallographic orientation should be built to test the theory. The directivity factor related to the superposition function of many emitters is what mainly determines the directivity function and the directivity gain. The angular distribution of GWs for a quantum system is derived in Halpern (1964). For J=M=2 it takes the form:

$$\cos^8\left(\frac{\vartheta}{2}\right)+\sin^8\left(\frac{\vartheta}{2}\right). \tag{1}$$

It has been found that the maximum amount of gravitational radiation occurs in a direction for which the corresponding electromagnetic radiation is excluded or is a minimal. The *d-wave* wavefunction in HTSCs develops in the *a-b* crystallographic axes (Narlikar, 2003), making a maximum of the gravitational radiation emitted in the direction of the *c* axis. This emission is bi-directional.

Structure

The structure of the proposed HTSC GASER is the one proposed in Fontana and Baker (2003b).

The superposition of a large number of coherent sources is expressed by the interference pattern that they project on a detector at a large distance with respect to the wavelength λ. For instance, the maximum emission for a linear array is for $a \sin\vartheta = n\lambda$, where a is the spacing of the point sources, and n is an integer to which the maximum is associated. The amplitude of the maxima is N^2 times the amplitude produced by each source, where N is the number of sources. More generally a circular planar surface distribution of point sources will produce a beam of radiation orthogonal to the plane of the point sources provided that the wavelength is much shorter than the diameter of the

distribution. The emission is bi-directional. A binary neutron star pair is a celestial example in which the orbit plane is the source of bi-directional GW normal to that orbit plane.

Interestingly it is possible to conceive a distribution of coherent point sources on a spherical surface, as shown in FIGURE 1. For outgoing waves they mimic a point source located at the center of the sphere with a power equal to the coherent summation of the radiation emitted by all the point sources. The radiation directed towards the center is focused to the center of the sphere, therefore a large power density can be obtained. The order of magnitude of the power density gain for a given total input power is A/λ^2, where A is the total area covered by the point sources.

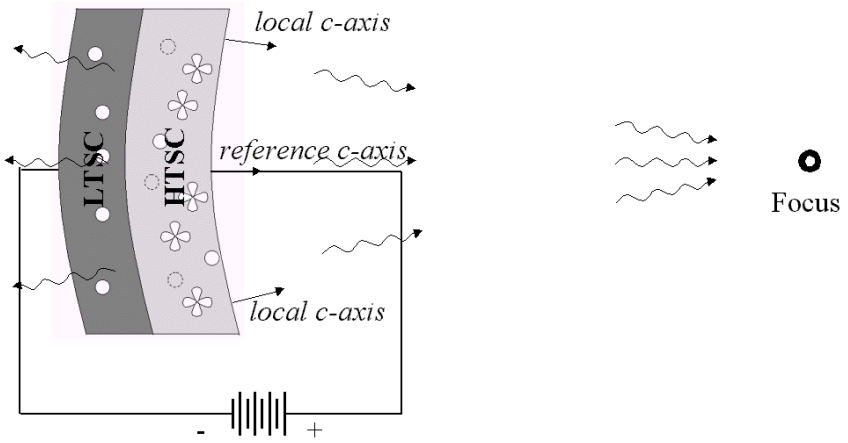

FIGURE 1. The Curved HTSC GASER (Section). The Section is Revolved around the *Reference c-axis*.

To produce curved wavefronts it is necessary to produce a thin HTSC film with the required crystallographic orientation, followed by bending the crystal as required to keep the wavefunction coherence on a curved spherical surface. Alternatively a more complex structure should be devised, based on a spherical surface tiled with planar polygons of HTSC interconnected among each other, each with the c-axis directed toward the focus.

The HTSC GASER is a dual layered device, the HTSC *s-wave/d-wave* layer is the one requiring the highest care, because the crystallographic orientation is important for the device to work properly. We therefore need to discuss the HTSC layer with more detail.

Production techniques and materials.

Orthorombic cuprate HTSC mono-crystals can be produced using different techniques. For bulk material, which appears suitable to planar devices, the melt-textured techniques seem acceptable. This technique requires the sintering of the precursor powders to produce unaligned, grainy HTSC. Afterward, a thermal process termed incongruent melting is performed. The grainy HTSC melts and reacts to form another solid plus a liquid phase. An oriented solidification is then performed, using a $SmBa_2Cu_3O_x$ seed to facilitate the crystallization with the required orientation. Very precise thermal gradients and time-temperature processing are involved. The melt-textured techniques and the related different methods are reviewed by Desgardin (1999).

Thin film techniques seem better suited for making curved GASERs, unfortunately there is no need in current technological applications of curved HTSC films similar to those required here, therefore a new production technology should be developed. Thin film depositions are reviewed by Narlikar (2003). Silicon or Aluminum substrates, buffered by thin layers of CeO_2 and Y-stabilized ZrO_2 can be coated with HTSCs. Thermal coevaporation may offer 20-30 nm/min growth rates. Pulsed laser deposition (PLD) offers similar rates. Magnetron sputtering is widely used for the deposition of layers of metals with high melting temperatures, it easily adapts to the deposition of HTSC with rates of about 10 nm/min. Metalorganic chemical vapor deposition (MOCVD) may offer 1 μm/min. Sol-gel techniques have also been successfully employed for the preparation of thin films of HTSCs.

Because the coherence gain is proportional to the volume of the HTSC, the melt-textured HTSC seems the best choice for a possible first prototype.

The production of HTSC/LTSC Josephson junction is a standard technique, see for instance the article by Moessle (1999). The Pb LTSC can be evaporated on the HTSC surface directly or with the interposition of an Au or Ag interlayer having thickness between 1 and 6 nm. The HTSC GASER must operate at temperatures below the lowest transition temperature of both HTSC and LTSC, i.e. liquid helium for Pb LTSC. The recently discovered superconductor MgB_2 is an extremely interesting option for the LTSC layer because of its high transition temperature of 39 K (Canfield, 2003) and low cost.

The isotopic purity of the raw materials used for sintering the HTSC layer appears a key factor for successfully manufacturing the HTSC GASER. Superconductors in which phonons play a role in inducing electron pairing exhibit a well known isotope effect (Bardeen, 1957; McMillan, 1968). The situation in HTSCs is not completely understood, with experiments giving controversial results, with the latest ones confirming the isotope effect (Bernhard, 2003). The HTSC GASER is based on a very precise transition between two energy levels (macroscopically related to critical temperatures $Tc \propto M^{-\alpha}$, with M mass of the element and α isotope effect). Isotopic mixtures are detrimental at the microscopic scale, where the wavefunction is perturbed with reduction of coherence.

Experimental setup and driving electronics.

It is possible to conceive a setup based on a planar, disk shaped, GASER with area of about 100 cm^2 and thickness of the order of 1 cm. A planar thyristor (SCR – semiconductor controlled rectifier) or a gas thyratron is connected in series with the HTSC GASER and a large set of parallel connected capacitors (C) close the circuit. The capacitors are distributed all around the sandwich. The configuration is intended for pulsed operation with high current. It offers low circuit inductance (L) and low series resistance (R), and is electrically similar to the configuration used for pulsed laser diodes. If the Q of the series equivalent RLC circuit is higher than 1, with a single discharge the GASER will emit a series of exponentially damped pulses of HFGWs with modulation frequency of $1/2\pi\sqrt{(LC)}$. To permit the complete discharge of the capacitors, the thyristor must conduct for the full discharge time and a recirculation diode should be connected in parallel with it. GaAs-based semiconductors can operate at liquid helium temperatures, instead Si-based semiconductors can operate at liquid nitrogen temperatures.

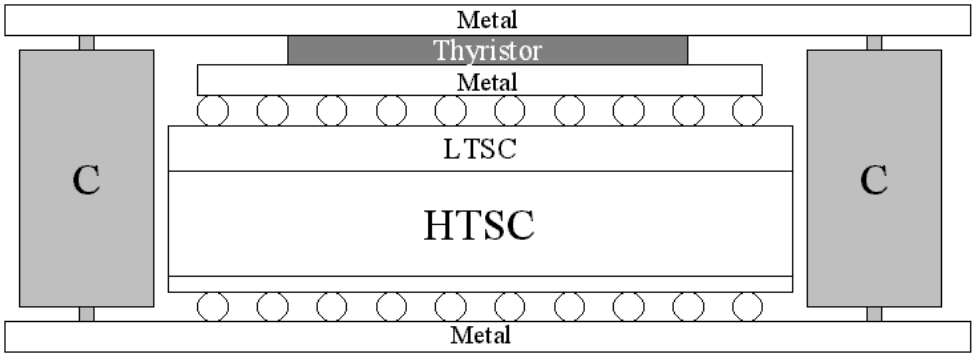

FIGURE 2. The Proposed Experimental Setup (Vertical Section).

FIGURE 2 shows a vertical section of the experimental setup for pulsed operations. Differently from standard Josephson junctions used in research instrumentation, the HTSC GASER is a high power device with current densities up to 10 kA/cm^2. Indium or Bismuth collapsible ball contacts may facilitate the connection of the device to the GASER cage and driving electronics. A voltage generator should be connected to the top and bottom electrodes for charging the capacitors, it should be disconnected before the discharge. Assuming $Q=R^{-1}\sqrt{(L/C)} >> 1$, the peak current is $I_P=V_C\sqrt{(C/L)}$. With capacitance of the order of 10 μF and inductance of the order of 0.1μH, peak currents of the order of 100 kA can be obtained with about 10000 V of charging voltage.

DETECTION OF HFGWs AND EXPECTED RESULTS.

Gravitational waves, possibly emitted by the HTSC GASER, can be detected by specialized detectors for HFGW in the GHz to THz range. It has been shown that the detection of 1.3 THz HFGW with $h \geq 10^{-30}$, as it is expected from the proposed planar HTSC GASER, could be possible with the synchroresonance converter described by Li (2003). Many different detector are also described in the literature as reported by Baker (2004) and in the book by Misner (1973) and many other articles (Thorne, 1980a-b), unfortunately many detectors have been developed for low frequency GWs and it is unclear if they can be adapted to the THz range. Additionally, it should be emphasized that the "classical" theory of gravitational wave propagation and detection is based on the solution of the linearized Einstein equations, intended to treat small perturbations on flat spacetime. Unfortunately for the approach, our spacetime is not flat but is characterized by a constant curvature (Λ term, de Sitter spacetime). Moreover, the energy density near the microscopic sources in the GASER may favor nonlinear effects. Usual simplification conditions seem violated in our approach, which has the potential to make the "classical" detection uncertain.

The expected instanton solutions (Gibbons, 1993; Sanchez, 1982), massive graviton solutions in spacetime with a cosmological constant (Novello, 2003) and self-interaction effects (Ferrari, 1988a and 1988b; Veneziano, 1987; Alekseev, 1996) might indeed simplify the detection of GASER radiation. Standard gravimeters and accelerometers could be the detection instruments. Invoking self-interaction effects, the curved GASER with the parameters already described might produce E≈1mJ of gravitational energy, which is able to accelerate test masses in the vicinity of the focus. The possibility of controlling the operations of the source allows the adoption of lock-in techniques for synchronous detection, thus improving the signal to noise ratio with long integration time.

Claims of observation of gravitational anomalies near HTSC excited by electromagnetic fields have already appeared in the scientific literature (Podkletnov, 1992). Unfortunately, it was not possible to replicate the results till now. This fact might be explained with the incomplete understanding of the phenomenology. Woods (2004) presents a review covering the subject and, more generally, the claims of interaction between gravitation and HTSC.

CONCLUSION

High Frequency Gravitational Waves have great potential for old, new and unexpected applications. Many interesting and new phenomena have been predicted to become possible by using HFGW. Among them we may cite the possibility to communicate directly through objects opaque to electromagnetic radiation and the possibility of 3D imaging of the internal structure of large and very dense objects like the Earth itself (Baker, 2000). Space travel is an old application that may strongly benefit from HFGW. As soon as powerful generators of HFGW will be made available, spacecrafts capable of fast interstellar travel could be constructed. It is superfluous to cite the extraordinary benefits of the discovery of extra-solar planets and their possible life forms. Commercial airlines could operate a fleet of planes with HFGW propulsion, permitting a faster and more comfortable trip to the destination. The HTSC GASER is the proposed device capable of generating ~1 THz HFGWs with high conversion efficiency and is intended to start the new era. This article has presented an approach for the construction of a proof-of-concept prototype, comprising the design of the GASER structure, choice of the materials and basic electronics designed for pulsed operations. Techniques for the detection of the emitted radiation have also been discussed.

The coupled seismic to gravitational surface wave fields are analyzed in a liquid layer lying on the gravitating elastic, low-rigidity half-space. Solution is obtained within the framework of the normal mode formalism applied to the flat ocean-solid Earth model. From the theory of propagation of coupled surface waves (Rayleigh and Love) in layered media, we find the individual multipliers that determine the surface wave spectrum over the entire frequency range. Spectra of excitation functions are investigated for dip-slip point source in the half-space. Main results can be summarized as follows. When the half-space is filled with sediments, dip-slip excitation functions of gravity and Rayleigh waves are one order of magnitude larger than for the half-space composed of hard rocks. Including gravity in the elastic medium essentially changes the character of gravity wave spectrum, leading to an appearance of the third maximum. At the deepening of the source amplitude of this maximum increases. Theoretical marigrams show that including gravity in the half-space also increases period of the gravity wave excited by deep sources by a factor of two, up to 10 minutes. At the same time, presence of gravity force in the half-space has no effect on the spectrum of the Rayleigh wave.

1. Introduction

Considerable effort has been taken to develop both the analytical description of the propagation process of long period gravity (tsunami) and ocean Rayleigh waves for the case of uniform depth (Yamashita and Sato, 1974; Ward, 1980; Comer, 1984a, b; Okal, 1988; *et al.*) and the numerical one for actual bathymetry (e.g. Hwang, 1972; Satake, 1985).

Yamashita and Sato (1974, 1976), using the fully coupled ocean-solid Earth model, analyzed the influence of a number of focal parameters-dip-angle, fault length and focal depth and the rise time of the source time function- on the tsunami (long period gravity wave) and Rayleigh waves. Earthquake source was modeled by the point dislocation and a finite-moving source. Numerical computations have been performed for the dip-slip source model, because large submarine earthquakes near Japan are of this type. Their results can be summarized as follows. In the case of tsunami wave, such parameters as dip-angle, fault length and depth all play an important role in generation process. The maximum amplitudes in the wave trains at azimuths $\varphi = 90^\circ$ and $\varphi = 270^\circ$ become large for large dip-angles. In the case of $\varphi = 0^\circ$, the maximum amplitude is the largest when dip-angle is 45°. The fault length also significantly affects the directivity. When the ratio- of 'fault width to its length increases, the directivity at the azimuth $\varphi = 90^\circ$ and $\varphi = 270^\circ$ become very strong. Velocity of rupture propagation and rise time do not affect much the tsunami amplitude and waveform. In the case of Rayleigh wave, the spectral amplitude decreases monotonously, with as the increase of focal depth. The dip-angle factor has the entirely opposite effect compared to the tsunami wave. The spectral amplitude of Rayleigh wave predominates for smaller dip-angle. The rise time parameter also affects strongly the Rayleigh wave, which become essentially suppressed-as rise time increases.

Ward (1980) considered the tsunami generation problem in the context of a spherically symmetric self-gravitating and elastic ocean-Earth model using the normal mode formalism. He formulated and solved full linearized equations of motion in a manner similar to that originally applied to the Earth's free oscillations. Using moment tensor representation for both point and line seismic source he has derived expressions for tsunami wave displacement in near- and far-field zones.

Consequently Comer (1984a, b) introduced a solution for the tsunami mode excitation in the flat Earth by a point source. He emphasized that the excitation problem in the flat Earth differs substantially from the corresponding problem for the spherical Earth. There is a continuum of frequencies and wavenumbers for the flat Earth but frequencies and angular orders are discrete on the spherical Earth. Also, the normal modes of a finite body form a complete basis for the small oscillations of the body but those of an infinite body, like the flat Earth, do not. In common with Ward, Comer assumed the ocean to be non-viscid and only considered linearized equations of motion and boundary conditions. Alike the earlier authors investigations (Pod"yapol'sky, 1968, 1970; Alexeev and Gusiakov, 1976) he has shown that far-field tsunami in the fully coupled ocean-solid Earth model depend strongly on the source depth, duration, moment and mechanism.

Okal's study (1988) was largely based on Ward formalism considering tsunami wave as the superposition of the free oscillations of an elastic self-gravitating Earth, excited by a seismic sources. Extending the range of source depths to 250

km he showed that this parameter plays only a limited role in controlling the tsunami amplitude. More important are the effects of directivity due to rupture propagation along the fault and the possibility of enhanced tsunami excitation in an elastically weak material. Analyzing tsunami and Rayleigh wave generation by non-double couple sources, he found, in particular, that a landslide involving weak sediments could result in very large tsunami.

In the description of tsunami and Rayleigh waves propagation in most models, discussed above, the gravity force was included only in the liquid layer. Since in the present study we take gravity into account also in the solid Earth, we briefly review the previous works in this direction.

Surface wave propagation in the elastic medium under the influence of gravity was considered by a number of authors (Matuzawa, 1925; Gilbert, 1967; Lomnitz, 1970, 1990, 1991; De and Sengupta, 1976). Gilbert (1967) described a gravitationally perturbed Rayleigh wave in a low-rigidity medium which forms a linear continuum ranging from a solid rocks to water. In this approach everything is attributed to the variation of a single parameter- the rigidity. Gilbert has made energy estimations for surface waves and showed that in a low rigidity medium such as unconsolidated sediments the energy of gravity is comparable with the shear strain energy. In the case of Rayleigh wave propagated in the non-gravitating half-space the $\overline{S}$ is more dominant pulse. In the present of gravity, as β decreases, the $\overline{S}$ pulse becomes insignificant, and the $\overline{P}$ pulse becomes dispersive and approaches the behavior of the classical gravity wave.

Lomnitz (1990), analyzing the behavior of sediments during the Mexico 1985 earthquake, has supposed that a nonlinear mechanism could make the rheology of the Mexico City soft clay nearer to a fluid than to a solid. At large amplitudes, when the stress-strain relation becomes strongly nonlinear sediments may liquefy, and in such conditions the gravity wave propagates as in a liquid. It is worth mentioning here that originally Matuzawa (1925) proposed the idea of existence and propagation of waves of hydrodynamic origin in soils. Based on the study of Tokyo 1923 earthquake, he speculated that sediments could behave like solids at high frequencies and like fluids at low frequencies.

Dealing with gravity wave propagation in the system consisting of the liquid layer and elastic half-space it is possible to neglect the gravity in an elastic medium, since it is small in comparison with the elastic forces. General effect of gravity on the wave propagation in such a system is determined by gravity effect in the liquid. When the ocean bottom consists of rigid rocks the above assumption is reasonable. Although in this case too, including the gravity force in the motion equations of the elastic substratum, changes slightly the dispersion curve at the 10000 seconds period (Pod"yapol'sky, 1968, 1970; Alexeev and Gusiakov, 1974). In the present work, however, we focus on the wave excitation by seismic sources located in low-rigidity media. Therefore it is appropriate not to omit gravity from the description of this medium, since its effects can be evaluated to some extent even within the framework of linear theory.

Present study is focused on the developing an analytical model of gravity and Rayleigh waves excitation by a realistic earthquake source located in the gravitating low-rigidity half-space. We do not deal in detail with the effects of focal parameters on the gravity and Rayleigh wave generation, because it was already done in previous studies mentioned above. It is worth noting that in the case of gravity wave we analyze the wave spectrum in the whole range of frequencies, not limited by its long-period component (tsunami). We will describe the seismic response in function of source location in the half-space and compare the results obtained for a liquid layer and a gravitating half-space model with a liquid layer plus a non-gravitating half-space.

2. Statement of the Problem

Consider gravity and Rayleigh waves in a compressible liquid layer of uniform thickness H over a half-space. Gravity acts in both media. We assume: (1) both media are homogeneous; (2) in the solid medium stress and deformation are related through Hooke's law and in the liquid pressure is proportional to the degree of compression; (3) deformations are small and displacements in the liquid are small compared to the liquid layer thickness and characteristic wavelengths. The latter condition allows us to neglect the distinction between Eulerian and Lagrangian variables in the equations of motion (Pod"yapol'sky, 1968, 1970; Comer, 1984a).

Linear approximation is used to formulate the equations of motion. This means that we neglect the variation of the displacement field on distances comparable with displacement. We also neglect the displacements of the boundary, since these displacements are very small compare to the characteristic wavelengths.

Based on the above approximation and on the main postulates of the fluid dynamics (Landau and Lifschitz, 1980) the linearized equations for the dynamic displacement field in liquid and in elastic medium will be respectively (after Pod"yapol'sky, 1968, 1970):

$$c_f^2 \nabla \mathrm{div}\mathbf{u}_1 - g\mathbf{e}_z \mathrm{div}\mathbf{u}_1 = \frac{\partial \mathbf{u}_1}{\partial t^2} \qquad 0 < z < H \quad (1)$$

$$a^2 \nabla \mathrm{div}\mathbf{u}_2 - b^2 \nabla \times (\nabla \times \mathbf{u}_2) - g\mathbf{e}_z \mathrm{div}\mathbf{u}_2 = \frac{\partial^2 \mathbf{u}_2}{\partial t^2} \qquad z > H, \quad (2)$$

Boundary conditions at the ocean surface ($z = 0$) and the bottom ($z = H$) are:

$$c_f^2 \mathrm{div}\mathbf{u} - gW \Big|_{z=0} = 0, \quad (3)$$

$$W_1(H) = W_2(H), \quad (4)$$

$$p_f \left[c_f^2 \mathrm{div}\mathbf{u} - gW_1 \Big|_{z=H} \right] = \rho \left[\left(a^2 - 2b^2\right) \mathrm{div}\mathbf{u} + 2b^2 \frac{\partial W_2}{\partial z} - gW_2 \Big|_{z=H} \right]$$

$$\mu \left(\frac{\partial W_2}{\partial x} + \frac{\partial U_2}{\partial z} \right) \Big|_{z=H} = 0,$$

$$\mu \left(\frac{\partial V_2}{\partial z} + \frac{\partial W_2}{\partial y} \right) \Big|_{z=H} = 0, \quad (5)$$

At infinity the displacement vanishes:

$$\mathbf{u} \to 0 \quad \text{at} \quad z \to 0. \quad (6)$$

Here c_f is the velocity of the acoustic wave in the liquid layer, ρ_f is the density of the liquid, H is the thickness of the liquid layer, λ and μ are the Lame coefficients in the elastic half-space, ρ is the density of the elastic medium, a and b are the velocities of P- and S-waves, $\mathbf{u}_i = (U_i, 0, W_i)$ is the displacement vector ($i = 1$ liquid layer, $i = 2$ elastic half-space), g is gravity, is the angular frequency, and z is the vertical distance from the initial (undisturbed) position of the free surface (positive downwards).

3. Solution

The solution of Eqs. (1) and (2) may be written in the form of a stationary plane wave propagating along the x axis

$$\mathbf{u}_i(x, z, \omega, t) = \mathbf{v}_i(z, \omega) \exp\left[i\omega(t - x/c)\right]. \tag{7}$$

Substituting (7) into Eqs. (1) and (2) and introducing the boundary condition at $z \to \infty$, the wave amplitudes as a function of depth are found as

$$\begin{aligned} U_1(z, \omega) = {} & \frac{ic_f^2}{\omega c}\left[-B\exp(-\eta_2 z/c_f)\right. \\ & \left. + C\exp(-\eta_1 z/c_f)\right], \end{aligned} \tag{8}$$

$$\begin{aligned} W_1(z, \omega) = {} & -\frac{c_f}{\omega^2}\left[-\eta_1 B\exp(-\eta_2 z/c_f)\right. \\ & \left. + \eta_2 C\exp(-\eta_1 z/c_f)\right], \end{aligned} \tag{9}$$

where, for the liquid layer,

$$\eta_1 = -\omega\gamma - g/2c_f \tag{10}$$

$$\eta_2 = -\omega\gamma - g/2c_f \tag{11}$$

$$\gamma^2 = \frac{c_f^2}{c} - 1 + \frac{g^2}{4c_f^2\omega^2}, \tag{12}$$

and for the half-space,

$$\begin{aligned} U_2(z, \omega) = {} & \frac{ia^2}{\omega c} D\exp(-\omega\alpha(z - H)/a) \\ & - \frac{ib\beta}{\omega} F\exp(-\omega\beta(z - H)/b), \end{aligned} \tag{13}$$

$$\begin{aligned} W_2(z, \omega) = {} & \frac{a\alpha}{\omega}\left(1 + \frac{g}{2\omega\alpha a}\right) \\ & \cdot D\exp\left(\left(-\omega\alpha + \frac{g}{2a}\right)(z - H)/a\right) \\ & - \frac{b^2}{\omega c} F\exp(-\omega\beta(z - H)/b), \end{aligned} \tag{14}$$

where

$$\alpha^2 = a^2/c^2 - 1 + \frac{g^2}{4a^2\omega^2}$$

and

$$\beta^2 = b^2/c^2 - 1.$$

Equations (3) to (14) yield a set of four homogeneous equations in four unknown coefficients, namely B, C, D and F, which has a non-trivial solution when the determinant is zero.

The dispersion equation is obtained as follows:

$$\begin{aligned} & m\Big[-\gamma\cosh\left(\omega\gamma H/c_f\right) \\ & \quad + \frac{g}{2c_f\omega}\left(\frac{2c_f^2}{c^2} - 1\right)\sinh\left(\omega\gamma H/c_f\right)\Big] \\ & \quad \cdot\left[-a^2\left(1 - \frac{2b^2}{c^2} - \frac{g^2}{2\omega^2a^2}\right) + 4b^3a\alpha\beta/c^2\right] \\ & \quad - c_f\left(a\alpha - \frac{g\beta^2}{2\omega}\right) \\ & \quad \cdot\left[\frac{g\gamma}{c_f\omega}\cosh(\omega\gamma H/c_f) - \left(1 - \frac{g^2}{2c_f^2\omega^2}\right)\right. \\ & \qquad \left. \cdot\sinh\left(\omega\gamma H/c_f\right) - \frac{g\gamma}{c_f\omega}\exp(-gH/2c_f^2)\right] \\ & \quad - \frac{ga\alpha}{\omega^2\left(1 - \frac{c_f^2}{c^2}\right)} \\ & \quad \cdot\left[\omega\gamma\exp\left(-gH/2c_f^2\right) - \omega\gamma\cosh\left(\omega\gamma H/c_f\right)\right. \\ & \qquad \left. - \frac{g}{2c_f}\left(\frac{2c_f^2}{c^2} - 1\right)\sinh\left(\omega\gamma H/c_f\right)\right] = 0, \end{aligned} \tag{15}$$

where

$$m = \frac{\rho}{\rho_f}.$$

We follow the approach of surface-wave theory. Consider the displacement of a stationary surface wave excited by a point source in a homogeneous half-space (Aki, 1980; Keilis-Borok, 1989):

$$\begin{aligned} \mathbf{u}(r, \varphi, \omega, t) = {} & \frac{\exp(-i\pi/4)}{\sqrt{8\pi}}\frac{\exp(i\omega(t - r/c))}{\sqrt{\omega\ \ r/c}} \\ & \cdot\frac{\mathrm{U}(z, \omega)}{\sqrt{cuI_0}}\frac{\mathrm{Q}(h, \varphi, \omega)}{\sqrt{cuI_0}}; \end{aligned} \tag{16}$$

for a constant thickness of the liquid layer, or

$$\begin{aligned} \mathbf{u}(r, \varphi, \omega, t) = {} & \frac{\exp(-i\pi/4)}{\sqrt{8\pi}} \\ & \cdot\frac{\exp\left(i\omega\left(t - \int_M^N \frac{dx}{c(\omega, x)}\right)\right)}{\sqrt{\omega J(x)/c}} \\ & \cdot\left(\frac{\mathbf{U}(z, \omega)}{\sqrt{cuI_0}}\right)_N\left(\frac{\mathrm{Q}(h, \omega)}{\sqrt{cuI_0}}\right)_M, \end{aligned} \tag{17}$$

for a variable thickness of the liquid layer, where $\mathbf{U}(z, \omega) = U(z, \omega)\mathbf{e}_r + W(z, \omega)\mathbf{e}_z$, $\mathrm{Q}(h, \varphi, \omega) = m_{rs}(\omega)B_{rs}(h, \varphi, \omega)$ is the excitation function, $m_{rs}(\omega)$ is the spectrum of the seismic moment tensor, $B_{rs}(h, \varphi, \omega)$ is a tensor which can be expressed via the eigenfunctions $U(z, \omega)$ and $W(z, \omega)$ and their derivatives and which depends on the axis orientation of the source,

$$I_0 = \int_0^\infty \rho\left[U^2(z, \omega) + W^2(z, \omega)\right]dz$$

Table 1.

Media density [g/cm^3]		Wave velocities [km/s]		Layer thickness (H-for liquid) [km.]; depth of source location (h-for half-space) [km.]
Model I				
Liquid layer	1	Acoustic wave	1.45	$H = 4$
Half-space	2.03	P-wave	2.0	$h = 10$–30
		S-wave	1.15

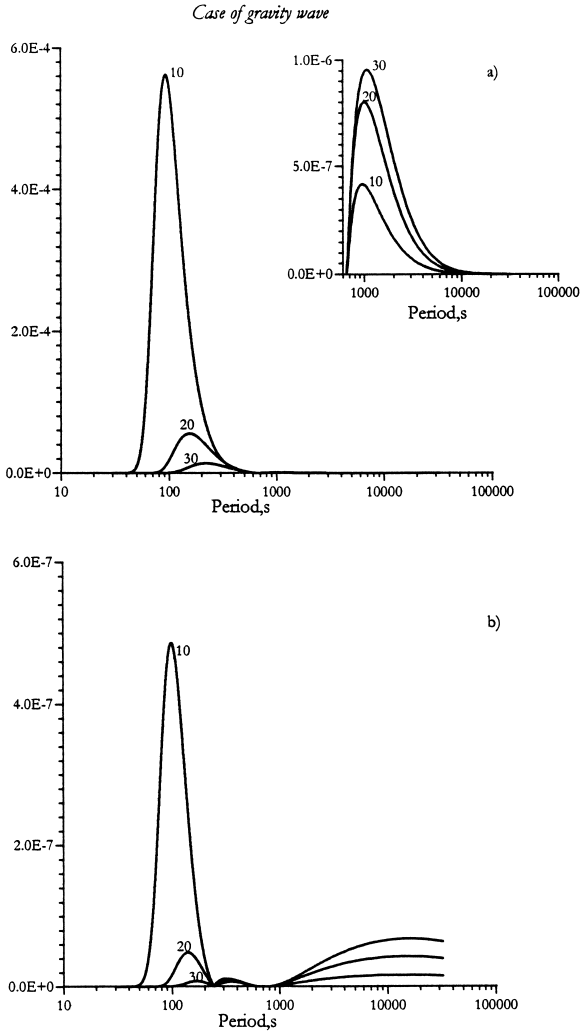

Fig. 2. The dependence of $|q(h, \omega, \varphi)|$ with period for dip-slip source located a) in non-gravitating half-space, b) in gravitating half-space. Numbers at the curves indicate the source depth in half-space.

is the energy integral, u is the group velocity and $J(x)$ is the geometrical divergence in the x-y plane.

In Eqs. (16) and (17), the second term describes the effect of geometrical divergence of the energy flow on the wave propagation. The third term depends on the depth of the receiver, and the fourth term depends on depth, focal mechanism and radiation spectrum in the half-space.

As we shall see, the presence of gravity in the half-space leads to new properties of the gravity wave spectrum. In the following we consider the case of surface waves excited by a dip-slip point source.

4. Dip-Slip Source

Let the fault plane be orthogonal to the x-axis and let displacement be vertical. Then the seismic moment tensor has two non-zero components:

$$m_{xz} = m_{zx} = M_0 F(\omega), \tag{18}$$

where M_0 is the seismic moment and $F(\omega)$ is the seismic moment spectrum. The corresponding components of tensor **B** are

$$B_{xz} = B_{zx} = \frac{i\cos\varphi}{2}\left(-W_2 + \frac{dU_2}{dz}\right). \tag{19}$$

Thus

$$Q(h,\omega,\varphi) = iM_0\cos\varphi\left(-\xi W_2 + \frac{dU_2}{dz}\right)F(\omega), \tag{20}$$

$$q(h,\omega,\varphi) = \frac{i\cos\varphi\left[-\xi W_2(h,\omega) + \left.\frac{dU_2(z,\omega)}{dz}\right|_{z=h}\right]}{\sqrt{cuI_0}}, \tag{21}$$

where $\xi = \omega/c$ is the wave number.

To estimate the source radiation function, some value of the seismic moment M_0 and its spectrum $F(\omega)$ must be assumed. We assume values of the radiation function up to the factor M_0 and for that azimuth along which seismic radiation is maximal. Thus

$$F(\omega) = \frac{1}{i\omega(i\omega\tau_0 + 1)}, \tag{22}$$

where τ_0 is the rise time.

5. Numerical Results

The parameters of our model are shown in Table 1 (Nafe and Drake, 1963).

We focused on the influence of gravitating sediments on excitation of gravity and Rayleigh waves. Although in real Earth thickness of ocean sediments seldom exceeds a few kilometers (Mooney *et al.*, 1998), for our numerical experiment we used structures with thick sedimentary mass like deep-sea trenches (Yoshii *et al.*, 1970; Westbrook *et al.*, 1973), and we vary the source location from shallow to deep. In spite of that we are using real paremeters of the ocean-Earth structure, proposed model is still a theoretical one, whose purpose is to explore some physical aspects of the role of sediments in the excitation of gravity and Rayleigh waves.

5.1 Case of gravity wave

As shown previously (Novikova, 1997), compressibility of the liquid leads to the appearance of two maxima (Figs. 1(a)–3(a)) in the spectrum of gravity waves, namely a high-frequency maximum at periods of 100–200 s and a low-frequency maximum around at 1000 s. For all liquid half-space models (Table 1) in the 10–30 km depth interval, the amplitude of the high-frequency maximum is larger than that of the low frequency maximum. When the half-space is composed of sediments excitation function of gravity wave is one order of magnitude larger compared with that in hard rock half-space (Figs. 1(a)–3(a)). Theoretical marigrams (vertical component) of gravity wave, calculated by integrating formula (16) at the epicentral distance of 1000 km, prove this as well (Figs. 4(a) and 5(a)). We assume that the seismic moment M_0 for the source model is 6×10^{21}Nm, corresponding roughly to an earthquake of magnitude 8.5.

By including the action of gravity in the half-space character of the excitation function spectrum changes. Third maximum appears (Figs. 1(b)–3(b)) and at the deepening of source its amplitude increases. Theoretical marigrams (Figs. 4(b) and 5(b)) show that including gravity in the half-space increases period of the gravity wave excited by deep sources by a factor of two, up to 10 minutes.

One possible explanation of this third maximum is that including gravity in the elastic medium results in the additional (gravity) root in the dispersion equation. This root corresponds to a gravity wave propagating at the liquid-elastic medium interface (Gusiakov, 1972) and cases the change in excitation spectrum.

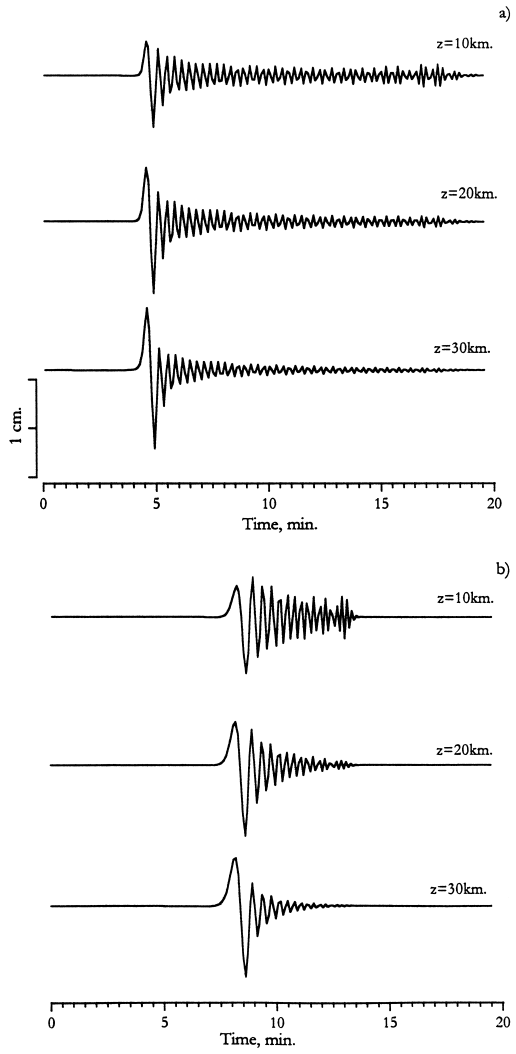

Fig. 7. A comparison of theoretical marigrams of Rayleigh wave from the dip-slip source a) for model III, b) for model II with gravitating half-space. Results without gravitational force are identical. The right numbers at the curves indicate the source depth in half-space.

5.2 Case of Rayleigh wave

Figures 6 and 7 demonstrate that low-rigidity media also amplify the excitation and propagation of Rayleigh waves.

At the deepening of source Rayleigh wave amplitude decreases, similar to the case of gravity wave. Including gravity in the half-space has no effect on the Raylegh wave (excitation function curves and theoretical marigrams with and without gravity coincide). It can be explained as follows. In case of Rayleigh wave the restoring force is elastic, not gravity. Gilbert (1967) showed that influence of gravity acting in an elastic medium, on a surface wave is important only if the medium is filled with soft sediments with wave velocities $b < 100$ m/s. In our model, however, s-wave velocities vary from 1.1 to 4.1 km/s, i.e. our model medium is rigid enough to suppress action of gravity on surface wave.

6. Conclusions

Excitation and propagation of gravity and Rayleigh waves are treated in the frame of model considering them as surface waves of the coupled type in a liquid layer overlying the gravitating half-space filled with sediments. Normal mode formalism was applied to calculate far-field displacement of surface waves generated by dip-slip point source located at different depths in the solid Earth underneath the ocean.

Using the liquid-solid model with different parameters of half-space we found that low-rigidity medium may be seen as an amplifier for both gravity and Rayleigh waves.

Including gravity in the half-space changes the character of excitation spectrum of gravity wave. The difference is more obvious for the gravity wave excited by a deep source in the weak media. In such conditions gravity wave becomes more long-period.

Proposed model is the theoretical one aimed to study the influence of gravitating sediments on the wave excitation. Consequently, for future investigations, it is assumed to use a more realistic structure with layered ocean crust. In particular, such model will be important for the study of Rayleigh waves that depend considerably on the layered structure (especially in the 1–10 seconds period range).

In further study of gravity waves, the results of the present work will be generalized for the case of "tsunami-earthquake" events, using a more realistic model of a finite size seismic source. Recent investigations (Houston, 1999; Bilek and Lay, 1999) suggested that some earthquakes rupture slowly because of the presence of shallow, unconsolidated sediments. The process of gravity wave excitation by a slow rupture on a shallow fault may be relevant, as slow rupture can generate large low-frequency gravity waves which take the form of tsunami waves at the ocean surface.

Abstract. Evidence for in situ generated atmospheric gravity waves associated with a stratospheric temperature enhancement (STE) are presented. The signatures of two sets of gravity waves are observed by molecular-aerosol lidar in conjunction with the early December 2000 STE event above Sondrestrom, Greenland. The first set of gravity waves shows downward phase progression with a vertical wavelength of ∼8 km while the second set shows upward phase progression with a vertical wavelength of ∼9 km. With estimates of the background wind fields from synoptic analyses, the various intrinsic gravity wave parameters of these two wave structures are found. The observed wave features compare well to previous numerical modeling predictions.

1 Introduction

Stratospheric temperature enhancements (STEs) have been experimentally observed, theoretically and numerically modeled, and discussed in the scientific literature for some time, often under differing nomenclature such as: stratospheric baroclinic zones, stratospheric sudden warmings (SSWs), winter stratospheric temperature anomalies, etc. SSW or a major warming is defined by the World Meteorological Organization as an increase in zonal-mean temperature of the polar region such that the net zonal-mean zonal winds become easterly north of 60° N at 10 hPa or below. An STE, such as the one discussed in this paper, leaves the lower stratosphere relatively undisturbed from a global context and is therefore considered distinct from an SSW. Meriwether and Gerrard (2004) have reviewed the phenomenology of STEs and have highlighted the interesting attributes of the structures, including (1) the nature of their development and evolution, (2) how STEs may serve as precursors to sudden stratospheric warmings, and (3) the role of STEs as in situ generators of middle atmospheric gravity waves. The first issue has been addressed by a number of authors, including a companion paper by Thayer and Livingston (2008). This paper addresses the third issue by analyzing a STE event in December 2000, when the height of the stratopause dropped to ∼42 km and temperatures were enhanced by ∼50 K, described in that earlier Thayer and Livingston (2008) paper.

As noted in the review by Meriwether and Gerrard (2004), numerical modeling of STE events by Fairlie et al. (1990) suggest that gravity waves are generated at the location of the STE. More recently, Vadas and Fritts (2001), and Fritts et al. (2006) have discussed strong temperature anomalies and subsequent local adjustment as potential generators of gravity waves. As reproduced from Fairlie et al. (1990) in Fig. 1, upward propagating gravity waves are seen in model runs with horizontal wavelengths of ∼1200 km, vertical wavelengths of ∼8 km, and intrinsic periods of ∼10 h. Though single large-scale wave such as this does not transport large amounts of horizontal momentum vertically, their presence may nonetheless assist smaller-scale gravity waves to move towards convective or dynamical instability due to localized wave-wave interactions (Fritts and Alexander, 2003). Furthermore, it is not clear to what extent the associated localized momentum deposition plays a role in the re-stabilization of the high latitude middle atmosphere system (i.e., the reformation of the polar vortex) and return to geostrophy.

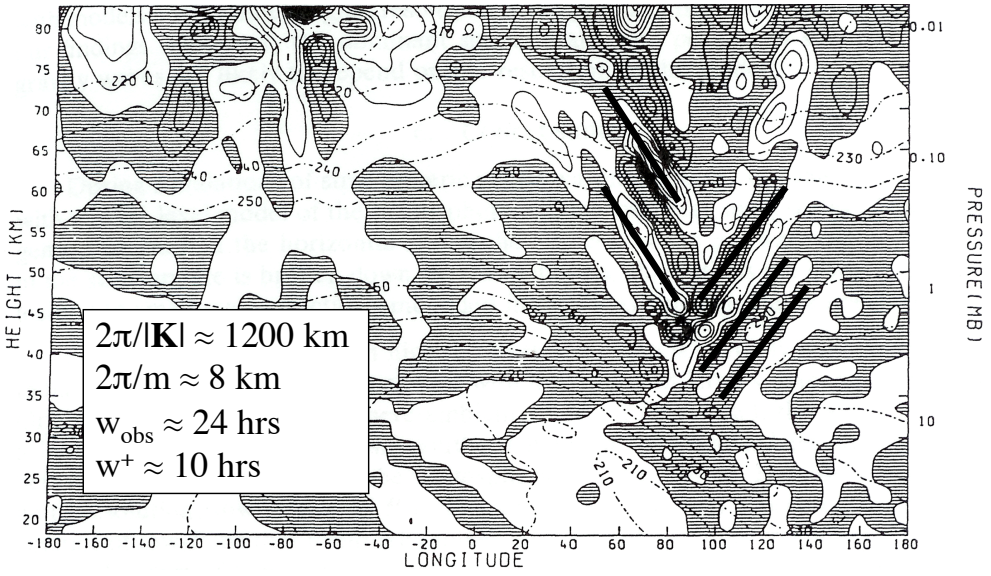

Fig. 1. From Fairlie et al. (1990). Simulated cross-section of temperature (dashed, units of K) and the divergence of the horizontal wind (solid, units of $10^{-6}\,s^{-1}$) at 57.5° N on 25 February 1979. Regions of convergence are shaded. Note that the the original pressure axis of millibars (written as mB) has been retained. The figure has been modified to highlight modeled, upwardly propagating gravity waves to both the west and east of the STE/baroclinic zone. Estimated gravity wave parameters are listed.

In situ observations of STE-associated gravity waves have not been reported (Meriwether and Gerrard, 2004). To our knowledge, this paper presents the first observations of such gravity wave signatures and associated wave structures generated during an STE event. The observations were taken during 11–12 December 2000 above Sondrestrom, Greenland. Synoptic scale conditions prevalent during this STE were presented in Thayer and Livingston (2008); this study deals exclusively with the period of peak STE temperatures over Sondrestrom. In Sect. 2 we present a brief overview of the instrumentation and analysis, in Sect. 3 we discuss the gravity wave characteristics, and in Sect. 4 we discuss these findings.

2 Instrumentation and analysis

Data used in this study originate from the ARCLITE molecular-aerosol lidar system located at Sondrestrom, Greenland. The ARCLITE system is discussed in detail in Thayer et al. (1997) and data from this system consist of range-time resolved temperature profiles of the upper stratosphere and lower mesosphere, relative gravity wave activity in the upper stratosphere, and aerosol volume backscatter coefficients. The data products have been used to explore mesospheric clouds (Thayer et al., 2003), relationship between gravity waves and mesospheric clouds (Gerrard et al., 1998, 2004a,b), thermal and gravity wave climatologies (Gerrard et al., 2000), and the synoptic development of the polar vortex (Gerrard et al., 2002). In Fig. 2 we present interpolated temperature profiles taken by the Sondrestrom lidar system in early December 2000 (Thayer and Livingston, 2008). Measurements were taken on the days indicated by black markers and interpolated across the entire duration of the STE event. Uncertainty of the lidar-deduced temperatures is less than 3 K below 70 km. Of particular note is the lidar data from 11–12 December [day of year 346–347] , whose time evolution is also portrayed in Fig. 3. The temperature data here was low pass filtered in the vertical with a cutoff at 7 km. Uncertainty on the measured temperatures is less than 5 K below 74 km. In these data the STE is clearly evident as a narrow ridge of temperatures exceeding 320 K; over 40 K above the climatological value (Gerrard et al., 2000).

From the ∼25 h long set of molecular – aerosol lidar data spanning this time period, it is possible to obtain time-resolved relative atmospheric density perturbations between 30 km and 70 km as outlined in Gerrard et al. (1998, 2004b). The density perturbation data (relative to an estimated atmospheric background), available in 5 min by 192 m vertical resolution bins, have been low pass filtered with cutoffs at 2 km in the vertical and 30 min in the temporal. These relative density perturbations are shown in Fig. 3.

In a perturbation analysis of the base-state parameters of an ideal gas, it can be shown that regions of high density perturbations correspond to regions of lower temperatures. This is the case on inspection of Figs. 2 and 3, where high density perturbations are 180° out of phase with the corresponding temperatures. As such, Figs. 2 and 3 essentially show the same thing, but gravity wave signatures are more readily extracted and analyzed in the relative density perturbations. From these figures, one sees that the STE peak temperatures

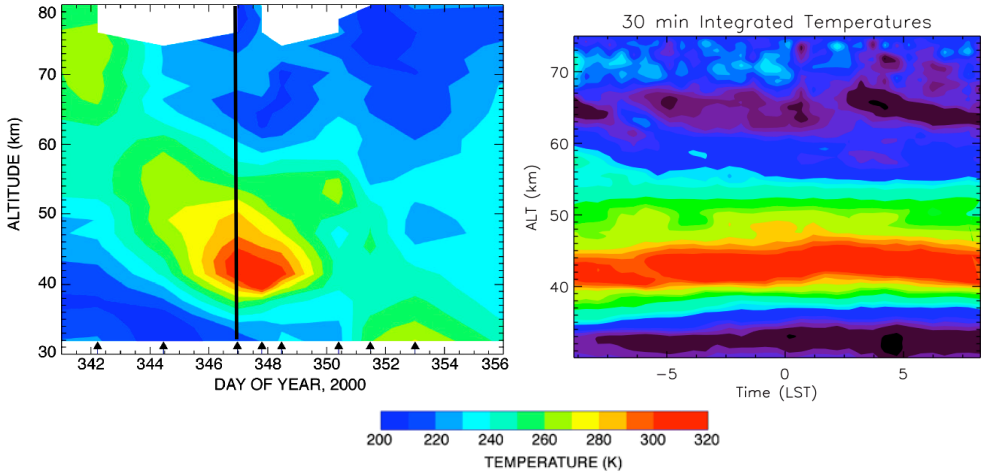

Fig. 2. From Thayer and Livingston (2008). Evolution of middle atmospheric temperatures over Sondrestrom, Greenland in December 2000 as measured by the molecular/aerosol lidar system. The vertical black line represents the day under study herein. (right) Range-time temperature evolution over Sondrestrom over the day near the estimated peak STE represented by the vertical black line (i.e., day of year 346–347, night of 11–12 December 2000, leap year). Time is local solar time (LST) with 00:00 representing midnight of 11 December.

at ∼42 km fluctuates by a few kilometers in height and in peak intensity through the course of the observations. This is presumably due to the time-varying nature of the baroclinic zone and other atmospheric structures, like gravity wave activity.

3 Gravity wave structures

Inspection of Fig. 3 shows at least two regions of relatively coherent wave-phase progression. These two areas of wave-like structure are highlighted in Fig. 3, where the waves in the upper left corner (centered at ∼04:00 LST and ∼65 km, and indicated by red streaks sketched by inspection of the data) are referred to as "set 1", and the waves on the right (centered at ∼09:00] LST and ∼50 km, and represented by blue streaks) are referred to as "set 2." No wave structures were apparent in the data below ∼45 km.

Addressing wave set 1, the wave structure has a downward phase progression in time, a vertical wavelength of ∼8 km and an observed period of ∼5 h. This type of structure is common over Sondrestrom (for e.g., seen in data presented in Gerrard et al., 1998 and Gerrard et al., 2000), and has the characteristic of an atmospheric gravity wave propagating upwards in height (i.e., the phase progression is downward, which is indicative of upward energy progression). Strictly speaking, downward phase propagation results in upward propagation of energy in a fluid at rest or in a frame moving with the background wind. This would hold approximately true if the polar vortex mass did not move significantly during the STE event. Such an assumption is not unreasonable; for instance, analysis presented in Bhattacharya and Gerrard (2010) using stratospheric assimilated data from

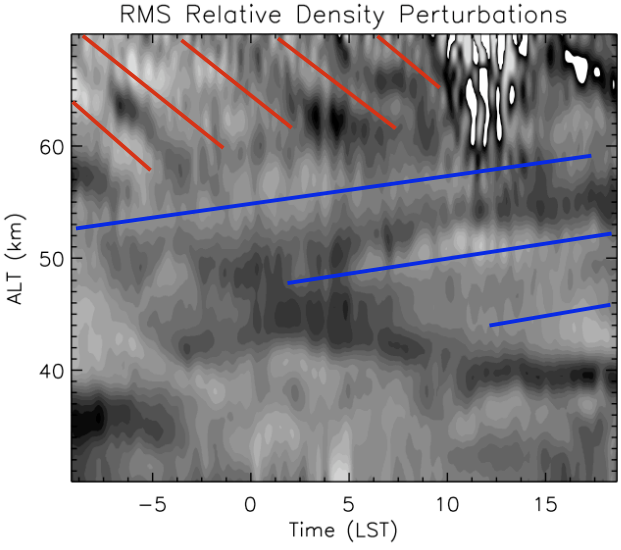

Fig. 3. Relative upper stratospheric and lower mesospheric density perturbations observed by the molecular/aerosol lidar system at Sondrestrom for the same range-time of Fig. 2. The relative density perturbations are scaled from −10 % to 10 % in 20 grey-scale intervals. Black represents the negative perturbations, while white represents the positive perturbations. Solar noise is present in the 60- to 70 km region of the figures around 12:00 LST which prohibited robust calculation of the temperatures in Fig. 2. Phase peaks of upward and downward phase lines corresponding to the two gravity wave sets are determined by inspection and highlighted.

United Kingdom Met Office (UKMO) shows that geopotential height at 10 hPa remained relatively constant (∼36 km) over Resolute Bay (75° N, 95° W) during the STE period

reported here. Assimilated data from National Center for Environmental Prediction (NCEP) gives the average horizontal wind velocity $\sim$50 m s^{-1} at $\sim$65 km.

If the wind velocity vector $\boldsymbol{U}$ is aligned with the gravity wave horizontal wavenumber vector $\boldsymbol{U}$ (in general, gravity waves with such aspect ratios propagate in the direction of wind as modeled in Gerrard et al., 2004a), and using the buoyancy frequency N deduced from the nightly averaged temperature profile, the horizontal wavelength and intrinsic period ω^+ of the wave can be estimated from the gravity wave dispersion relationship in the form:

$$(\omega^+)^2 = (\omega - \boldsymbol{U}\boldsymbol{k})^2 = \frac{N^2k^2 + f^2m^2}{k^2 + m^2} \quad (1)$$

where, aside from the variables already described earlier, ω is the ground-based frequency, f is the Coriolis parameter, and m is the gravity wave vertical wavenumber. The group velocity of the gravity wave can also be determined from this equation by taking the derivative of w with respect to the horizontal or vertical wavenumber to yield the horizontal group velocity or vertical group velocity, respectively.

Numerical solution of the dispersion relation using a Laguerre method yields two real roots and two imaginary roots. The imaginary roots are discarded as they represent evanescent structures. The first real root results in a gravity wave with a horizontal wavelength of $\sim$1700 km and an intrinsic wave period of $\sim$10.5 h, with positive horizontal and vertical group velocities indicating an upward propagating gravity wave moving in the direction of the background wind. The second root yields horizontal wavelength of $\sim$400 km and an intrinsic wave period of $\sim$4 h, with a positive horizontal group velocity and negative vertical group velocity indicating a downward propagating gravity wave moving in the direction of the background wind.

Addressing wave set 2, the wave structure has an upward phase progression in time, a vertical wavelength of $\sim$9 km, and an observed period of $\sim$26 h. Estimating that the background wind velocity from NCEP analyses to be +70 m s^{-1}, coupled with the assumption of wave vector k approximately aligned with U, the first real root yields a gravity wave with a horizontal wavelength of $\sim$1870 km and an intrinsic wave period of $\sim$10.4 h, with positive horizontal and vertical group velocities indicating an upwards propagating gravity wave moving in the direction of the background wind. The second real root yields a wave with a horizontal wavelength of $\sim$6200 km and an intrinsic wave period of $\sim$12.6 h, with a positive horizontal group velocity and negative vertical group velocity indicating a downward propagating gravity wave moving in the direction of the background wind.

It can be shown that uncertainties of $\pm$1 km in the vertical wavelengths, $\pm$1 h in the observed periods, and $\pm$10 m s^{-1} do not dramatically alter the estimated horizontal wavelengths and intrinsic periods.

4 Conclusions

Assuming that the first real root of set 1 and the first real root of set 2 are the physically meaningful roots (i.e., both indicating upwards gravity waves propagating from the STE region which fits the physical model), the observed gravity wave characteristics compare very well with model output of Fairlie et al. (1990). Furthermore, there was no indication of any wave structures below the STE temperature peak (i.e., between 30 km and 45 km) to indicate a gravity wave passing through the STE. As such, we conclude that this is strong evidence for an observation of upward propagating gravity waves generated in situ by a STE event.

It should be noted that higher than normal total ozone content were reported in the Arctic vortex (until 63° N latitude for which ozone data was available) for the 2000–2001 winter; for December 2000, total ozone was higher by $\sim$20 ,% compared to early 1980s (NCEP-NOAA Winter Bulletin, 2000–2001). An unusual and extensive $\sim$3 km thick aerosol cloud layer, spanning almost the entire polar vortex around $\sim$38 km altitude also formed in the first two weeks of December 2000, as reported by Gerding et al. (2003) observed from four different Arctic stations. Bhattacharya et al. (2004) have also reported increased gravity wave activity in the mesopause (hydroxyl airglow layer) polar vortex immediately following the STE events described in this paper. These observations in the current context increase the likelihood that the temperature enhancement, and the associated GW generation had their origins within a relatively shallow layer in the stratosphere. The long wavelength observed is also suggestive of a horizontally extensive forcing and a slower adjustment process (Fritts et al., 2006), unlike a vertically extended source typically found around the edges of a split vortex.

Based on this one observation, we are currently searching through the NCEP geopotential data archive for similar polar vortex configurations seen during this event. However, the combination of observing conditions, namely (a) the disruption of the polar vortex over Sondrestrom and actual occurrence of an STE when (b) there are clear sky conditions in which (c) the ARCLITE lidar system was collecting data is quite rare. Utilization of other lidar data archives, e.g., from the ALOMAR lidar system, the Poker Flat Lidar system, and the Eureka lidar system, would likely increase the probability of observing gravity waves associated with a STE.

In conclusion, in situ forcing of middle atmospheric gravity waves are of interest to the upper and lower atmospheric communities because, to date, little is known about the contribution that such waves may play in the global circulation. In this study we have demonstrated the likely origin of such in situ forcing associated with an observed STE. Further studies are necessary to better understand the role of such waves in the high latitude environment, how frequently such waves are generated, and the synoptic impacts on the surrounding atmospheric environment.

ABSTRACT

For over 1000 years electromagnetic radiation has been utilized for long-distance communication. heliographs, telegraphs, telephones and radio have all served our previous communication needs. Nevertheless, electromagnetic radiation has one major difficulty: it is easily absorbed. In this paper we consider a totally different radiation, a radiation that is not easily absorbed: gravitational radiation. Such radiation, like gravity itself, is not absorbed by earth, water or any material substance. In particular we discuss herein means to generate and detect high-frequency gravitational waves or HFGWs, and how they can be utilized for communication. There are two barriers to their practical utilization: they are extremely difficult to generate (a large power required to generate very weak GWs) and it is extremely difficult to detect weak GWs. We intend to demonstrate theoretically in this paper their phase-coherent generation utilizing an array of in-phase microelectro-mechanical systems or MEMS resonator elements in which the HFGW flux is proportional to the square of the number of elements. This process solves the transmitter difficulty. Three HFGW detectors have previously been built; but their sensitivity is insufficient for meaningful HFGW reception; greater sensitivity is necessary. A new Li-Baker HFGW detector, discussed herein, is based upon a different measurement technique than the other detectors and is predicted to achieve a sensitivity to satisfy HFGW communication needs.

Keywords: Gravitational waves, communications, Li-Baker detector, microelectromechanical systems, high-frequency gravitational waves.

1. INTRODUCTION

Since the dawn of civilization electromagnetic radiation has been utilized for long-distance communication: heliographs, telegraphs, telephones and radio have all served our previous communication needs. Nevertheless, electromagnetic radiation has one major drawback: it is easily absorbed. In this paper we consider a totally different radiation, a radiation that is not easily absorbed: gravitational radiation. Such radiation, like gravity itself, is not absorbed by earth, water or any material substance. In particular we discuss herein a means to generate and detect high-frequency gravitational waves or HFGWs and how they can be utilized for communication. HFGWs are defined as GWs having frequencies in excess of 100 kHz (Douglas and Braginsky [1]) and long-wavelength GW detectors such as LIGO, Virgo and GEO600 cannot sense HFGWs [2]. Global communications by means of HFGWs would be the ultimate wireless system. HFGW communication would greatly reduce communications costs since it would not require the following:

- No satellite transponders
- No microwave relays
- No underwater cables
- No coaxial cables

Since the Nobel Prize winning observations of Hulse and Taylor in the 1970s no one has doubted the existence of gravitational waves. There are two barriers to their practical utilization: they are extremely difficult to generate (a large power required to generate very weak GWs) and it is extremely difficult to detect weak GWs. In the past several decades hundreds of peer-reviewed journal articles have addressed these issues, for example Beckwith [3] and Grishchuk [4]. We intend to demonstrate theoretically in this paper that their generation utilizing superradiance (Scully and Svidzinsky. [5]), which involves a linear double-helix array of in-phase micro-electromechanical systems (MEMS) resonator elements, in which the HFGW flux is proportional to the square of the number of elements, solves the HFGW generation or transmitter difficulty. The use of a new, but well documented in peer-reviewed literature, effect discovered by Fangyu Li (Chongqing University, China, [6]) solves the detection difficulty. This Li-effect is the basis for the very sensitive Li-Baker HFGW detector, designed by Robert Baker and developed jointly by United States and Chinese HFGW research teams. As documented in peer-reviewed literature [7, 8, 9, 10] such a detector has sensitivity more than sufficient to receive the transmitted HFGW signal at a significant distance from the transmitter. Dehnen in Germany showed in an article [11] that HFGWs could be generated in the laboratory, using General Relativity, through the use of crystal oscillators. His work is the basis for an efficient HFGW generator or transmitter. The critical element in Dehnen's HFGW generator or transmitter had been the large size and power requirements of his crystal oscillators. This difficulty is removed through the use of modern MEMS technology. There have been other challenges to HFGW communications based upon the mistaken belief that GW generators or transmitters can only be designed using spinning rods or the effect described by Gertsenshtein in 1962 [12] and analyzed by Eardley in 2008 in the JASON report [13]. Both of these methods for generating GWs are unsatisfactory and produce negligible GW power.

2. HFGW GENERATORS (Transmitters)

There exist several sources for HFGWs or means for their generation. The first generation means is the same for gravitational waves (GWs) of all frequencies and is based upon the quadrupole equation first derived by Einstein in 1918.[14] A formulation of the quadrupole that is easily related to the orbital motion of binary stars or black holes, rotating rods, laboratory HFGW generation, etc. is based upon the jerk or shake of mass (time rate of change of acceleration), such as the change in centrifugal force vector with time; for example as masses move around each other on a circular orbit. Figure 1 describes that situation. Recognize, however, that change in force Δf need NOT be a gravitational force (see Einstein, 1918 [14]; Infeld quoted by Weber 1964 [15] p. 97; Grishchuk [16]). Electromagnetic forces are more than 10^{35} larger than gravitational forces and should be employed in laboratory GW generation. As Weber ([15] p. 97) points out: "The non-gravitational forces play a decisive role in methods for detection and generation of gravitational waves ..." The quadrupole equation is also termed "quadrupole formalism" and holds in weak gravitational fields (but well over 100 g's), for speeds of the generator "components" less than the speed of light and for the distance between two masses r less than the GW

wavelength. Certainly there would be GW generated for r greater than the GW wavelength, but the quadrupole "formalism" or equation might not apply exactly. For very small time change Δt the GW wavelength, $\lambda_{GW} = c\,\Delta t$ (where $c \sim 3\times10^8$ m s^{-1}, the speed of light) is very small and the GW frequency ν_{GW} is high. The concept is to produce two equal and opposite jerks or Δf 's at two masses, such as MEMS, a distance $2r$ apart. This situation is completely analogous to binary stars on orbit as shown in Figs. 1 and 2**.**

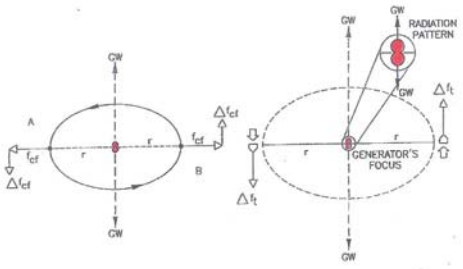

Figure 1. Change in Centrifugal Force of Orbiting Masses, Δf_{cf}, Creates Radiation.

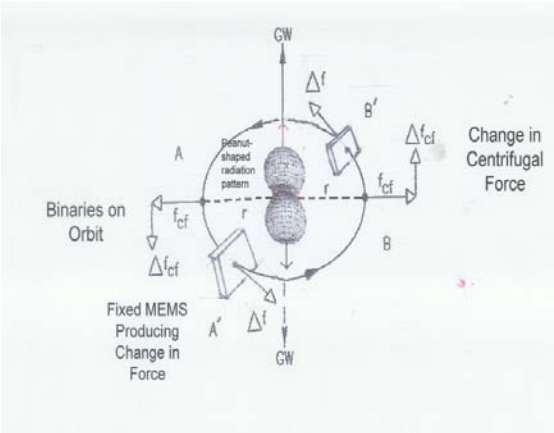

Figure 2. Radiation Pattern Calculated by Landau and Lifshitz [17] Section 110 Page 356.

Next we consider an array of GW sources. Consider a stack of orbit planes, each one involving a pair of masses circling each other on opposite sides of a circular orbit as in Fig. 3. Let the planes be stacked one light hour apart (that is, $60\times60\times3\times10^8 = 1.08\times10^{12}$ meters apart) and each orbit exactly on top of another (coaxial circles). According to Landau and Lifshitz [17] on each plane a GW will be generated that radiates from the center of each circular orbit. The details of that generation process are that as the masses orbit a radiation pattern is generated. In simplified terms (from the equations shown on page 356 of Landau and Lifshitz [17]) an elliptically shaped polarized arc of radiation is formed on each side of the orbit plane (mirror images). As the two masses orbit each other 180^0 the arcs sweep out figures of revolution. Together these figures of revolution become shaped like a peanut as shown in Fig. 2.

The general concept of the present HFGW generator is to utilize an array of force-producing elements arranged in pairs in a cylindrical formation such as a double helix as in Fig. 4. This is analogous to the binary-star arrays of Fig. 3 in which an imaginary cylinder could be formed or constructed from the collection of orbits. As a wavefront of energizing radiation proceeds along the cylindrical axis of symmetry of such a double-helix array, shown in Fig. 4 the force-producing element pairs (such as pairs of film-bulk acoustic resonators or FBARs) are energized simultaneously and jerk, that is they exhibit a third time

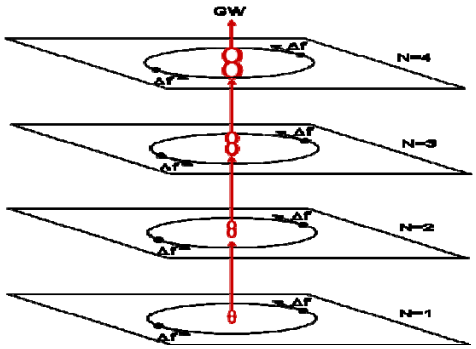

Figure 3. GW Flux Growth Analogous to Stack of *N* Orbital Planes.

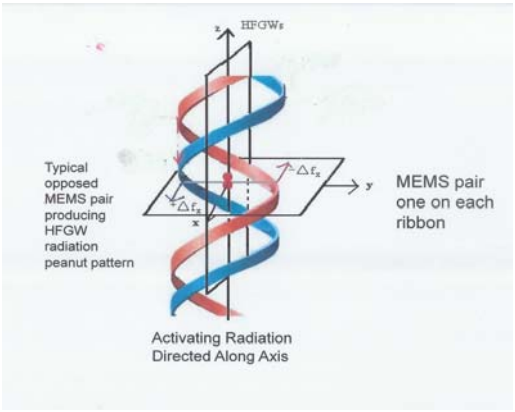

Figure 4. Double-Helix HFGW Generator Array (Patent Pending)

derivative of motion and the flux (W m^{-2}) thereby increased. Utilizing General Relativity, Dehnen and Romero-Borja [11] computed a superradiance build up of "… needle-like radiation …" HFGWs beam emanating from a closely packed but very long linear array of crystal oscillators. Their oscillators were essentially two vibrating masses a distance b apart whereas a pair of vibrating FBAR masses is a distance $2r$ apart as shown in Fig. 5, but operates in an analogous fashion as piezoelectric crystals.

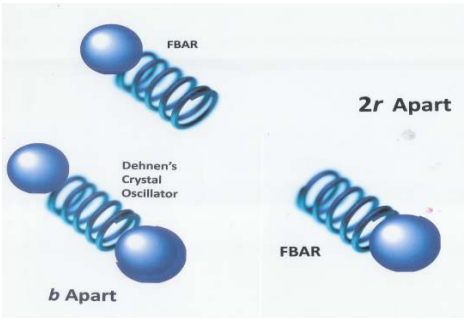

Figure 5. Comparison of Dehnen and Romero-Borja [11] crystal oscillator and FBAR-pair system.

Superradiance also occurs when emitting sources such as atoms "…are close together compared to the wavelength of the radiation …" (Scully and Svidzinsky [5] p.1510). Note that it is not necessary to have the FBAR elements perfectly aligned (that is, the FBARs *exactly* across from each other) since it is only necessary that the energizing wave front (from Magnetrons in the case of the MEMS or FBARs as in Baker, Woods and Li [18]) reaches a couple of nearly opposite FBARs at the same time so that a coherent radiation source or focus is produced

between the two FBARs. The energizing transmitters, such as Magnetrons, can be placed along the helixes' array axes between separate segments of the array or, more efficiently, at the base of the double helixes so that a superradiance force change, Δf, produced by energizing one off-the-shelf FBAR is 2 N microwave beam is projected up the axis of the helixes. The according to Woods and Baker [19], so that the power is given by the equation derived in Baker [20]:

$$P = 1.76\times10^{-52}\,(2r\,\Delta f/\Delta t)^2 \quad \text{W.} \qquad (1)$$

Let the activating radiation for the FBARs be conventional Magnetrons as employed in one-thousand watt microwave ovens. The frequency would be ν_{EM} = 2.5 GHz (thus Δt = 4×10^{-10} s and λ_{EM} = 12 cm**).** The HFGW frequency is twice that of the activating EM radiation or ν_{GW5} = 5 GHz**.** For Eq (1) the calculation of the combined Δf of all the pulsating MEMS or FBARs requires more consideration. We will set the length of a double-helix array cylinder as 20 m, but recognize that it can be separated into segments along the same axis with energizing transmitters, e.g., Magnetrons installed on the cylinder axis between the segments. The transmitters could also be phase coherent and arranged in a line along the double-helix axis at its base. If, for example, there were 1000 one-kilowatt Magnetrons feeding in on one hundred 12-cm, (λ_{EM}, wide levels) and each of their beams covered a 10-cm radius circle, then the energizing radiation flux would be 3.2×10^4 W m^{-2}. According to superradiance there would result a needle-like microwave radiation directed along the axis of the double helixes amounting to 32 gigawatts per square meter. In order to create a perfectly planner wave front, with no irregularities, the cylindrically symmetric MEMS array could be contained in a wave guide or possibly a very wide coaxial "cable," surrounded by a robust one megawatt heat sink. To increase instantaneous power to the array, bursts of gigawatt power, for example, every millisecond could be employed that would maintain a megawatt average power input.

The walls of the cylindrical array are taken to be 30-cm thick. Thus the volume of the twenty meter long array is $\pi(r_1^2 - r_2^2)$ ×20 m^3, where r_1 is the outside radius = 0.35 m and r_2 is the inside radius = 0.05 m. Thus the volume is 7.5 m^3. The FBAR is a mechanical (acoustic) resonator consisting of a vibrating membrane (typically about $100\times100\mu m^2$ in plan form, and about 1μm thickness), fabricated using well-established integrated circuit (IC) micro fabrication technology. A typical off-the-shelf FBAR as shown schematically in Fig. 6, usually has overall dimensions 500 μm by 500 μm by approximately 100 μm thick. For our purposes, in which a high number density is important, we will trim the FBARs to a minimum size. In order to account for fabrication margins we will take the dimensions as 110 μm by 110 μm by 20 μm for an FBAR volume of $2.42\times10^{-13}m^3$.

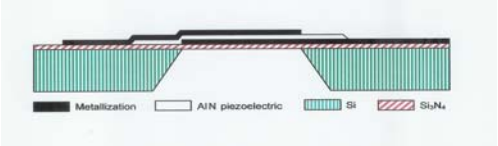

Figure 6. Basic FBAR Construction (cross-section side view, not to scale).

Thus the total number of FBARs in the double-helix cylindrical array is 2.85×10^{12} and the number of pairs is half of that. There would be $N = 1.425\times10^{12}$ FBAR pairs in the double-helix cylindrical array. Since each FBAR exhibits a jerking force of 2 N the combined Δf of all the jerking FBAR pairs is 2.85×10^{12} N. if the jerking pairs (or "orbits") moved in concert**.** From Eq. (1) the total power produced by the double-helix array is $P = 1.76\times10^{=52}(0.2\times2.85\times10^{12}/4\times10^{-10})^2 = 3.57\times10^{-10}$ W. But due to the N levels, each one of which represents an individual GW focus, there exists a "Superradiance" condition in which the HFGW beam becomes very narrow as shown schematically in Fig. B of [5]. Thus the HFGW flux, in W m^{-2}, becomes much larger at the cap of the radiation pattern. According to the analyses of Baker and Black [21] the area of the half-power cap is given by

$$A_{cap} = A_{1/2(N=1)} / N \quad m^2 \qquad (2)$$

A more conservative approach would be that there are N individual GW power sources each with a Δf = 2 N. Thus from Eq. (1), with $2r_{rms} = 2\sqrt{[(r_1^2 + r_2^2)/2]} = 0.5$ m, the total power produced by the double-helix array is $P = 1.55\times10^{13} \times1.76\times10^{-52}(0.5\times2/4\times10^{-10})^2 = 1.69\times10^{-20}$ W. But due to the N levels, each one of which represents an individual GW focus, there exists a "Superradiance" condition in which the HFGW beam becomes very narrow as shown schematically in Fig. B of Scully and Svidzinsky [5]. Thus the HFGW flux, in W m^{-2}, becomes much larger at the cap of the radiation pattern. According to the analyses of Baker and Black [21] the area of the half-power cap is proportional to $1/N$ and the GW flux is:

$$S(1) = (P/4)(1.71/N) = (1.69\times10^{-20}/4)/(1.71/1.55\times10^{13}) = 3.8\times10^{8}\ \text{W m}^{-2} \quad . \qquad (3)$$

From Baker, et al. [22], Eq. (6A) of the Appendix, the amplitude of the dimensionless strain in the fabric of spacetime is

$$A = 1.28\times10^{-18}\sqrt{S}/\nu_{GW} \quad \text{m/m} \quad . \qquad (4)$$

So that at a one-meter distance $A = 5\times10^{-32}$ m/m. If the FBARs in all of the helix levels are not activated as individual pairs, then the situation changes. For example, let all of the FBARs in a 6-cm wide level (½ λ_{EM}) be energized in concert. The number of levels would be reduced to N = 20 m/0.06 m = 333. But, because the FBAR-pairs in each level act together, Δf = (2 N)$(1.55\times10^{13}$ / 333). Thus the changes in Eq. (1) cancel out and there is no change in HFGW flux.

The HFGW beam is very narrow. From Eq. (4b) of [21] for $N = 1.55\times10^{13}$ it would be $\sin^{-1}(0.737)/\sqrt{1.55\times10^{13}} = 1.87\times10^{-7}$ radians. For N = 333 the angle is 0.0022 radians. This is still narrow, but the double helix configuration certainly reduces the width of the HFGW beam. Additionally multiple HFGW carrier frequencies can be used with modulation schemes e.g., pulse carrier phase shift key, so the signal is very difficult to intercept, and is therefore useful as a low-probability-of-intercept (LPI) signal, even with widespread adoption of the HFGW technology.

From Woods, et al. [23] the current estimated sensitivity of the Chinese Li-Baker HFGW Detector is $A = 1.0\times10^{-30}$ m/m to 1.0×10^{-32} m/m with a signal to noise ratio of over 1500 (Woods, et al [23] p. 511) or if we were at a $1.3x10^7$ m (diameter of Earth) distance, then $S = 1.33\times10^{-20}$ Wm^{-2}. and the amplitude A of the HFGW is given by $A = 3.8\times10^{-39}$ m/m. Although the best theoretical sensitivity of the Li-Baker HFGW detector is on the order of 10^{-32} m/m, its sensitivity can be increased dramatically (Li and Baker, [9] by introducing superconductor resonance chambers into the interaction volume (which also improves the Standard Quantum Limit; Stephenson [24]) and two others between the interaction volume and the two microwave receivers. Together they provide an increase in

sensitivity of five orders of magnitude and result in a theoretical sensitivity of the Li-Baker detector to HFGWs having amplitudes of 10^{-37} m/m. There also could be a HFGW superconductor lens, as described by Woods [25], which could concentrate very high frequency gravitational waves at the detector or receiver. Thus with Chinese Li-Baker HFGW detector program successful and the Wood's lens practical, **the Li-Baker detector will exhibit sufficient sensitivity to receive the generated HFGW signal globally.**

3. HFGW DETECTORS (Receivers)

Operational HFGW Receivers

In the past few years HFGW detectors, as exhibited in Figs. 7**,** 8 and 9 have been fabricated at *Birmingham University*, England, *INFN Genoa,* Italy and in Japan. These types of detectors may be promising for the detection of the HFGWs in the GHz band (MHz band for the Japanese) in the future, but currently, their sensitivities are orders of magnitude less than what is required. Such a detection capability is to be expected, however, utilizing the Li-Baker detector. Based upon the theory of Li, Tang and Zhao [6] termed the Li-effect, the detector was proposed by Baker during the period 1999-2000, a patent for it was filed in P. R. China in 2001, subsequently granted in 2007 [26.] (http://www.gravwave.com/docs/Chinese%20Detector%20Patent%2020081027.pdf).

Preliminary details were published later by Baker, Stephenson and Li [22]. This detector was conceived to be sensitive to relic HFGWs (or high-frequency relic gravitational waves, termed HFRGWs) having amplitudes as small as 10^{-32} to 10^{-30}, but using resonance chambers to 10^{-37} or possibly smaller [9].

The Birmingham HFGW detector measures changes in the polarization state of a microwave beam (indicating the presence of a GW) moving in a waveguide about one meter across as shown in Fig. 7. (Please see Cruise [27]; and Cruise and Ingley [28].) It is expected to be sensitive to HFGWs having spacetime strains whose amplitudes are $A \sim 2 \times 10^{-13}$.

Figure 7 *Birmingham University* **HFGW Detector**

The *INFN Genoa* HFGW resonant antenna consists of two coupled, superconducting, spherical, harmonic oscillators a few centimeters in diameter. Please see Fig. 8. The oscillators are designed to have (when uncoupled) almost equal resonant frequencies. In theory the system is expected to have a sensitivity to HFGWs with size of about $A \sim 2\times10^{-17}$ with an expectation to reach a sensitivity of $\sim 2\times10^{-20}$. (Bernard, Gemme, Parodi, and Picasso [29]); Chincarini and Gemme [30]). As of this date, however, there is no further development of the *INFN Genoa* HFGW detector.

Figure 8 . *INFN Genoa* **HFGW Detector**

The Kawamura 100 MHz HFGW detector has been built by the *Astronomical Observatory of Japan.* It consists of two synchronous interferometers exhibiting an arms length of 75 cm. Please see Fig. 9. Its sensitivity is now about $A \approx 10^{-16}$ (Nishizawa et al., [31]). According to Cruise [32]) of *Birmingham University* its frequency is limited to 100 MHz and at higher frequencies its sensitivity diminishes.

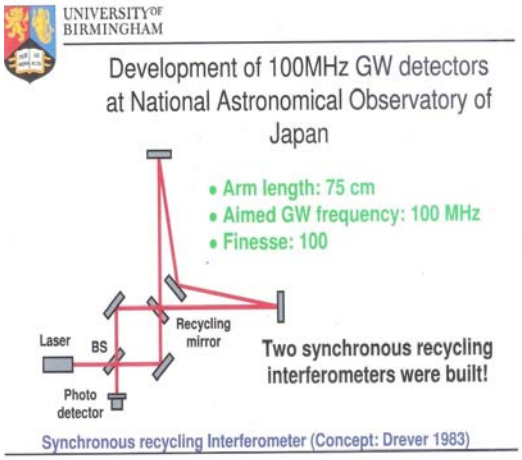

Figure 9. The National Astronomical Observatory of Japan 100MHz Detector. Cruise [31].

Concept (Li-Effect)

The Li-Effect or Li-Theory was first published in 1992 [6]. Subsequently the "Li Effect" was validated by secveral journal articles, independently peer reviewed by scientists well versed in General Relativity, [7, 8, 9, 10] including capstone paper, Li, et al [32]). The reader is encouraged to review the key results and formulas found in Li et al., [10] and the detailed discussion of the coupling among HFGWs, a magnetic field and a microwave beam found in Li et al. [10]. The Li-Effect is *very different* from the classical *(inverse)* Gertsenshtein- Effect. With the Li-Effect, a gravitational wave transfers energy to a separately generated electromagnetic (EM) wave in the presence of a static magnetic field. That EM wave has the same frequency as the GW and moves in the same direction. This is the "*synchro-resonance condition***,**" in which the EM and GW waves are synchronized and is **unlike the Gertsenshtein-Effect**.[12] The result of the intersection of the parallel and superimposed EM and GW beams, according to the Li-Effect, is *new EM photons moving off in a direction perpendicular to the*

beams and the magnetic field directions. These photons signal the presence of HFGWs and are termed a "perturbative photon flux" or PPF. Thus, these new photons occupy a separate region of space (see Fig. 10) that can be made essentially noise-free and the synchro-resonance EM beam itself (in this case a Gaussian beam) is not sensed there, so it does not interfere with detection of the photons. The existence of the transverse movement of new EM photons is a **fundamental physical requirement**; otherwise the EM fields will not satisfy the Helmholtz equation, the electrodynamics equation in curved spacetime, the non-divergence condition in free space, the boundary and will violate the laws of energy and total radiation power flux conservation. In this connection it should be recognized that *unlike the Gertsenshtein effect,* the Li-effect produces a *first-order* perturbative photon flux (PPF), proportional to the amplitude of the gravitational wave . A not A^2. In the case of the Gertsenshtein-Effect such photons are a second-order effect and according to Eq. (7) of Li, et al. [33] the number of EM photons are "…proportional to the amplitude squared of the relic HFGWs, A^2," … and that it would be necessary to accumulate such EM photons for at least 1.4×10^{16} seconds in order to achieve relic HFGW detection (Li et al., [33]) utilizing the Gertsenshtein-Effect. In the case of the Li theory the number of EM photons is proportional to the amplitude of the relic HFGWs, $A \approx 10^{-30}$, not the square, so that it would be necessary to accumulate such EM photons for less than about 1000 seconds in order to achieve relic HFGW detection (Li et al., [10]). The JASON report (Eardley, [13]) confuses the two effects and erroneously suggests that the Li-Baker HFGW Detector utilizes the inverse Gertsenshtein effect. It does not and does have a theoretical sensitivity that is about $A/A^2 = 10^{30}$ greater than that incorrectly assumed in the JASON report for the detection of relic HFGWs.

The Li-Baker HFGW detector operates as follows:

1. The perturbative photon flux (PPF), which signals the detection of a passing gravitational wave (GW), is generated when the two waves (EM and GW) have the same frequency, direction and suitable phase. This situation is termed "synchro-resonance." These PPF detection photons are generated (in the presence of a magnetic field) as the EM wave propagates along its *z*-axis path, which is also the path of the GWs, as shown in Figs. 10 and 11.

2. The magnetic field **B** is in the y-direction. According to the Li effect, the PPF detection photon flux (also called the "Poynting Vector") moves out along the x-axis in both directions.

3. The signal (the PPF) and the noise, or background photon flux (BPF) from the Gaussian beam have very different physical behaviors. The BPF (background noise photons) are from the synchro-resonant EM Gaussian beam and move in the z-direction, whereas the PPF (signal photons) move out in the x-direction along the x-axis and only occur when the magnet is on.

4. The PPF signal can be intercepted by microwave-absorbent shielded microwave receivers located on the *x*-axis (isolated from the synchro-resonance Gaussian EM field, which is along the *z*-axis).

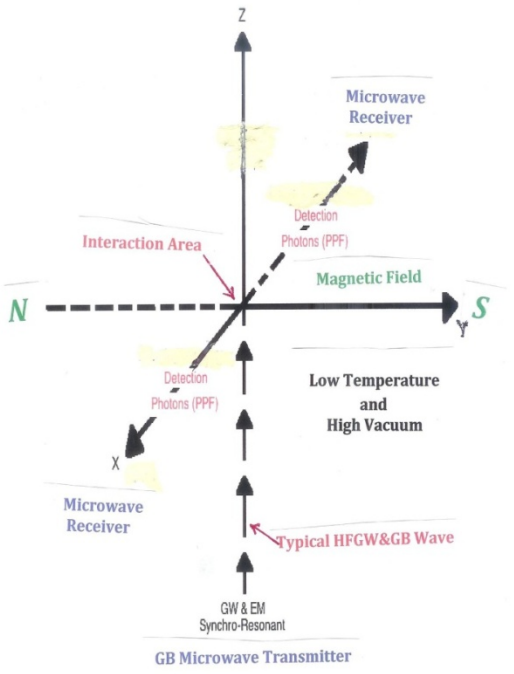

Figure 10.. Detection Photons Sent to Locations that are Less Affected by Noise.

5. The absorption is by means of off-the-shelf -40 db microwave pyramid reflectors/absorbers and by layers of metamaterial or MM absorbers (Landy, et al. 2008, Woods et al. [23] and Patent Pending) that also seal off out gassing. As discussed in detail by Woods, et al. [23] absorption of about –220 dB or an absorption coefficient of 10^{-22} for the two double MM layers, can be achieved. As noted by Landy, et al. [34] since "…impedance matching is possible, and with multiple layers, a *perfect* [absorbance] can be achieved." In addition, isolation is further improved by cooling the microwave receiver apparatus to reduce thermal noise background to a negligible amount as has been accomplished in single-photon receivers (Buller, [35]). In order to achieve a larger field of view and account for any curvature in the magnetic field, an array of microwave receivers having multiple horns (the two receivers having, for example, 12 cm by 12 cm horns (four such horns some two HFGW wavelengths or $2\lambda_{GW}$ on a side) could be installed at x = ± 100 cm (arrayed in planes parallel to the y-z plane). As noted in the following Table, all sources of noise in the Li-Baker HFGW detector such as *diffraction* from the intense Gaussian beam (Woods [36]), *dark-background shot noise, signal shot noise, Johnson noise, preamplifier noise, quantization noise, mechanical thermal noise, phase* or *frequency noise,* can be reduced to negligible amounts in a properly designed Li-Baker detector.

Noise Contributor	Brief Description of Noise source	Mitigation/Elimination Means	Nominal Computed Value photons s^{-1}, NEP W
Dark-background shot noise	GB noise especially diffraction	Wall geometry and absorbing wall materials	$4.2\times10^{-23}s^{-1}$,2.8 10^{-46}W
Signal shot noise	Noise in the signal itself	Part of useful data and not to be eliminated	--
Johnson noise	Thermal agitation in a power amplifier resistance	Refrigeration to low temperature	$5\times10^{-3}s^{-1}$,3×10^{-28} W
Preamplifier kTC noise	Stray capacitance and load resistance	Reducing bandwidth, load resistance and/or stray capacitance.	$1\times10^{-6}s^{-1}$, 8×10^{-30} W
Quantization noise	Analog to Digital Converter	Increasing the number of bits used	$2\times10^{-3}s^{-1}$, 1×10^{-28} W
Mechanical thermal noise	Brownian motion of sensor components.	Refrigeration to low temperature	$3\times10^{-4}s^{-1}$,2×10^{-29} W
Phase or Frequency noise	Fluctuations in the frequency of the microwave source for the GB.	Cavity-lock loop or a phase-compensating feedback loop	$5\times10^{-15}s^{-1}$,3×10^{-38} W

Summary Table of Li-Baker detector noise based upon experimental data concerning its components (Woods et al. [33]).

The total noise equivalent power or NEP is 1.02×10^{-26} W (noise flux is 1.54×10^{-3} photons per second). If need be the receivers could be further cooled and shielded from diffraction noise by baffles and optimum detector geometry as shown in Woods et al. [23]. Given a signal that exhibits the nominal value given in the Summary Table above of Woods et al. [23] of 99.2 s^{-1} photons, one quarter of which is focused on each of the microwave receivers, which is 24.8 s^{-1} photons or 1.6×10^{-22} W, the signal-to-noise ratio for each receiver is better than 1500:1 [23].

4. CONCLUSIONS

The utilization of modern MEMS technology and a double-helix array of them would allow for the construction of a HFGW generator or transmitter involving superradiance that exhibits sufficient strength to transmit HFGW signals globally. This is possible even though the conversion rate of EM power to GW power is exceedingly small and, like EM radiation, the GW signal power falls off as the inverse square of the distance. It is shown herein that a properly designed double-helix array of MEMS (or FBARS) can generate sufficient power to reach a receiver on the opposite side of the globe. Three HFGW detectors or HFGW receivers have previously been fabricated and others theoretically proposed, but analyses of their sensitivity suggest that for meaningful HFGW reception, greater sensitivity is necessary. The theoretical sensitivity of the Li-Baker HFGW detector discussed herein, that is based upon a different measurement technique than the other detectors, is predicted to satisfy HFGW communication needs The detector can be built from off-the-shelf, readily available components and, when coupled with the double-helix MEMS or FBAR array transmitter, could provide for transglobal HFGW communications.

Abstract

High-Frequency Gravitational Wave (HFGW) generators are separated into 3 general categories. Precursor, component-validation, laboratory experiments for each category except, possibly, the third are identified in general terms. The categories are:

(1) The electromechanical category includes micro- and nano-element, piezoelectric crystal, and multi-dielectric film HFGW generators.

(2) The high-temperature superconductor category includes gasers, impressed magnetic fields, and transformation of electromagnetic radiation into gravitational waves (Gertsenshtein effect) HFGWgenerators.

(3) The laser/plasma category includes laser-energized mirrors, synchrotron light, nuclear fusion, plasma toroid, and nonlinear optical-acoustical, molecular-level HFGW generators.

A perusal of HFGW literature reveals that since the 1960s, many authors have contributed designs of mechanisms and devices that relate to the terrestrial generation of gravitational waves. Only in the last few years, however, have any researchers demonstrated that their proposed devices were practical HFGW generators capable of producing kilowatts of power that were operational in a laboratory setting.

These recent devices make use of new technology and generate high-frequency (GHz and above) gravitational waves using non-gravitational forces. Most of the generators considered in this paper have been recently discussed at the May, 2003 Gravitational Wave Conference at The MITRE Corporation,

McLean, VA, which was the very first International Conference dedicated to HFGW and attracted 25 research papers from 9 countries. Although no detailed experimental tasks are discussed, experimental test objectives in the form of a roadmap are proposed for each category.

Introduction

There exist 3 general categories of High-Frequency Gravitational Wave (HFGW) generators: **(1) electromechanical**, **(2) high-temperature superconductor**, and **(3) laser/plasma**. We will not consider the very low-frequency (down to MHz) gravitational waves generated celestially by gravitational forces of interest to astrophysicists, which relate to a totally different technology (HFGW technology is different from that utilized in LIGO, GEO6000, VIRGO, et al).

For each of the devices comprising these general categories, there is a precursor experimental protocol that is generally described herein and is useful for experimental planning. By "precursor", I mean experimental tasks that are predecessors to the test of the capability of devices in question to actually generate detectable HFGW in the laboratory. These are component-validation, laboratory experiments. As an example of a precursor experiment, let us consider the micro- and nano-element devices included in the (1) electromechanical, HFGW-generator category.

The concept of these devices is to impart a large jerk to a mass or system of masses and thereby generate significant HFGW. In this case, the actual devices involve a myriad of energizing and energizable elements. Precursor experimental tasks would involve testing the efficacy of a single element or mechanism. That is, to measure the jerk produced in one single energizable element (in this case a small permanent magnet). If the jerk is successfully produced, then the mechanism can be replicated. Those replicated mechanisms -- when controlled by a computer logic system -- can be utilized as micro- or nano-elements in these devices, which are now capable of generating many kilowatts of HFGW in the laboratory.

This paper includes sections that are devoted to each of the 3 categories of HFGW generators. These sections then reference the specific research efforts involved in the particular category and explain the device's approach in each of the categories for HFGW generation in general terms. Most of the generators considered in this paper have been recently discussed at the May, 2003 Gravitational Wave Conference at The MITRE Corporation, McLean VA 22102, USA which was the very first International Conference dedicated to HFGW and attracted 25 researchers from 9 countries. Various precursor experiments (the experiment list is not intended to be comprehensive) are quite generally described as a guide to the device's development process.

(1) ElectroMechanical HFGW Generators

The precursor experimental tasks for the micro- and nano-device electromechanical HFGW generators (please see Baker, 2000a, 2000b, and 2003 for a description of a 380-kilowatt HFGW generator). In this category, the tasks have been discussed in the foregoing and in Baker (2004). In a little more detail regarding them, it is necessary to test the ability to produce very short (e.g., picosecond or less duration) energizing pulses (e.g., current, electromagnetic, laser, etc.). Next, the ability of various sensing or measuring instruments (e.g., strain gages, Doppler laser, interferometers, piezoelectric crystals, etc.) to measure the energizable element's jerk must be tested in order to calibrate such an experiment.

With regard to the utilization of an array of piezoelectric **electromechanical** crystals for HFGW generation, the recent paper by Dehnen and Romero-Borja (2003) describes such devices best. The concept here (as originally suggested by Weber, 1960) is to stress the crystals at high frequency (THz or

higher) by means of electrical pulses and utilize the resulting vibration, oscillation, or jerk (contractions and expansions of the crystals) to generate HFGW. An array of such crystals is connected to a computer logic system required to energize each crystal as the HFGW wavefront passes and generates a coherent and needle-like, super-radiant beam of HFGW.

At least 2 precursor experimental tasks would be of value here. First, the response of a piezoelectric crystal of various sizes and shapes to high-frequency pulses should be measured. Second, a single row of crystal vibrators (which are elements of the chain of such rows comprising the device) should be fabricated and tested at high frequency, and the motion and internal strain characteristics of the piezoelectric crystals studied.

As indicated by Portilla and Lapiedra (2001), "An electric charge shaken (or jerked) in a homogeneous stationary magnetic field produces both electromagnetic and gravitational waves (Gertsenshtein waves)." In addition, Portilla (2003) suggested that such a device could be "...utilized to construct a (**electromechanical**) generator of HFGW and ... by connecting the generator elements to a computer controlled logic system our device could be incorporated in a communications system."

The latest publication (Navarro, Portilla, and Valdes, 2004) suggests a test of such a concept through use of an electron paramagnetic resonant spectrometer. Precursor tests of the strong magnetic field, vacuum chamber, and microwave generator are also in order. The sensitivity of their antenna should be studied. Finally, several configurations of a waveguide contained multi-dielectric film should be tested.

In summary, the precursor experiments that are, in general, generic to this category are elucidated in Baker (2004) and Navarro, Portilla, and Valdes (2004).

(2) High-Temperature Superconductor HFGW Generators

The HFGW generator equivalent of the laser (the **gaser)** was originally proposed by Halpern and Laurent (1968); again suggested by Fontana (1998); and then presented in more detail by Fontana and Baker (2003). In this latter article, they adopted a combination of 3 theories on gravitational-wave emission at the quantum level (the jerk) to show that their approach can offer the required smallness of the transition line-width and the required increase of the emission probability.

In their gaser concept, coherence would be provided by the collective wave-function of Cooper pairs in a **High-Temperature SuperConductor** (HTSC) to generate high-frequency gravitational waves (HFGW). They calculated the output power of the HFGW (10 megawatts at 1.3 THz) and also proposed a configuration capable of producing a focused beam of radiation of HFGW. The focus can be dynamically adjusted by "...a mechanical connection of the generator elements to a computer controlled logic system." Fontana (2004) suggests a test methodology that would involve precursor tests of the electric current source, the gaser material, and the HTSC.

Ning Li (2003) looked at a curved space and at the gravitational scalar and vector potentials. The scalar potential is ignored because it is too difficult to deal with. When Li completes her algebra, it appears that High-Temperature SuperConductors (HTSC) -- by virtue of the jerk of the Cooper-pair electrons -- can generate **11 kilowatts** of gravitational-wave power under an impressed magnetic field controlled by a computer logic system similar to the concept of Fang-Yu Li, Tang, and Shi (2003). Precursor experiments would involve the test of an alternating (AC) magnetic field: its intensity, its highest frequency and variation of strength, and the ability to fabricate a YBCO HTSC of sufficient size to generate the HFGW.

Chiao (2002) describes an experiment in which he plans to convert electromagnetic (EM) waves into HFGW (Gertsenshtein effect) inside a device that is poised to go from a normally conducting state to a superconducting state. Specifically, "...that **Type II high-temperature superconductors** (such as YBCO) are considered to be Macroscopic quantum gravitational antennas which can simultaneously also be used as efficient transducers (by jerking electrons) for converting EM into HFGW, and vice versa." Precursor experiments would involve activating and testing the EM generator to define its characteristics and testing various designs of the YBCO HTSC. **[StealthSkater note: also see the UNITEL proposals to use special Type II semiconductors in a unique quantum laser that would -- in combination with a special Niobium-Tin SED-implanted "smart skin" achieve Macroscpic quantum tunneling =>** doc pdf URL **]**

In summary, the precursor experiments that are -- in general -- generic to this category are elucidated in Fontana (2004) and Chiao (2002).

(3) Laser/Plasma HFGW Generators

Baker (2004) describes the use of a pulsed laser beam (very short -- e.g., femtosecond or attosecond -- pulses at high repetition frequencies -- e.g., MHz and higher) that produce jerks in a target-mirror energizable element (Baker 2000b) and about 6 kilowatts of HFGW power. The precursor tests involve the generation of the pulses and the tests of various target mirrors as discussed in more detail in Baker (2004).

Rudenko (2003) suggests that for HFGW generation one should utilize strong non-gravitational forces. Possibly those that exist within a HTSC, or a large array of micro-electromechanical devices, or large numbers of coherently excited nano-piezoelectric crystals, etc., or "...to keep the resonance condition (i.e., maximum vibration or jerk amplitude) one has to decrease the mass (scale) of elementary radiator taking into account a possibility of using a natural mass-quadrupole at the molecular level. The deficit of mass in this case might be covered by increasing the total number of coherent micro radiators and detectors N_r , N_d ..

"It is obvious the maximum density of cells can not exceed the value A= 10^{22}-10^{24} per cm^3. After this argumentation, it is reasonable to seek a solution of the problem of effective GW generation by means of collective excitation of molecular oscillations at optical frequencies taking place in a nonlinear optic-acoustical media. One has to choose a molecular with largest quadrupole moment. An instrument for their excitation might be a powerful optical **laser** beam. A **coupling of optical, acoustical, and gravitational waves** must be provided by nonlinear optical permeability of the media. A ccumulation of the GW power as well as its beaming might be provided by the synchronism conditions typical for interaction of waves traveling through nonlinear optical media."

Rudenko concludes that traveling electromagnetic (please see also Grishchuk, 2003 in this same regard) and acoustic (quadrupole) waves interacting (jerking) in nonlinear medium looks quite reasonable and promising at the range of optical frequencies, 10^{14}-10^{15} HZ) for the generation of HFGW recursor experiments would include tests of powerful laser beams, of nonlinear optical permeable materials, and traveling EM waves.

Stephenson (2003) suggests the use of strong synchrotron light in a strong magnetic field to generate HFGW via the Gertsenshtein effect. The quadrupole (jerk) modulation of a synchrotron light source (SLS) and a low-hysteresis target for light generation are proposed. The precursor experiments would include test of various SLS and target designs. Stephenson also suggests a **plasma** toroid approach using plasma modulation to couple quadrupolar energy flow for HFGW generation. Precursor

experiments would involve tests of various mass/plasma designs, confinement designs (e.g., tokomak), and tests of modulation equipment.

Nuclear fusion generation of gravitational waves was originally studied by Chapline, Nuckolls, and Woods(1974). More recently, Rudenko suggested "... **laser**-stimulated thermonuclear fusion or laser micro-target explosions look more promising for the laboratory generation of HFGW." It is difficult to suggest precursor experiments here due to the safety concerns with nuclear reactions. However scientists at, for example, the Lawrence Livermore National Laboratory or similar nuclear research facilities in Russia or China might have some suggestions.

This 3rd category of HFGW generators is the least mature of the group and may not be ready for component-validation laboratory experiments. It is, therefore, difficult to establish generic guidelines for precursor experiments. As Paul Murad has suggested (May 8, 2003), one might consider "... using a laser (energizing element) to radiate a gas such that shock waves are formed to create a pressure pulse that induces a particle (energizable element) jerk." Measurement of such an imbedded particle (or gas molecule) jerk might reveal the capability of such a process -- with greatly increased power -- to generate HFGW.

Conclusions

It is self evident from the research efforts cited in this paper that significant theoretical analysis has been devoted of late to the laboratory or terrestrial generation of HFGW.

Now is the time to supplement these studies with a series of precursor experiments. Experiments that will incrementally lead to the fabrication and test of one or more HFGW generators and the detection of their emanations by the HFGW detectors that have already been fabricated in England (please see Cruise, 2000), Italy (please see Chincarini and Gemme, 2003) and China (please see Li, Tang, and Shi, 2003).

The time is right, *carpe diem* ... seize the moment!

Acknowledgment

I wish to express my great appreciation to Paul Murad for his editorial and substantive contributions to this paper.

Generation and Detection of Gravitational Waves at Microwave Frequencies by Means of a Superconducting Two-body System

R.Y. CHIAO*
School of Natural Sciences and School of Engineering, University of California, P.O. Box 2039, Merced, CA 95344, U.S.A.

Abstract: The 2-body system of a superconducting sphere levitated in the magnetic field generated by a persistent current in a superconducting ring, can possibly convert gravitational waves into electromagnetic waves, and vice versa. Faraday's law of induction implies that the time-varying distance between the sphere and the ring caused by the tidal force of an incident gravitational wave induces time-varying electrical currents, which are the source of an electromagnetic wave at the same frequency as the incident gravitational wave. At sufficiently low temperatures, the internal degrees of freedom of the superconductors are frozen out because of the superconducting energy gap, and only external degrees of freedom, which are coupled to the radiation fields, remain. Hence this wave-conversion process is loss-free and therefore efficient, and by time-reversal symmetry, so is the reverse process. A Hertz-like experiment at microwave frequencies should therefore be practical to perform. This would open up observations of the gravitational-wave analog of the Cosmic Microwave Background from the extremely early Big Bang, and also communications directly through the interior of the Earth.

Consider the configuration of a superconducting sphere levitated above a superconducting ring, as shown in Figure 1 [this was suggested by Clive Rowe, personal communication]. For levitation to occur, it is required that the downwards force of Earth's gravity $\mathbf{F}_{\mathrm{GR}}(0)$

on sphere be exactly balanced by the upwards electromagnetic force $\mathbf{F}_{\mathrm{EM}}(0)$

on the sphere due to the complete expulsion of the $\mathbf{B}$ field in the Meissner effect [1], so that

$$\mathbf{F}_{\mathrm{EM}}^{(0)} = -\mathbf{F}_{\mathrm{GR}}^{(0)}$$

* rchiao@merced.edu

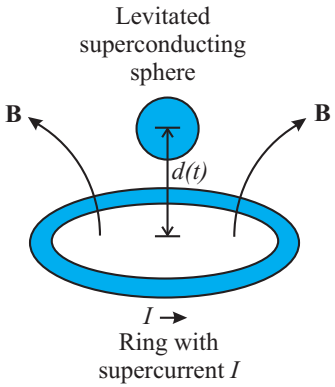

Figure 1: The DC magnetic **B** field generated by a superconducting ring with a persistent current I levitates a superconducting sphere. When a (+) polarized gravitational wave propagates radially inwards and converges upon the center of mass of this two-body system, the distance between the sphere and the ring $d(t)$ changes periodically with time, for example, at a microwave frequency, with small-amplitude excursions around an average distance of on the order of the microwave wavelength. This superconducting two-body configuration, viewed as a gravitational-wave antenna, can possibly efficiently convert this incident gravitational (GR) wave into an electromagnetic (EM) wave, and vice versa. Under the operation of time reversal, the current I and the magnetic field **B** of the ring in this Figure are reversed in direction, in order to achieve the time-reversed process of converting the EM wave back into the GR wave.

Note that the zero superscripts denote forces that are evaluated in the zeroth order of perturbation theory, i.e. in the absence of any perturbing radiation fields.

Now let a single mode of a weak, linearly polarized gravitational wave [2] at a microwave frequency (such as from the Big Bang), with one of its polarization axes along the vertical axis, be incident upon this two-body system. For simplicity, let us assume that the mass of the ring is much larger than that of the sphere, so that the reduced mass of the two-body system becomes simply that of the sphere, and the center of mass of the system approximately coincides with the center of the ring. The gravitational wave then exerts a time-varying tidal force upon the sphere relative to the ring. According to a distant inertial observer, the space between the

sphere and the ring is being periodically squeezed and stretched with time, so that the distance $d(t)$ is a sinusoidal function of time.

The mechanism for the wave conversion is the following: In the presence of the DC **B** field of the superconducting ring, Faraday's law of induction implies that the time-varying distance $d(t)$ between the sphere and the ring causes induced electrical currents to circulate azimuthally around the bottom pole of the sphere at a microwave frequency, and similarly, induced countercurrents around the ring. These time-varying induced currents are a source of electromagnetic radiation at the same frequency as that of the incident gravitational radiation. Thus a gravitational (GR) wave can in principle be converted into an electromagnetic (EM) wave [3]. Lenz's law implies that there exists an instantaneous EM force $\mathbf{F}_{\mathrm{EM}}$ acting on the sphere which opposes the instantaneous GR wave tidal force $\mathbf{F}_{\mathrm{GR}}$ acting on the sphere, such that under certain circumstances (to be discussed below) quasi-static mechanical equilibrium holds, i.e.,

$$\mathbf{F}_{\mathrm{EM}} = -\mathbf{F}_{\mathrm{GR}}.$$

Note that this equation implies an equality of the magnitudes of the electromagnetic and gravitational forces on the sphere.

Let us now examine whether or not there can exist circumstances under which a complete conversion of incoming GR wave power into outgoing EM wave power in Figure 1 can in principle occur. Under these circumstances, energy conservation demands that, in terms of quantities as measured by the distant inertial observer, the power absorbed from GR wave is equal to the power emitted into EM wave,

$$\langle \mathbf{F}_{\mathrm{GR}} \cdot \mathbf{v}_{\mathrm{rad}} \rangle = -\langle \mathbf{F}_{\mathrm{EM}} \cdot \mathbf{v}_{\mathrm{rad}} \rangle \qquad (1)$$

The angular brackets denote the time average over one period of the radiation fields, and $\mathbf{v}_{\mathrm{rad}}$ is the instantaneous radiation-damping velocity of the sphere undergoing rigid-body motion relative to the ring, which is parallel to, and in phase with, the instantaneous force $\mathbf{F}_{\mathrm{GR}}$, as seen by the distant observer. These circumstances can occur in a regime in which the electromagnetic radiation damping of the motion of the superconducting two-body system is the dominant damping mechanism as compared to all other loss mechanisms.

The superconducting sphere and ring can both undergo rigid-body motion in response to the gravitational wave, because the quantum adiabatic theorem [3, 4] applies to all perturbations due to any kind of radiation, whenever the frequency of these perturbations is below the BCS gap frequency [1]. Superconductors stay adiabatically, hence rigidly, in the BCS ground

state of the system, because no internal excitations are allowed within the BCS energy gap [1, 3, 5].

Also, there must be little energy dissipation, such as into heat, other than that due to radiation damping or conversion. This requirement is satisfied by the strictly zero resistance of the superconductors, which follows from the fact that no dissipative excitations into heat due to ohmic processes (or phonon generation to be discussed later) are allowed within the BCS energy gap, when the frequency of the radiation is lower than the BCS gap frequency [1, 3, 5].

Thus we see that a complete, loss-free conversion from GR wave energy to EM wave energy can indeed occur, provided that all internal degrees of freedom of the superconducting two-body system are frozen at low temperatures, so that only its external degrees of freedom remain. For these external degrees of freedom, in the case when electromagnetic radiation damping is dominant, there then can exist a quasi-static mechanical equilibrium at each instant of time, such that the instantaneous forces obey the equality $\mathbf{F}_{\mathrm{GR}} = -\mathbf{F}_{\mathrm{EM}}$, just like in the case of a linear induction motor (or generator). Then the power in a single, incoming GR wave mode can be completely converted into the power in a single, outgoing EM wave mode.

Under the operation of time reversal, the single, outgoing EM wave mode becomes a single, incoming EM wave mode incident upon the superconducting two-body system. This EM wave mode is then back-converted into an outgoing GR wave mode. This reverse (or reciprocal) process has the same complete, loss-free conversion efficiency as the forward process by time-reversal symmetry [3, 6]. Energy conservation demands that, the power absorbed from EM wave is equal to the power emitted into GR wave,

$$\langle \mathbf{F}_{\mathrm{EM}} \cdot \mathbf{v}_{\mathrm{rad}} \rangle = -\langle \mathbf{F}_{\mathrm{GR}} \cdot \mathbf{v}_{\mathrm{rad}} \rangle \tag{2}$$

But this is satisfied by Lenz's law and the equality $\mathbf{F}_{\mathrm{GR}} = -\mathbf{F}_{\mathrm{EM}}$ that is also valid for the reverse process. Here the force $\mathbf{F}_{\mathrm{EM}}$ is squeezing and stretching periodically the space between the sphere and the ring, so that the sphere is acting upon space, not moving through space, in a time-reversal of the forward process.

Under the action of the gravitational wave, the space between the sphere and the ring is undergoing small amplitude, anisotropic, periodic time-varying strains h_{ij} of the metric tensor [2], as if the space were an elastic medium. According to the Equivalence Principle [2], in both the forward and the reverse processes, the sphere is not accelerating at all with respect to a tiny, local inertial observer located at its center, so that the sphere is not moving, i.e., accelerating, through space. Hence the objection that its

inertia limits the amount of emitted GR radiation to extremely small values is invalid; see section 12 of [3]a. Similarly, the objection that the motion of the sphere through a flat-space background must be relativistic (i.e., with velocities close to c) in order to generate any appreciable amount of GR waves is also invalid.

Therefore we propose here to perform a Hertz-like experiment at 12 GHz, in which the EM-to-GR wave-conversion process becomes the source of GR waves, and the GR-to-EM wave-conversion process becomes the receiver of GR waves. Faraday cages consisting of normal metals at room temperature (the metallic casings of the two well-separated liquid helium storage dewars to be described below) prevent the transmission of EM waves, so that only GR waves, which can easily pass through all ordinary, classical matter, such as the normal (i.e., dissipative) metals of which standard, room-temperature Faraday cages are composed, are transmitted between the two halves of the apparatus that serve as the source and the receiver, respectively [3]. Such an experiment should be practical to perform using standard microwave sources and receivers, since the scattering cross-sections and the wave conversion efficiencies of the two-body superconducting system such as the one depicted in Figure 1, when viewed as a gravitational-wave antenna, should be large enough to be experimentally interesting [3]; see also below].

We plan to use lead (Pb) as the type I superconducting material for both the sphere and the ring. The sphere could consist of a light, low-density material (e.g., Styrofoam) coated on its surface with a Pb film which is much thicker than the penetration depth [5]. The ring could consist of a flat copper gasket electroplated with a thick coating of Pb. The central hole of the gasket could have a diameter of 34 mm, which should levitate the superconducting sphere above the hole of the ring at a distance of around 6 mm, i.e., approximately a quarter of a microwave wavelength at 12 GHz where we plan to work (12 GHz is over an order of magnitude below the BCS gap frequency of Pb, so that the losses at this frequency are negligible [3]). A persistent current in the ring sufficient to levitate the sphere could be induced by means of a nearby permanent magnet, which would then be removed after the ring has been cooled to become superconducting below the transition temperature of Pb at 7.2 K [5]. We plan also to experiment with other two-body geometries, such as with a pair of superconducting coaxial rings with opposing trapped magnetic flux [suggested by S. Minter], as realizations of the superconducting two-body system. We have chosen to use a type I superconductor instead of a type II superconductor, in order to avoid microwave losses arising from the Abrikosov vortex-motion degrees of freedom.

We propose to perform the first experiments in a standard 4 K liquid helium storage dewar using a dewar insert, which consists of a 50 mm diameter cylindrical structure with a detachable sample holder that is capable of containing a specific sphere-ring configuration (or other superconducting two-body geometries) at its bottom end. Such a dewar insert could be inserted directly into the liquid helium inside a storage dewar, in order to explore the parameters for the levitation of the sphere by the ring, by adjusting the dimensions of the sphere-ring configuration. Optical access and viewing could be made possible by means of glass prisms placed inside the sample can near the ring. Alternatively, a Hall probe sensor could detect the onset of the Meissner effect and levitation of the sphere. These dewar-insert experiments would enable us to test the computer simulations we are presently conducting for the levitation of type I superconducting spheres by various magnetic field configurations.

Two of these dewar inserts, each with a sphere-ring configuration (or some other superconducting two-body configuration) immersed deep inside two well separated 4 K liquid helium dewars, with the associated microwave electronics, would then allow us to perform the Hertz-like experiment. In preparation for this experiment, we plan to determine at room temperature the microwave antenna design parameters of the sphere-ring and the two-coaxial-ring configurations (and other possible configurations) using a network analyzer. We plan to use an appropriately designed magnetic loop antenna to couple to the TE_{01} microwave cylindrical mode of a superconducting ring for transferring energy from the GR wave mode to the EM wave mode, and vice versa.

We have already built and tested microwave sources and receivers at 12 GHz [6]. We have used a frequency-doubled 6 GHz microwave-cavity oscillator as the source, with an output power level at 12 GHz of around 10 mW, and have measured that a standard, commercial satellite-dish KU band receiver [Precision model PMJ-LNB KU gold label series from Astrotel Communications Corp.] has a noise figure of 0.6 dB at 12 GHz, so that our receiver system Noise-Equivalent-Power (NEP) sensitivity will be on the order of 10^{-25} W/Hz$^{1/2}$. This will allow us to achieve a very good signal-to-noise ratio for the Hertz-like experiment [3], assuming that our estimates for the cross-sections and wave-conversion efficiencies for the sphere-ring system are of the correct orders of magnitude.

If we should be successful in the Hertz-like experiment, one of the first tests to see if we truly have GR rather than EM coupling between the transmitter (or source) and receiver (or detector) halves of the apparatus, is to tilt the transmitter part of the apparatus by $+22.5^\circ$ with respect to the vertical

around the line of sight joining the transmitter and receiver, and to tilt the receiver part of the apparatus by -22.5° with respect to the line of sight. The signal should be extinguished at the resulting 45° relative orientation between the two halves of the apparatus, and not at 90°, as would the case for EM waves. This would be a clear signature that we have successfully generated and detected GR waves rather than EM waves [this was suggested by Kirk Wegter-McNelly, personal communication].

Another of our initial goals if we should be successful in detecting a signal in the Hertz-like experiment would be to directly measure the speed of gravitational waves for the first time. This can be done either by changing the distance between the two experimental dewars containing the two sphere-ring (or other) configurations, and then measuring the resulting change in phase of the received signal relative to that of the source signal, or by modulating the carrier signal, and measuring the delay in the arrival time of the demodulated signal. We will thereby be able to directly check experimentally in the laboratory for the first time the theoretical prediction by Einstein that the speed of these waves is identical to that of light in vacuum $c = 3.00 \cdot 10^8$ m/s [2] , to within $\pm 1\%$ accuracy.

It may be objected that sound waves will be generated as a dissipative mechanism in the proposed experiment. However, sound waves have a speed that is typically five orders of magnitude smaller than c. If Einstein were correct, then the typical generated sound wavelength of 250 nm or smaller would be much less than the gravitational wavelength of 25 mm, so that the typical sound wave would be badly mismatched to the incident GR wave. The generation of sound waves (or phonons) within the superconductor at microwave frequencies inside the BCS gap by the incident gravitational wave would therefore be forbidden due to the Mössbauer-like (or zero-phonon) effect described in section 9 of [3]a; see also [3]b. Hence the sphere and the ring would undergo rigid-body motion in response to the incident gravitational wave.

It may also be objected that the microwave-frequency electrical currents induced through Faraday's law in the GR to EM wave conversion process may be too feeble and too difficult to detect. However, we are not proposing to detect these currents, but rather to detect the power transmitted from the GR wave to the EM wave, and vice versa. With an antenna design which takes into account impedance-matching and cross-section considerations properly, the power transmitted from the source to the receiver should be readily measurable.

To better understand the cross-section estimate for the above proposed experiment, it is useful to introduce a weak-field representation of the lin-

earized Einstein equations for the gravito-electric field $\mathbf{E}_{\rm G} \equiv \mathbf{g}$ (i.e., the gravitational acceleration of a test mass), and for the gravito-magnetic field $\mathbf{B}_{\rm G}$ (i.e., the far-field, time-varying analog of the Lense-Thirring field), as observed in the coordinate system of a distant inertial observer. This representation takes the form of the Maxwell-like equations [7]

$$\nabla \cdot \mathbf{E}_{\rm G} = -\frac{\rho_{\rm G}}{\varepsilon_{\rm G}} \tag{3}$$

$$\nabla \times \mathbf{E}_{\rm G} = -\frac{\partial \mathbf{B}_{\rm G}}{\partial t} \tag{4}$$

$$\nabla \cdot \mathbf{B}_{\rm G} = 0 \tag{5}$$

$$\nabla \times \mathbf{B}_{\rm G} = \mu_{\rm G}\left(-\mathbf{j}_{\rm G} + \varepsilon_{\rm G}\frac{\partial \mathbf{E}_{\rm G}}{\partial t}\right) \tag{6}$$

where $\rho_{\rm G}$ is the mass density and $\mathbf{j}_{\rm G}$ is the mass current density of slowly-moving matter in the source, and the gravitational analog of the electric permittivity of free space ε_0 is

$$\varepsilon_{\rm G} = \frac{1}{4\pi G} = 1.19{\cdot}10^{9} \text{ units} \tag{7}$$

where G is Newton's constant, and the gravitational analog of the magnetic permeability μ_0 of free space is

$$\mu_{\rm G} = \frac{4\pi G}{c^2} = 9.31{\cdot}10^{-27} \text{ units} \tag{8}$$

where c is the speed of light.

The fields $\mathbf{E}_{\rm G} \equiv \mathbf{g}$ and $\mathbf{B}_{\rm G}$ are measurable quantities that obey the gravitational analog of the Lorentz force law [7]

$$\mathbf{F} = m(\mathbf{E}_{\rm G} + 4\mathbf{v} \times \mathbf{B}_{\rm G}) \tag{9}$$

where m is the mass of a test particle, and $\mathbf{v}$ is its velocity, as seen by the distant inertial observer.

These Maxwell-like equations are linear, so that the fields obey the superposition principle not only in the vacuum outside of the source, but also in the matter inside the source, provided that the field strengths are sufficiently weak and the matter is sufficiently slowly moving, so that there exists a regime of a linear response of the matter to the applied fields. The resulting optics for gravitational waves is therefore linear, just like the linear optics for electromagnetic waves.

Therefore any argument involving the characteristic power scale [2]

$$P_0 = \frac{c^5}{G} = 3.6{\cdot}10^{52}\,\mathrm{W} \tag{10}$$

is irrelevant in the context of linear optical devices such as linear mirrors, since it should always be possible to reduce the intensity of the incident GR waves so that there exists a linear regime of response of such devices to these sufficiently weak GR wave amplitudes. Then there cannot exist any characteristic scale of power in any linear response of such devices, such as that given by Equation (10).

Also, it is important to emphasize that the matter generating the GW waves in such linear devices as the two-body superconducting system described above, needs not be moving relativistically with velocities close to the speed of light c relative to each other, in order to generate any appreciable amount of GR waves. By the time-reversal symmetry argument given above, it is clear that the generation of GR waves by the two-body superconducting system is not due to the matter moving through space, but rather is due to the matter acting upon space directly. Hence it is irrelevant whether such matter is moving close to c through space or not.

In the case of the vacuum, where ρ_G and $\mathbf{j}_G$ both vanish, these equations lead to wave propagation at a wave speed exactly equal to the speed of light

$$c = \frac{1}{\sqrt{\varepsilon_G \mu_G}} = 3{\cdot}10^8\,\mathrm{SI\ units}. \tag{11}$$

A plane wave solution of the Maxwell-like equations possesses the gravitational characteristic impedance of free space given by [8, 3]

$$Z_G = \sqrt{\frac{\mu_G}{\varepsilon_G}} = 2.79{\cdot}10^{-18}\,\mathrm{SI\ units}, \tag{12}$$

which is the analog of the electromagnetic characteristic impedance of free space

$$Z_0 = \sqrt{\frac{\mu_0}{\varepsilon_0}} = 377\,\mathrm{Ohms}. \tag{13}$$

The gravitational characteristic impedance of free space Z_G, like Z_0, plays a central role in all radiation problems, such as in a comparison of the radiation resistance of gravitational-wave antennas to the value of this impedance, in order to estimate the coupling efficiency of these antennas to free space. The numerical value of Z_G is extremely small, but the impedance of all material objects must be "impedance matched" to this

extremely small quantity before significant power can be transferred efficiently from gravitational waves to these objects, or vice versa.

In contrast to the electromagnetic-wave case, in the gravitational-wave case, all ordinary, classical matter, such as Weber bars, possesses impedances much larger than that of the gravitational characteristic impedance of free space Z_G. It is therefore extremely difficult to impedance-match gravitational waves to any ordinary, classical matter. As a consequence, it is a general rule that all ordinary, classical matter, such as a Weber bar, is essentially completely transparent to these waves.

However, phase-coherent, loss-free quantum matter, such as superconductors, which can possess strictly zero dissipation due to the presence of the BCS energy gap, can be exceptions to this general rule. Experimental evidence for this "quantum dissipationlessness" is the fact that persistent currents in annular superconducting rings have been observed to last much longer than the age of the Universe [1]. One important consequence of the zero-dissipation property of a superconductor is that a mirror-like reflection of sufficiently low-frequency gravitational waves can occur at a planar interface between the vacuum and the superconductor. Note that by "low frequency" we mean frequencies much less than the BCS gap frequency.

In the electromagnetic case, the reflection coefficient R of a wave being transmitted down a transmission line with impedance Z, which is terminated by a resistance R which vanishes like that of a superconductor, is given by

$$R_G = \left| \frac{Z - R}{Z + R} \right|^2 \rightarrow 100\% \quad \text{as} \quad R \rightarrow 0. \tag{14}$$

This implies that a mirror-like reflection of the wave occurs from a superconductor, when it is used as a short-circuit termination of the transmission line.

Similarly, the reflection coefficient RG of a sufficiently low-frequency gravitational wave from a superconductor-vacuum interface is given by

$$R_G = \left| \frac{Z_G - R_G}{Z_G + R_G} \right|^2 \rightarrow 100\% \quad \text{as} \quad R_G \rightarrow 0. \tag{15}$$

where the gravitational characteristic impedance of free space Z_G is given by Equation (12), and R_G is the gravitational analog of the resistance R of the superconductor. This implies that a mirror-like reflection of a sufficiently low-frequency gravitational wave could in principle occur from the surface of the superconductor.

Therefore mirrors for gravitational waves can in principle exist. Curved, parabolic mirrors can focus these waves, and Newtonian telescopes for gravitational radiation can in principle be constructed. In the case of scattering of gravitational waves from superconducting bodies, the above mirror-like-reflection condition implies hard-wall boundary conditions at the surfaces of these superconducting bodies, so that the scattering cross-section of these waves from large superconducting bodies can in principle be geometric, e.g., hard-sphere, in size. For example, for a superconductor in the form of a sphere of radius which is much larger than the wavelength, the cross-section for GR wave scattering by the sphere is given by

$$\sigma_{\text{hardsphere}} = 2\pi a^2, \tag{16}$$

where a is the radius of the superconductor.

It may be objected that any kind of reflection of gravitational waves from matter, including any kind of partial reflection, would constitute a kind of "anti-gravity" effect. Now it is certainly true that only positive masses exist in nature, and therefore that the screening of longitudinal gravito-electric fields, like the Earth's gravitational field, including its partial screening by any kind of matter, including superconductors as has been falsely claimed in the so-called "Podkletnov effect", is impossible. However, both positive and negative mass currents can exist in nature, and therefore the screening of transverse gravito-magnetic fields, like those of a gravitational wave, including the partial screening by the reflection of these waves from matter, should indeed be possible. The strength of the reflection can in principle depend on the details of the nature of the matter.

A closely related objection is that, according to one interpretation of the Equivalence Principle, the response of all kinds of matter, whether classical or quantum mechanical in nature, should be universally the same to all gravitational fields. Locally, all dropped objects undergo exactly the same free-fall motion, which is independent of their mass, composition, or thermodynamic state. Specifically, the response of all matter to gravitational fields, such as the Earth's, is independent of whether the thermodynamic state of the matter is classical or quantum mechanical in nature.

Thus this interpretation of the Equivalence Principle would forbid any difference between the linear response of incoherent classical matter, such as Weber bars, and the linear response of coherent quantum mechanical matter, such as superconductors, to any kind of gravitational field. However, whilst this interpretation is valid for the local response of any kind of matter, whether coherent or incoherent, to all gravito-electric fields, like that of all dropped, freely-falling objects in their response to the gravitational field

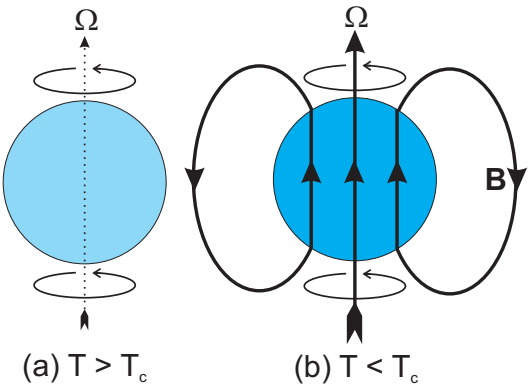

Figure 2: Comparison of a rotating normal metal with a rotating superconductor. In (a), the normal metal is a neutral sphere consisting of a rotating superconducting metal at a temperature above its transition temperature T_c. In (b), this body is slowly cooled down below T_c, whilst it is rotating. Now there is the onset of a magnetic field **B** proportional to its rate of rotation Ω with respect to the distant "fixed stars".

of the Earth, it is not valid for the nonlocal response of matter, whether coherent or incoherent, to gravito-magnetic fields, such as to the Lense-Thirring field arising from the distant matter of the Universe (i.e., from the distant "fixed stars").

Empirical evidence for this latter fact lies in the difference between the response of normal metals and the response of superconductors which are rotating with respect to the distant "fixed stars" [9]. Consider an experiment in which there is a spherical body rotating at a fixed angular speed Ω, which consists of a normal metal that is a superconductor above its transition temperature T_c. For all temperatures $T > T_c$, no magnetic field is produced by this neutral, rotating body.

Now consider what happens when this rotating body is slowly cooled, whilst it is undergoing rotation with respect to the distant "fixed stars," down below its transition temperature T_c. Now for all temperatures $T < T_c$, there exists a magnetic field B produced by this rotating superconducting body in the "London moment" effect. The London moment arises from the constructive quantum interference of the Cooper pairs of electrons in the superconductor near its surface after one round trip around the perimeter of the body, as seen by the distant inertial observer. This quantum interference effect implies that the Cooper pairs everywhere near

the surface of the body in its lowest energy state will come to a complete halt with respect to the distant "fixed stars". The nuclei near the surface, however, continue to rotate with respect to the distant "fixed stars". Thus this differential motion of the Cooper pairs with respect to the nuclei near the surface produces a surface electrical current. It is this current that produces the magnetic field B which is sketched in Figure 2(b).

However, according to the above interpretation of the Equivalence Principle, there cannot be any difference in the response of the rotating body above or below its transition temperature to any kind of gravitational field, including the Lense-Thirring field which arises from the distant "fixed stars". Specifically, the response of the rotating body to the Lense-Thirring field arising from these distant "fixed stars" should be independent of the thermodynamic state of this body, and in particular, it should be independent of whether the rotating body is composed of incoherent, classical matter, or coherent, quantum mechanical matter. This interpretation of the Equivalence Principle is contradicted by experiments that demonstrate the existence of the London moment [9].

Let us now generalize the above considerations to the case of the time-varying, transverse fields of gravitational radiation, when the frequency of the radiation is much lower than the BCS gap frequency, so that the quantum adiabatic theorem holds. Let us first consider the case of a normal metal, which consists of a superconducting metal above its transition temperature T_c. Let this neutral metallic body have the shape of a planar slab with a thickness of half a wavelength of the incident gravitational plane wave, which is propagating towards the slab at normal incidence along the x axis from the left, as depicted in Figure 3. The entrance face of the slab is at $x = 0$, and the exit face of the slab is at $x = \lambda/2$.

The linear response of a normal electron above the superconducting transition temperature Tc near the surface of the metal to the tidal field g of the incident wave is represented by the local, instantaneous velocity vector v, which would be the free-fall velocity of the normal electron, assuming the absence of any dissipation in the metal. (All measurable quantities are those that are being measured by a distant inertial observer represented by the eye in Figure 3). Since the normal electrons undergo local free fall together with the nearby nuclei (neglecting for the moment the weak restoring forces arising from the ionic lattice), no electrical currents are produced in the linear response of this neutral body to the local, instantaneous accelerations due to gravity g arising from tidal forces of the gravitational wave.

Let us now choose two rectangular loops, one above the center of mass (c.m.) of the system, and one below it, as shown in Figure 3, in order to

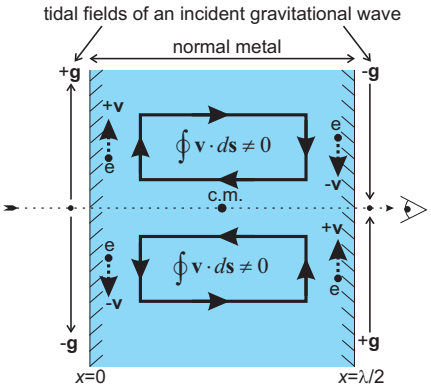

Figure 3: A slab of normal metal half a wavelength thick, which is a superconducting metal above its transition temperature T_c, in its linear response to the tidal fields of a normally incident gravitational plane wave. The center of mass of the slab is represented by the dot below the label "c.m." The eye on the right represents a distant inertial observer. However, below T_c, the upper and lower electrons form a Cooper pair in a Bohm singlet state, that is an entangled state which violates Bell's theorem and is nonlocal. The electrons local free-fall motion is thus suppressed.

evaluate the circulation of the normal electrons around these loops in their linear response to the incident wave. It is obvious upon inspection of Figure 3 that these two closed loop integrals of the velocity v of the normal electron, as seen by the distant inertial observer, obey the inequality

$$\oint \mathbf{v} \cdot \mathrm{d}\mathbf{s} \neq 0, \tag{17}$$

so that the circulation of the normal electrons around these loops does not vanish. This is because there is a reversal of the sign of the tidal forces as the wave propagates from the entrance face of the slab at $x = 0$ to the exit face at $x = \lambda/2$, and therefore there is also a reversal of the sign of the normal electron velocity in their linear response to these tidal forces.

Next, let us slowly cool this system down below the superconducting transition temperature T_c whilst the incident gravitational wave is still present. The normal electrons now become Cooper pairs, which possess quantum phase coherence over long distances. If the Cooper pairs near the surface of the metal in Figure 3 were to undergo free fall with exactly the same instantaneous, local velocity $\mathbf{v}$ in their linear response to the tidal fields g of the incident gravitational wave, as the instantaneous, local free-fall veloc-

ity $\mathbf{v}$ of the normal electrons in the normal state of the metal (as would be demanded by the above erroneous interpretation of the Equivalence Principle), then their macroscopic wavefunction (or the complex order parameter of Ginzburg and Landau) would no longer by single valued after one round trip around the closed loop, and the constructive quantum interference for these Cooper pairs after a round trip would be impossible. This is because the instantaneous velocity $\mathbf{v}$ is related to the phase ϕ of the Cooper pair macroscopic wavefunction (or of the complex order parameter) by

$$\mathbf{v} = \frac{\hbar}{m}\nabla\phi, \tag{18}$$

where $\hbar$ is Planck's constant$/2\pi$ and m is the mass of a Cooper pair.

However, experiments verifying the existence of the London moment [9] demonstrate that the Cooper pairs do in fact always possess a single-valued macroscopic wavefunction (or complex order parameter), as determined by the observations in the inertial frame of the distant observer, i.e., that of the distant "fixed stars". Hence it must be the case that below the temperature T_c, the circulation of the Cooper pairs vanishes identically, i.e.,

$$\oint \mathbf{v}\cdot d\mathbf{s} = 0, \tag{19}$$

in the case of the lowest energy state of the Cooper pairs. This implies that their local, instantaneous velocity vanishes everywhere along the left and the right vertical segments at $x = 0$ and $x = \lambda/2$ of the arbitrarily chosen closed loops in Figure 3, so that in the limit of arbitrarily skinny loops, it follows that

$$\mathbf{v} = 0 \tag{20}$$

everywhere near the surface of the superconductor. Therefore it follows that the time-dependent, transverse gravito-electric field

$$\mathbf{E}_G \equiv \mathbf{g} = \left(\frac{\partial \mathbf{v}}{\partial t}\right)_{\text{near surface}} = 0 \tag{21}$$

also vanishes everywhere near the surface of the superconductor. This also implies hard-wall boundary conditions that lead to a mirror-like reflection of gravitational waves. (See also footnotes 11 and 12 of [3a].)

The above conclusions also follow from the fact that the entire superconducting slab stays adiabatically in the BCS ground state of the system with a single value of the global phase ϕ of the macroscopic wavefunction (or of the complex order parameter) inside the entire superconducting body, i.e.,

$$\phi = \text{constant everywhere.} \tag{22}$$

This is true even in the presence of the weak, local perturbations due to the incident gravitational wave, provided that the wave frequency is well below the BCS gap frequency, so that the wave cannot cause any quantum transitions out of the BCS ground state.

The Cooper pairs in the BCS ground state are in entangled states of momentum and spin, which are nonlocal, so it is impossible to know whether it is the upper or the lower electron in Figure 3 that is moving upwards or downwards in response to the tidal g fields. The large number of these phase-coherent electrons in the system (on the order of Avogadro's number) in the case of superconductors, compensates for the usual weakness of the interaction between gravitation radiation and matter, and leads to a superradiant, mirror-like reflection [3b].

Therefore, just as in the case of the London moment below the transition temperature T_c, the Cooper pairs everywhere near the entrance and exit faces of the superconducting slab must come to a complete halt with respect to the distant inertial observer (i.e., with respect to the distant "fixed stars") below Tc. The vanishing of v everywhere near the surfaces of the slab must be independent of the size of the small amplitude of a sufficiently weak gravitational wave, in the regime of the linear response of the superconductor to the wave. This is the behavior of an extremely rigid material in its linear response to the gravitational wave, so that, once again, one concludes that a mirror-like reflection of a sufficiently weak incident gravitational wave should occur at the planar superconductor-vacuum interface. The resulting scattering cross-section for large superconducting bodies should therefore once again be of the order of magnitude of the geometric cross-section given by Equation (16). These counter-intuitive predictions will be tested in the above proposed experiment.

It is to be emphasized that throughout the above discussion, all measurable quantities in the above equations are those which are being observed and measured by the distant inertial observer. The coordinate system being used in these measurements is the one set up by means of light signals sent to and from this distant observer, and the time coordinate being used is the one set up by means of this observer's clock [11].

This experiment could lead to important applications in science and engineering. In science, it would open up the possibility of gravitational-wave astronomy at microwave frequencies. One important problem to explore would be observations of the analog of the Cosmic Microwave Background (CMB) in gravitational radiation. Since the Universe is much more transparent to gravitational waves than to electromagnetic waves, such observations would allow a much more penetrating look into the extremely

early Big Bang towards the Planck scale of time, than the presently well-studied CMB. Different cosmological models of the very early Universe give widely differing predictions of the spectrum of this penetrating radiation, so that by measurements of the spectrum, one could tell which model, if any, is close to the truth [10]. The anisotropy in this radiation would also be very important to observe.

In engineering, it could open up the possibility of intercontinental communications by means of microwave-frequency gravitational waves directly through the interior of the Earth, which is transparent to such waves. This would eliminate the need of communications satellites, and would allow an economical means of communication with people deep underground or underwater in submarines in the oceans. Such a new direction of gravitational-wave engineering could aptly be called "gravity radio" [3].

PULSAR GLITCHES AS A GRAVITATIONAL WAVE SOURCE

Corey Bathurst

Draft version August 15, 2013

ABSTRACT

This report describes research completed in in Dr. Hyung Mok Lee's group at Seoul National University through the University of Florida's International Research Experience for Undergraduates funded by the National Science Foundation. This project explores the possibility of pulsar glitches as a source of gravitational radiation through hydrodynamic code with applied perturbations that mimic the glitch event. The two perturbations considered mimic the star quake model and angular momentum transfer by vortex unpinning at crust-core interface model. We estimate the characteristic amplitude of the gravitational waves from the evolution of the quadrapole moment of the simulated star.

We use the weak field metric with a generalized source term to Poisson's equation to gain closer agreement with a full general relativistic treatment. This report discusses the validity of this method and some of the testing done to see how well our method agrees with other methods such as linear perturbative analysis. We find that our pseudo-Newtonian method gives better agreement with general relativity than similar methods without a generalized source term.

We find that current detectors are unable to reach the sensitivity to detect gravitational radiation from a glitch phenomena. For both perturbations, strain amplitudes were approximately 10^{-25}. We find that the vortex unpinning model excite the inertial mode more effectively than the star quake model.

1. INTRODUCTION

Neutron stars offer insight into physical states not achievable in any earth based laboratory today. Observations of these exotic stars allow for testing of many modern theories in physics. Unfortunately, their size, distance, and luminosities make it difficult to observe them under most conditions. Fortunately, we can observe neutron stars as pulsars. Neutron stars emit directed radiation along their magnetic axis and, if they are appropriately aligned with Earth, we can observe this radiation as regular pulses due to the rotation of the star.

Pulsars rotate at exceptionally regular rates but are constantly slowing down as they transfer energy to their environment. On occasion, though, pulsars are observed to suddenly speed up without explanation. This increase in rotational velocity if know as a glitch. Since the first pulsar glitch was observed over 100 glitches have been found. Typically, the fractional spin up rates ($\Delta\Omega/\Omega$) of a glitch range from 10^{-9} to 10^{-6} while the largest glitch ever observed had an amplitude of $\sim 3.3\times10^{-5}$(Manchester & Hobbs 2011). Glitches are the result of a sudden internal change of the state of the star and therefore give a unique look into the state of the star. More interestingly, a glitch should excite oscillations within the star which have the potential to emit gravitational radiation.

Observations of gravitational radiation from a glitch would have many benefits scientifically including the possibility of being the very first detection of gravitational radiation. In addition, the state of the star is highly dependent upon the equation of state (EoS) which is largely unknown for extremely dense regions such as those of a neutron star. Therefore, observations of gravitational radiation from pulsar glitches could offer further constraint on the candidates for a neutron star's EoS.

As previously mentioned, the exact mechanism of a pulsar glitch is still widely debated. Currently there exists two major hypotheses. The first is known as the star quake model (Ruderman 1969). In these models the star is treated as two regions, the core and the crust. As the neutron star slows down it adapts a more spherical shape. This model assumes the crust is rigid which causes it to maintain its ellipsoidal shape. The core on the other hand is adapting a spherical shape and is applying pressures on the crust to do the same. When the pressures become great enough, the crust breaks up to become more spherical and the moment of inertia of the star suddenly changes. It is this sudden change in the moment of inertia that leads to the observed change in rotational rate. The second model is vortex unpinning of a superfluid at the crust-core interface (Packard 1972; Anderson and Itoh 1975). The rate at which pulsars slow down is much lower than expected for a rotating normal fluid. For this reason, it is believed that the core of the star is a superfluid. In this model the core is considered a superfluid while the crust is considered a normal fluid. This leads to differential rotation between the core and the crust. Once the difference becomes too great, vortices coupling the core and crust unpin, causing the core to transfer angular momentum to the crust. This transfer of momentum to the crust is the cause of the observed spin up.

The goal of this project is to determine the modes and amplitudes of gravitational radiation resulting from a glitch event. The normal modes of a star can be predicted by linearized methods but these methods cannot predict

which modes are excited nor their amplitudes. Therefore the only realizable method for determining this information is through hydrodynamic simulations. In our simulations we create an equilibrium model of the star, apply a perturbation to mimic the glitch model, then follow the hydrodynamic evolution of the star. We use glitch perturbations that are much larger than real glitch magnitudes because of numerical limitations but use this data to extrapolate to real glitch magnitudes. From this information we can infer the maximum values for observed gravitational waves and the frequencies at which they occur.

This report will give some background on gravitational waves and their detection, information on what we know about pulsar glitches and the popular models for them, discuss the formulation used within our simulations and their validity, and finally predict the characteristic strain amplitudes of gravitational waves we might hope to one day see.

2. GRAVITATIONAL WAVES

In Einstein's theory of general relativity, gravity is considered to be the result of the curvature of spacetime due to mass and energy. Since the curvature is dependent on mass and energy any change in the location or density of mass and energy will result in a change in the curvature of spacetime. As one would expect, these changes propagate out from the source at the speed of light. This fact hints to the existence of gravitational waves. Just like electromagnetic radiation, gravitational waves depend on the acceleration of massive object, but, as gravitation is a much weaker force than the electromagnetic force, gravitational waves have very small amplitudes making them difficult to detect. In addition, due to the conservation of momentum, there can be no mass dipole radiation for gravitation unlike electromagnetic radiation. This means that not only does an object have to be very massive, it cannot be changing symmetrically for it to emit gravitational radiation. In other words, gravitational radiation with any chance of measurement must come from non-symmetric, massive systems. Sources commonly suggested for gravitational wave generation are binary systems consisting of neutron stars or black holes.

2.1. *Detection of Gravitational Radiation*

Since a gravitational wave is an actual fluctuation in the curvature of spacetime, when a wave passes through a portion of space, distances between two locations will appear to rhythmically increase and decrease with amplitudes depending on the gravitational wave. Therefore, to detect gravitational waves, one must detect these fluctuations in distance.

Gravitational radiation detectors must measure very precisely the distance between two points in space. Current detectors are all in the form of a laser interferometer. These interferometers take the form of a Michelson interferometer which splits the incoming laser into two different beams along orthogonal paths that reflect the light back to the splitting point and recombines the beams on the path to the detector. Depending on the path lengths of the split beams the detector will either see constructive or destructive interference. It is usually setup such that a dark fringe is registered at the detector normally, and if a gravitational wave were to pass through the detector, it would fluctuate the path length of the detector arms and break the destructive interference of light at the detector.

In addition, this interferometric setup is better utilized if it is placed in multiple locations. By having the similar systems in different locations it allows for a few different benefits. Firstly, it allows to confirm that a gravitational wave signal is real and not just noise in the system. Since the systems are far enough apart it would be uncommon for them to both be effected by the same transient noise signal at the same time. Also, by having largely seperated locations, the interferometers can time the signals when they start and stop. Due to their spatial seperation, the interferometers should observe the signals at slightly different times and allow for localization of the source of the signal.

In concept is a very simple setup but there are many obstacles that an interferometer must overcome to be able to detect the extremely weak spacetime fluctuations caused by a gravitational wave. The sensitivity of a detector must be so great that every source of noise must be minimized and accounted for if one is to properly detect gravitational waves. These sources of noise include things such as power fluctuation of the laser source, seismic noise, photon pressure on the mirror at the end of each arm, thermal noise, and an incredible number of other sources. Locating and removing these sources of noise is the focus of much gravitational wave detectors today. In fact, one the largest gravitational wave detector project today, LIGO, was commissioned under the assumption that it would be very unlikely for it to detect gravitational waves in its initial state (LIGO). Currently, LIGO is an upgrade phase to Advanced LIGO where scientists believe it will likely be able to detect some of the strongest sources of gravitational radiation. During this pivotal point in time, it is important to consider all possible sources of gravitational radiation, what their signals would look like, and how likely it would be to these signals with current detectors.

3. FORMULATION

The overall goal of our hydrodynamic simulations is to measure how the quadrapole moment of a neutron star evolves after a glitch. Our formalism uses the weak-field metric meaning all special relativistic effects are taken into account while general relativistic effects are ignored. This is done because our simulations evolve gravitation with each time step and solving Einstein's equation that many times would be too computationally expensive. Instead, to increase

our agreement with a full general relativistic solution, we used a generalized source term to Poisson's equation which takes into account all forms of energy instead of just rest mass density. The following outline of our formulation follows that presented in Kim et. al 2009 and Kim et. al 2012.

Our formalism uses the weak field metric in cylindrical coordinates (R,Z,Φ),

$$\begin{aligned} ds^2 &= g_{\mu\nu}dx^\mu dx^\nu \\ &= -(1+2\Phi)dt^2 + (1+2\Phi)^{-1}\delta_{ij}dx^i dx^j \\ &= -(1+2\Phi)dt^2 + \frac{1}{1+2\Phi}(dR^2 + dZ^2 + R^2 d\phi^2) \end{aligned} \tag{1}$$

As mentioned before, we take a single Newtonian gravitational potential:

$$\nabla^2\Phi = 4\pi\rho_{\text{active}}. \tag{2}$$

Where ρ_{active} is known as the active mass density which was first conceived by Tolman (cite) with the form:

$$\rho_{\text{active}} = T - 2T_0^0 \tag{3}$$

Where T is the trace of the stress-energy tensor. In a full general relativistic treatment, the stress-energy tensor describes the density of mass and energy. For this reason it can be considered the source term for gravity in general relativity. By bringing the stress-energy tensor of a perfect fluid into our formalism and treating all forms of energy as the source to our Poisson's equation, we get significantly better agreement with a full general relativistic treatment than just rest mass density as our source term.

As is standard in most numerical simulations we assume our star to be a perfect fluid. This is both for simplicity as viscosity and other effects of a normal fluid becomes too complex as well as the fact that stress energy tensor for a perfect fluid is easily computed:

$$T^{\mu\nu} = \rho_0 h u^\mu u^\nu + P g^{\mu\nu}, \tag{4}$$

where h is the specific enthalpy, u^μ is the four velocity with respect to a Eulerian observer, and P is the pressure. The specific enthalpy takes the form:

$$h = 1 + \epsilon + \frac{P}{\rho_0}, \tag{5}$$

where ϵ is the internal energy. Using this in combination with the stress energy tensor for a perfect fluid we can find the active mass density to be given by:

$$\begin{aligned} \rho_{\text{active}} &= T - 2T_0^0 \\ &= T_i^i - T_0^0 \\ &= \rho_0 h\frac{1+v^2}{1-v^2} + 2P. \end{aligned} \tag{6}$$

We enforce axisymmetry as well as equatorial symmetry. We define the conservative variables (q) and primitive variables (w) as

$$q = \begin{pmatrix} D \\ S_R \\ S_Z \\ S_\phi \\ \tau \end{pmatrix} = \begin{pmatrix} \rho_0 W \\ \rho_0 h W^2 v_R \\ \rho_0 h W^2 v_Z \\ \rho_0 h W^2 v_\phi \\ \rho_0 h W^2 - P - D \end{pmatrix}, \tag{7}$$

$$w = \begin{pmatrix} \rho_0 \\ v^R \\ v^Z \\ v^\phi \\ P \end{pmatrix}, \tag{8}$$

Which just stand for the conservation of mass and angular momentum. Then we can obtain the hydrodynamic equations:

$$\frac{\partial\left(\sqrt{\gamma}q\right)}{\partial t} + \frac{\partial\left(\sqrt{-g}f^R\right)}{\partial R} + \frac{\partial\left(\sqrt{-g}f^Z\right)}{\partial Z} = \sqrt{-g}\Sigma \tag{9}$$

where

$$f^R = \begin{bmatrix} Dv^R \\ S_R v^R + P \\ S_Z v^R \\ S_\phi v^R \\ \tau v^R + P v^R \end{bmatrix} \tag{10}$$

$$f^Z = \begin{bmatrix} Dv^Z \\ S_R v^Z \\ S_Z v^Z + P \\ S_\phi v^Z \\ \tau v^Z + P v^Z \end{bmatrix} \tag{11}$$

$$\Sigma = \begin{bmatrix} 0 \\ -\frac{\rho_{\rm active}}{1+2\Phi}\frac{\partial \Phi}{\partial R} + \frac{S_\phi v^\phi}{R} + \frac{P}{R} \\ -\frac{\rho_{\rm active}}{1+2\Phi}\frac{\partial \Phi}{\partial Z} \\ 0 \\ -\left(S_R \frac{\partial \Phi}{\partial R} + S_Z \frac{\partial \Phi}{\partial Z}\right) \end{bmatrix}. \tag{12}$$

Finally, the gravitational potential in cylindrical coordinates is

$$\frac{1}{R}\frac{\partial}{\partial R}\left(R\frac{\partial \Phi}{\partial R}\right) + \frac{\partial^2 \Phi}{\partial Z^2} = 4\pi \rho_{\rm active}. \tag{13}$$

These hydrodynamic formulas are used to evolve the star after the glitch perturbation using a finite volume where each grid enforces the conservation laws. The follow sections discuss how the initial model of the star is generated and the perturbations to the initial model used to mimic a glitch event.

4. INITIAL MODEL

4.1. *Equilibrium Models of Rotating Stars*

For our simulations we use the Hachisu Self Consistent Field method (HSCF) to generate our initial star (Hachisu 1989a). The HSCF method uses an integral form to the hydrostatic equation instead of directly solving the differential equations. This is more computationally efficient and generates stable star systems. The special feature of Hachisu's method is that instead of using a rotational velocity parameter as a condition to generate the star it uses an axis ratio (r_p/r_e) to define the star. This allows one to define the star by its elliptical shape caused by the rotation. This is a more stable way to calculate a stars equilibrium state than just using a velocity which can be more cumbersome as well as fail in generating a stable star if the velocity condition is insufficient.

In addition to this, to complete our formulation for hydrostatic equilibrium we need a relation for the pressure of the star (the equation of state). The equation of state of a neutron star is a highly sought after quantity in physics. The densities of a neutron star cannot be found anywhere in the universe and are not achievable in any laboratory today. Discovering the equation of state of a neutron star would be a huge achievement in the astronomical physics as well as nuclear physics. Today, most scientists use a piecewise polytropic equation of state while enforcing continuity at the boundaries to model the equation of state of a neutron star. This is primarily because a polytropic equation of state can be tuned to produce stars of the proper mass and radius as a neutron star. In our simulations we assume a simple polytropic equation of state:

$$P = \kappa \rho^{1+\frac{1}{N}} \tag{14}$$

where κ and N are the polytropic coefficient and index respectively. For our simulations we use $\kappa = 100$ and $N = 2$ because they produce stars of the appropriate mass and radius.

In addition to our assumption of a simple polytropic equation of state, we assume that the rotation to be a rigid one. In other words, our stars are not rotating differentially. This is valid because neutron stars must turn to uniform rotation relatively quickly after birth due to shear viscosity and magnetic tensions in the star. Using these two assumptions, the integral form of our equilibrium stars becomes

$$\ln\left[(N+1)\kappa\rho_0^{1/N} + 1\right] + \frac{1}{2}\ln(1+2\Phi) + \frac{1}{2}\ln(1-v^2) = C \tag{15}$$

where C is the integration constant to be found based on boundary conditions. A more complete treatment of the methods used to generate our initial stars can be found in Kim et. al 2009 (Kim et al. 2009).

This report takes a case study of a neutron star with the largest mass ever observed, $2.0M_\odot$, at a distance of 1kpc. Since this represents some of the best known conditions for a pulsar in which glitch induced gravitational radiation, the magnitudes of the characteristic strain amplitudes in this report are higher than would be observed from most known pulsars.

5. GLITCH PERTURBATIONS

Pulsars usually slow down at a very slow and predictable pace as they transfer energy to their environment but occasionally without explanation spin up. These spin ups are known as a glitch and are not at all well understood. The first pulsar glitches were observed in 1969, glitches have been observed in over 30 different pulsars. Even 40 years later, the exact mechanism that causes these events is still under debate. Because it is known that a pulsar glitch is caused by internal mechanism, proving the exact mechanism by which a glitch occurs would give valuable information about the state and properties of pulsars. The following section discusses two major glitch mechanism models: the star quake model and the vortex unpinning at crust-core interface model.

The following subsections discuss the two glitch mechanisms we consider in our simulations and the perturbations we apply to our equilibrium star to model these mechanisms. For both perturbations we consider the effective crust depth to be 10% the radius of the star and ignore all effects of tension and other complex properties the star might have. In addition we hold the conservation laws, the conservation of baryonic mass (M_0) as well as total angular momentum (J):

$$\begin{aligned} M_0 &= \int \rho_0 W dV \\ &= 2\pi \int \frac{\rho_0 W}{(1+2\Phi)^{3/2}} R dR dZ \end{aligned} \tag{16}$$

$$\begin{aligned} J &= \int S_\phi dV \\ &= 2\pi \int \frac{\rho_0 W^2 R^2 \Omega}{(1+2\Phi)^{3/2}} R dR dZ \end{aligned} \tag{17}$$

5.1. *Star Quake Model*

After the first pulsar glitch was observed in 1969 Ruderman developed a mechanism by which a glitch could occur due to a change in the moment of inertia of the star. This model assumes the star to be two components, the crust and the core. The core is assumed to be fluid while the crust has some rigidity to it. As the pulsar slows down it begins to adapt a more spherical shape but since the crust is rigid it resists this change. While this occurs the core is becoming more spherical and is placing stress on the crust. Once the stresses become strong enough the crust is forced to adapt to the core and this causes a change in the moment of inertia of the star. This change in moment of inertia, due to the conversation of angular momentum, causes the star to spin up and we observe a glitch.

This model has been widely explored and it has been found that even just a vertical surface motion of more than a centimeter would generate a glitch magnitude of 10−6. However this model has problems explaining pulsars with multiple glitches in short time periods. It was found by Baym and Pines that a significant amount of energy must be transferred per glitch (cite). So much that it would not be possible for a pulsar to build up enough energy for a glitches to occur in a single pulsar as have been observed. Nevertheless, we consider this mechanism for one of our perturbation for comparison with our second mechanism, vortex unpinning at the crust-core interface.

The above figure shows the perturbation we apply for the star quake model. The stellar surface is shrunken by the asymmetric gaussian formula,

$$\frac{\delta\rho_0}{\rho_0} = \begin{cases} \lambda\ \mathrm{e}^{-\left(\frac{r-c}{\sigma_1}\right)^2} & \text{if } r \le c \\ (1+\lambda)\ \mathrm{e}^{-\left(\frac{r-c}{\sigma_2}\right)^2} - 1 & \text{if } r > c, \end{cases} \tag{18}$$

where $\delta\rho_0$ is the perturbation to the rest mass density, and c is the center of the Gaussian profile, which is not necessarily the crust-core interface. σ_1 and σ_2 represent the width of the Gaussian and are chosen from the conservation of mass. λ is the perturbation magnitude that we apply to the system and should not be confused with the observed glitch magnitude we are simulating. The perturbation to the angular velocity follows from this perturbation by the conservation of angular momentum. From the resulting angular momentum perturbation we measure the simulated glitch magnitude.

5.2. *Vortex Unpinning at the Crust-Core Interface Model*

As the problems with the star quake model were realized, Packard (Packard 1972) and soon after Anderson and Itoh (Anderson & Itoh 1975). Considered if the superfluidity of the core could be responsible for the glitch mechanism. As previously mentioned, the interior of a neutron star is considered to be a superfluid due to the slow rate at which they spin down. Because of this, if the core is considered a superfluid while the crust is a normal fluid, the core can be considered an angular momentum reservoir. The basic consideration of this model is that vortices at the crust-core interface couple the crust and the core. As the star spins down, the crust spins down faster than the core and differential rotation develops. At the point when this difference in velocity becomes too great, the vortices unpin and results in the core transferring momentum to the crust. This transfer causes the observed spin up during a pulsar glitch. This theory is generally the most accepted today but has yet to be set in stone.

The second perturbation, for the vortex unpinning model, gives only a change in rotational velocity while enforcing no perturbation in the mass density:

$$\begin{aligned} \frac{\delta\rho_0}{\rho_0} &= 0, \\ \frac{\delta\Omega}{\Omega} &= \begin{cases} -\lambda_J \ \mathrm{e}^{-\left(\frac{r-c}{\sigma}\right)^2} & \text{if } r \leq c \\ \lambda & \text{if } r > c \end{cases} \end{aligned} \tag{19}$$

In this case, λ is both the perturbation and glitch magnitude since we directly perturb the angular velocity. While λ_J is how much the angular momentum of the interior is reduced, and σ is a fitting parameter. Both values are determined by the conservation laws.

6. RADIAL PULSATION MODE TEST

6.1. *Stellar Pulsation*

To test the validity of our formulation and simulation methods we preformed a radial pulsation mode test. In theory, if our stars are in equilibrium, we should not observe any oscillations within the star. Yet, as with all numerical simulations, there are intrinsic errors that cause the star to oscillate including our resolution, floor values, truncation and limitations in describing the stellar surface (Kim et al. 2012). For this test we generate a stationary (non-rotating), spherical star. All stars have normal modes of oscillation depending on their state and our goal in this test is to compare the radial modes measured in our simulations to another method for generating the normal mode frequencies, linear perturbative analysis.

Although numerical simulations will cause oscillations within our modeled star, we apply a radial perturbation to our system to further excite these modes,

$$\delta\rho_0 = B \sin\left(\pi \frac{r}{r_s}\right). \tag{20}$$

This radial perturbation disturbs the steady, equilibrium state of the star and causes the star to oscillate when we evolve it dynamically. We measure the oscillation of the density in the star by measuring the central density of the star at each time step. These oscillation are usually complex and a superposition of the fundamental mode and its overtones. To analyze which modes are excited we use the standard of all oscillation analysis, Fourier analysis.

6.2. *Fast Fourier Transform*

For our discrete Fourier transform calculation we utilize the Fast Fourier Transform of the West algorithm package(Frigo & Johnson 2005). In addition, we use the zero-padding method to increase our sampling in the frequency domain. This adds no new real information to the transform but merely decreases the sample spacing in the frequency domain so that actual maximums are not missed due to insufficient sampling.

In addition to problems due to sampling we also deal with spectral leakage in the frequency domain by multiplying the time domain series by a window function. Spectral leakage can cause significant error in amplitude and frequency of maximum. In addition, weaker components can be complete washed out by spectral leakage. Fast Fourier transform algorithms assume the time domain sample is periodic in natural. Discontinuities in the time domain require many more sinusoidal frequencies to represent such complex features. These discontinuities resulting from the non-periodic nature of a time domain sample are the source of spectral leakage in the frequency domain. To reduce these errors we apply a window function which suppresses the magnitudes of the discontinuities thereby suppressing the spectral leakage in the frequency domain. Specifically we use the Hamming window function:

$$w_j = 0.54 - 0.46 \cos\left(\frac{2\pi j}{N}\right) \tag{21}$$

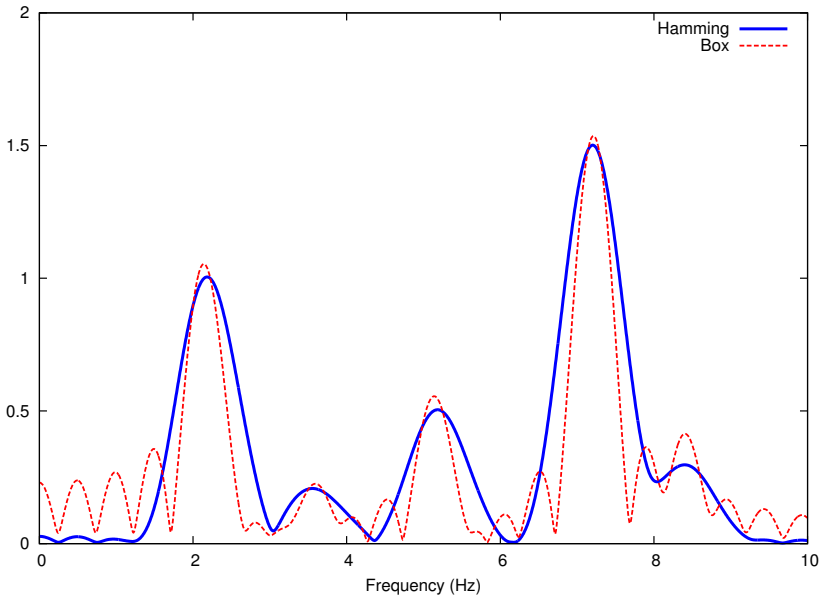

FIG. 1.— This figure shows the effects of a window function on a linear combination of simple sinusoidal waves. The box window is the Fourier transform without any window function. The Hamming window is with a window function modifying the time domain series. It is clear how effectively a window function reduces the error.

Figure one shows the effects of adding a window function to our time domain sample. It is important to note the addition of a window function decreases the overall spectral resolution of sample. So if two modes are located too close to each other, it may be difficult to accurately identify their amplitudes and frequencies.

6.3. *Radial Mode Test Results*

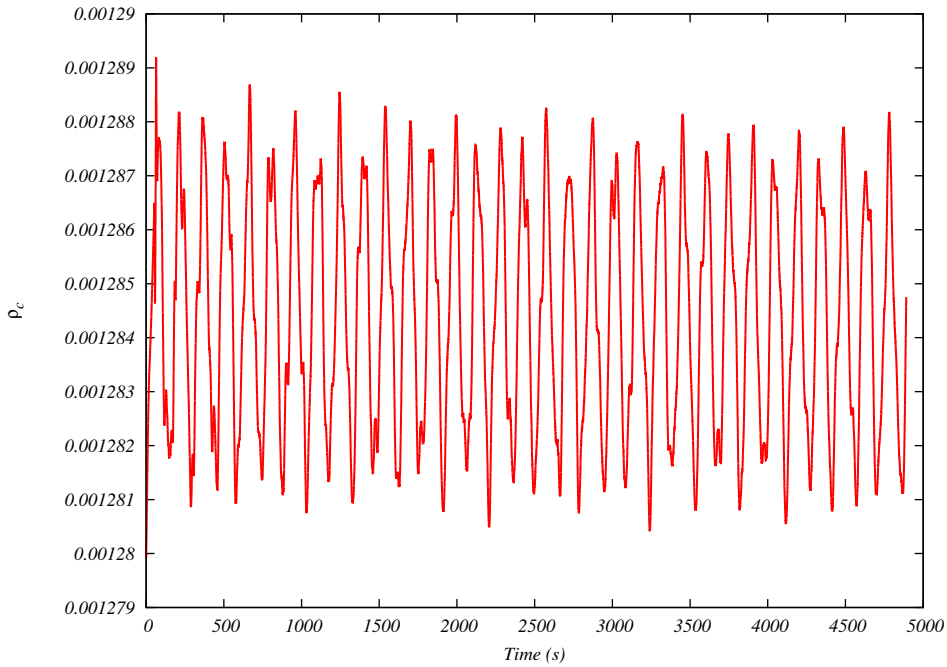

FIG. 2.— The above figure shows the oscillations of the central density of our simulated star in time.

The above figure shows the evolution of the central density of our simulated star in time. The simulation was ran for 100000 time steps to give a strong sample. The central density appears stable over the extent of the run. Below is the Fourier transform of the above central density.

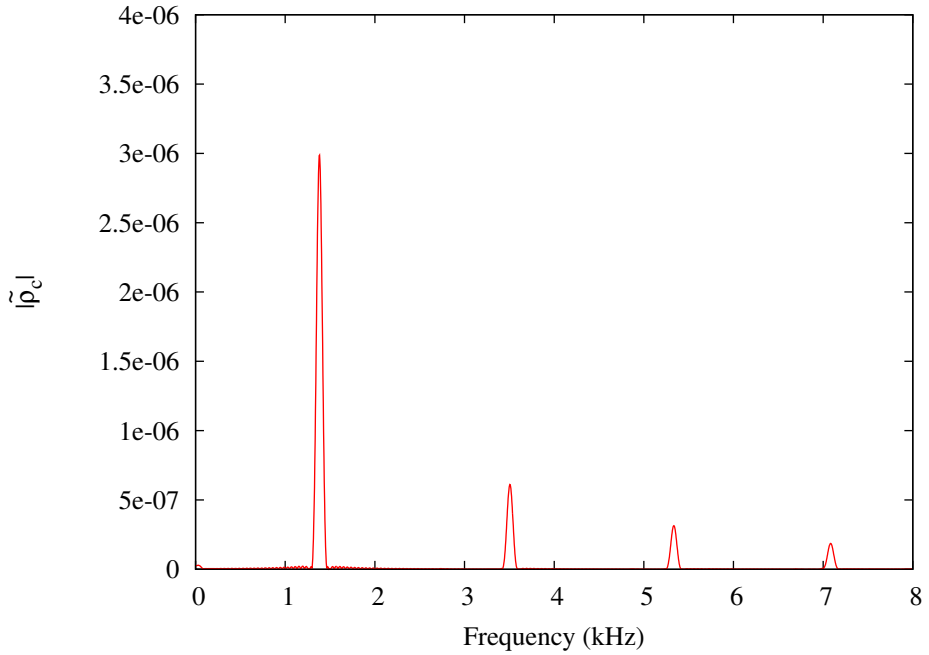

FIG. 3.— The above figure is the Fourier transform of our central density time sample. The transform clearly shows four excited radial modes, the fundamental and its three overtones.

	F	H_1	H_2	H_3
Simulations	1.382	3.505	5.330	7.083
σ	1.383	3.506	5.334	7.083
% Difference	0.07	0.03	0.07	0

The Fourier transform clearly shows four excited modes. We use the change in central density as opposed to the absolute central density so the modes stand out compared to low frequency components. We use a secondary code which utilizes linear perturbative analysis to compare to our simulations results. We find that our results agree very accurately with the linear analysis code.

7. MODE ANALYSIS

The goal of these simulations is to find the modes of gravitational radiation excited by the glitch event. Gravitational waves emitted by the star are related to the quadrapole moment of the star by

$$h_{ij}^{TT} = \frac{d^2 I_{kl}}{dt^2} P_{ik} P_{jl}. \tag{22}$$

Direct differentiation of the quadrapole moment introduces significant error. Instead, we take the Fourier transform of the quadrapole moment which allows us to find the amplitude and frequency of the gravitational radiation at the same time. In this form, the maximum characteristic strain amplitude is

$$h_c = \frac{64\pi^2}{r} f_c^2 \left| \tilde{I}_{xx}(f_c) \right| \tag{23}$$

Therefore, by taking the Fourier transform of quadrapole moment and multiplying by the mode frequency squared we can find the effective amplitude of the gravitational wave modes.

Because real glitch magnitudes are much too small to properly simulate, we run our simulations for many perturbation magnitudes on the same initial model. From this we apply a linear fit to each mode and extrapolate back to real glitch magnitudes. The below plots show the perturbation data used extrapolate back to real magnitudes.

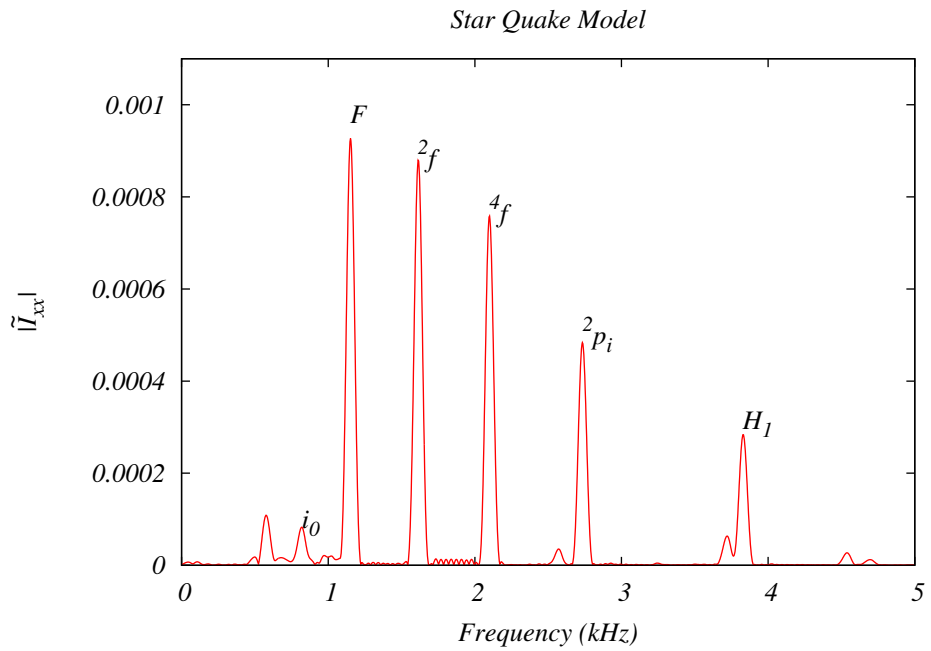

FIG. 4.— This plot is the Fourier transform of the quadrapole moment for a $2.0M_{\odot}$star for perturbation one with λ=0.001. The figure shows the modes excited. Although F and H_1 are radial modes, due to the nonspherical shape of the star they have a large quadrapole moment component.

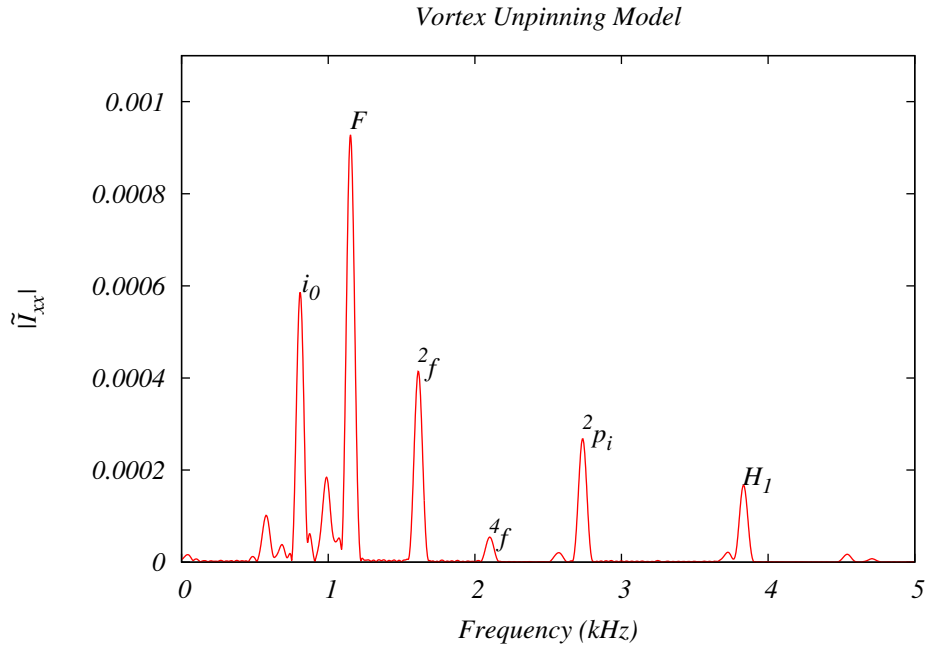

FIG. 5.— This plot is the Fourier transform of the quadrapole moment for a $2.0M_{\odot}$star for perturbation two with λ=0.001. The figure shows the modes excited.An interesting feature of this perturbation is that it highly excites the inertia mode of the star. This mode is known to have a long dampening time which can help increase the detect-ability of the modes.

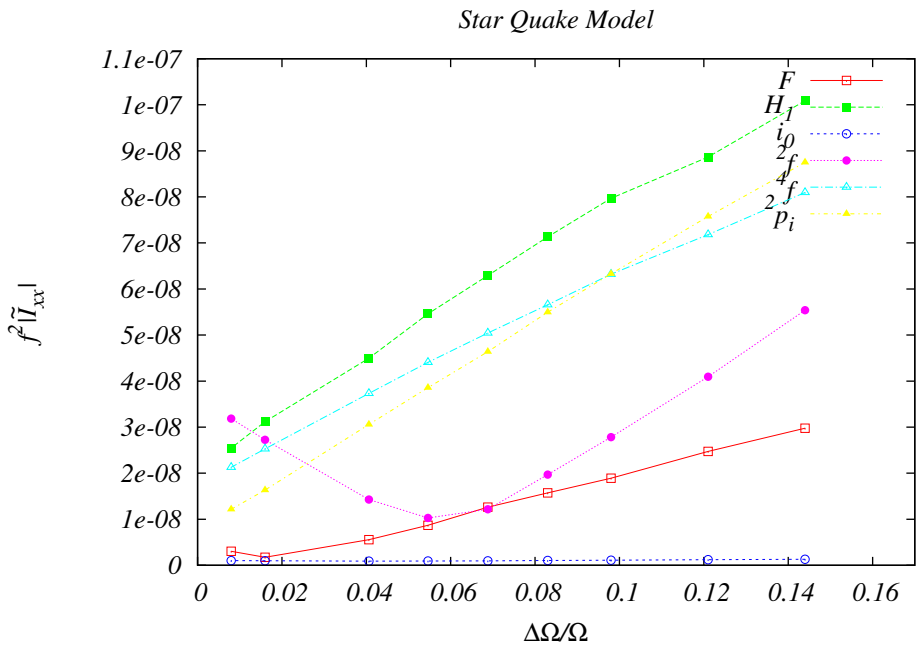

FIG. 6.— This figure shows the effective gravitational wave magnitudes for perturbation one. This data was used to extrapolate back to real glitch magnitudes. The nonphysical behavior exhibited by the ^{2}f mode is most likely caused by numerical errors.

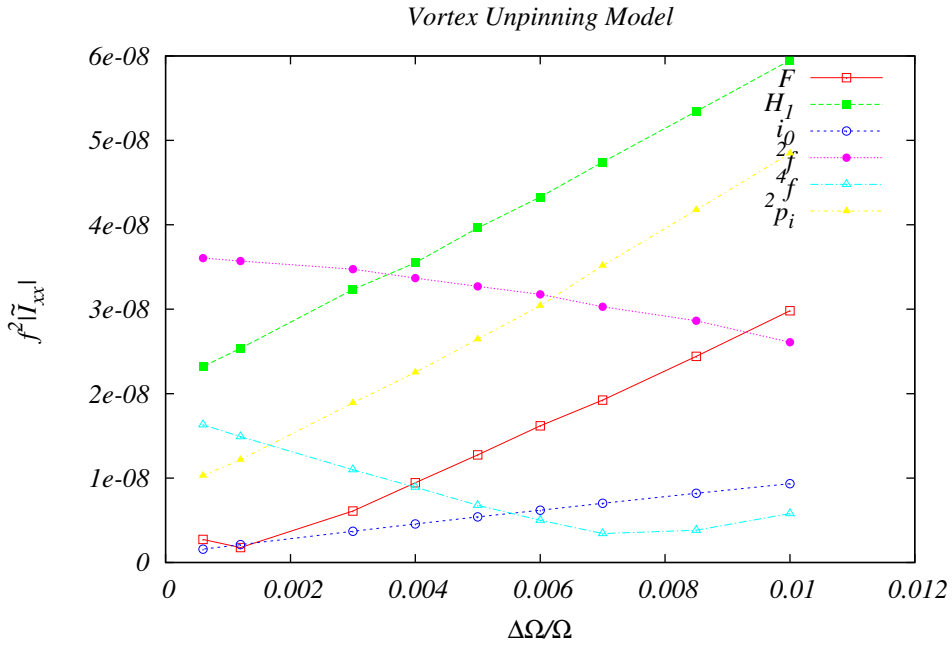

FIG. 7.— This figure shows the effective gravitational wave magnitudes for perturbation two for various glitch magnitudes. We use this data to extrapolate back to realistic glitch magnitudes. The nonphysical behavior of the ^{2}f and ^{4}f mode are currently under investigation.

8. DISCUSSION

	Frequency (kHz)	S.Q.	V.U.
F	1.152	1.11×10^{-27}	1.44×10^{-26}
H_1	3.828	1.10×10^{-24}	1.00×10^{-24}
i_0	0.808	4.20×10^{-26}	6.04×10^{-26}
^2f	1.613	6.58×10^{-25}	1.78×10^{-24}
^4f	2.100	9.12×10^{-25}	7.14×10^{-25}
^2p_i	2.734	3.78×10^{-25}	3.48×10^{-25}

TABLE 1
THE ABOVE TABLE SHOWS THE SUMMARY OF THE FINAL RESULTS FOR THE MAXIMUM CHARACTERISTIC STRAIN AMPLITUDE OF EACH MODE EXCITED BY THE DIFFERENT GLITCH MODELS. THESE VALUES ASSUME A GLITCH AMPLITUDE OF 10^{-5}, A NEUTRON STAR MASS OF $2.0M_\odot$, AND A DISTANCE OF 1 KPC.

Currently, detecting gravitational radiation from a pulsar glitch is very unlikely. The strongest strain amplitude calculated is located in a less sensitive frequency band as well as being an order of magnitude lower than the most sensitive band range of advanced LIGO. Future detectors such as the Einstein Telescope may reach the sensitivity necessary to measure such waves. It is important to reiterate that these strain values are for very good conditions; the highest mass neutron star observed, the highest glitch magnitude observed, and a rather close distance. In addition, we considered the maximum characteristic strain rate which assumes the best orientation of the star to us.

Overall, both perturbations excite the same modes to varying degrees. The vortex unpinning perturbation notably excites the inertial mode of the star which contains the majority of the kinetic energy and is located near the most sensitive frequency range of gravitational wave detectors (aLIGO). The star quake perturbation notably excites the ^4f mode more than the vortex unpinning model. Both perturbations exhibit nonphysical results in the ^4f and ^2f modes. Future work must be done to explain these features if these results are to be considered reputable.

Although the calculated strain amplitudes are below current detector sensitivity, they may be observable in the future depending on their dampening time. For periodic sources, the detection limit is inversely proportional to the observation time. Therefore, if the mode is excited for long enough, the low amplitudes may be overcame by the periodic nature of the signals. Future work could be done to explore dampening and incorporating it into our simulations.

9. ACKNOWLEDGMENTS

I'd like to thank both Bernard Whiting and Guido Mueller for choosing me for this year's IREU program. It was truly a once in a life time experience. I'd like to thank the National Science Foundation for funding such outstanding programs and motivating the next generation to get into science. I'd like to thank Dr. Hyung Mok Lee and Jinho Kim for welcoming me into their research group and helping me along the way. I'd also like to thank Peter Shaffery for being my partner in crime in everything Korean. I don't think I could have done it all without you.

Squeezed quantum states of a harmonic oscillator in the problem of gravitational-wave detection

L. P. Grishchuk and M. V. Sazhin

P. K. Shternberg State Astronomical Institute
(Submitted 13 December 1982)
Zh. Eksp. Teor. Fiz. **84**, 1937–1950 (June 1983)

A quantum harmonic oscillator subjected to a resonant force action and to a parametric action is considered. Account is taken of the coupling of the oscillator with the thermostat (and with the zero-point oscillations). Explicit solutions of the Heisenberg equations are obtained for the creation and annihilation operators. Various methods of producing squeezed states in the oscillator are considered, and the most suitable for the registration of a weak (gravitational) force are chosen. Concrete estimates are obtained of the improvement of the sensitivity through the use of squeezed states and are obtained. The advantages and shortcomings of the squeezed-states technique and of quantum nondemolition measurements are compared. Possible uses of the squeezed-states technique are discussed.

PACS numbers: 03.65.Ge, 04.80. + z

The expected gravitational-wave signals of cosmic or laboratory origin are so weak that an analysis of detection properties with allowance for their quantum-mechanical character has become urgently necessary.[1] The usual observation criterion is taken to be an excess of the signal S over the noise N, i.e., $S/N \gtrsim 1$. Even if the thermal noise is neglected and there are no other imperfections in the detecting apparatus, a contribution to the noise is made by the quantum-mechanical variance of the measured quantity. A recent analysis of the so-called quantum nondemolition measurements (QND) consists precisely of a demonstration that for certain observable quantities (Hermitian operators) the variance can be made equal to zero and remains equal to zero, despite the action of the signal that leads to a change in the average value of the measured quantity. It assumed that the vanishing of the variance is due to the act of the first measurement. The successive continuous tracking of the measured quantities does not change its variance, since the quantity is QND-variable. In this idealized case the sensitivity of the detector is formally equal to infinity. The corresponding Hermitian operators, suitable for nondemolition measurement of a force F or of parametric action P were respectively named QNDF (Ref. 2) and QNDP operators (Ref. 3).

The studies of this subject have the following shortcomings. First, as a rule, they have ignored the presence of thermal noise, i.e., no account was taken of the fact that the variance of the QND variable, even when equal to zero at the initial instant of time, must inevitably increase with time because of the interaction of the oscillator with the thermostat. Second, it is not quite clear how to realize in practice instruments corresponding to the rather abstract QNDF and QNDP operators.

In the present paper we change somewhat the approach of the problem. We start from the fact that what is measured is a well defined quantity, not necessarily QND-variable. Such a quantity can be, e.g., the energy. As for the decrease of the noise N, i.e., of the variance of the measured quantity and (or) of the amplification of the signal S, i.e., the response of the detector to an external action, these are reached by a special "preparation" of the quantum state of the oscillator with the aid of really existing laboratory devices. We consider concretely the development and use of what are called squeezed states. Thus, an arriving gravitational signal interacts with an oscillator that is in a squeezed state and not, say, in an n-quantum or coherent state.

In quantum theory of light, squeezed states are known as "two-proton coherent states" and under other names.[4] In connection with detection of gravitational waves, squeezed states were considered by Caves,[5] who has shown that their use makes it possible to increase the sensitivity of a laser interferometer without increasing the laser power. It was also noted[6] that the use of squeezed states is promising in laboratory gravitation-wave experiments.

In the present paper we take consistent account of the connection between the oscillator and the thermostat. This enables us, in particular to generalize the theory of QND measurements to include the case of the presence of thermal noise and to compare the results with the method proposed here of using squeezed states.

§1. FUNDAMENTAL EQUATIONS AND THEIR SOLUTION

An arbitrary harmonic oscillator, mechanical or electrostatic, will be described in standard fashion with the aid of the creation and annihilation operators:

$$a^+=\left(\frac{m\omega}{2\hbar}\right)^{1/2}\left(\hat{q}-i\frac{\hat{p}}{m\omega}\right), \quad a=\left(\frac{m\omega}{2\hbar}\right)^{1/2}\left(q+i\frac{\hat{p}}{m\omega}\right),$$

$$[a, a^+]=1.$$

It is convenient also to introduce the operators X_1 and X_2 of the complex amplitude of the oscillator, in accordance with the definition

$$X_1=l(e^{-i\omega t}a^+ + e^{i\omega t}a), \quad X_2=il(e^{-i\omega t}a^+ - e^{i\omega t}a),$$

where $l=(\hbar/2m\omega)^{1/2}$.

It is known that a coherent state $|\alpha\rangle \equiv D(\alpha)|0\rangle$ is defined with the aid of the displacement operator

 0038-5646/83/061128-08$04.00 © 1984 American Institute of Physics

$D(\alpha)=\exp(\alpha a^+ - \alpha^* a)$, where α is a complex number. Participating in the construction of the squeezed state $|\alpha,\beta\rangle \equiv D(\alpha)S(\beta)|0\rangle$ is also the squeezing operator

$$S(\beta)=\exp\left[{}^1/_2(\beta^* a^2-\beta a^{+2})\right],$$

where β is a complex number. A squeezed state is thus characterized by two complex numbers.

A coherent state results from the vacuum state $|0\rangle$ under the influence of a force, i.e., on account of a term of the type $F(t)(a+a^+)$ in the Hamiltonian. One of the possible methods of obtaining a squeezed state is the use of a degenerate parametric amplifier,[4,7] i.e., of a term of the type $P(t)(a^{+2}+a^2)$ in the Hamiltonian. If the parametric pumping is effected at the frequency 2ω and is of the form

$$P(t)=|p|\sin(2\omega t+\psi),$$

the term of interest to us in the Hamiltonian can be rewritten in the form

$$P(t)\,(a^2+a^{+2})$$

$$=\frac{1}{2i}(pe^{i2\omega t}a^{+2}-p^*e^{-i2\omega t}a^{+2}+pe^{i2\omega t}a^2-p^*e^{-i2\omega t}a^2), \qquad (1)$$

$$p=|p|e^{i\psi}$$

inasmuch as for free evolution of the oscillator we have

$$a(t)=a(0)\,e^{-i\omega t} \text{ and } a^+(t)=a^+(0)\,e^{i\omega t}.$$

The first and fourth terms in (1) are rapidly oscillating and can be neglected compared with the resonant, second and third, terms. Similarly, retaining only the terms resonant at the frequency ω, the force term in the Hamiltonian can be written in the form

$$F(t)\,(a+a^+)=fe^{-i\omega t}a^+ + f^*e^{i\omega t}a, \qquad f=|f|e^{i\varphi}.$$

We shall thus work with a Hamiltonian

$$H=\hbar\omega a^+a+{}^1/_2 ik\omega\,(p^*e^{i2\omega t}a^2-pe^{-i2\omega t}a^{+2})$$
$$+\hbar\omega\,(fe^{-i\omega t}a^+ + f^*e^{i\omega t}a), \qquad (2)$$

where p and f are arbitrary complex numbers.

We note that the Hamiltonian (2) is among those that describe resonant action of a gravitational wave on a mode of the electromagnetic oscillations in the resonator.[3] To be sure, in the case of a gravitational signal the coupling constants $|p_g|$ and $|f_g|$ are determined by the amplitude of a gravitational wave h and are quite small under real conditions, whereas the coupling constants with laboratory generators, $|p_l|$ and $|f_l|$, depend to a considerable degree on the experimenter. In the general case, it can be assumed that $p=p_l+p_g$ and $f=f_l+f_g$, but hereafter we shall deal for simplicity only with estimates of observing a gravitational force and therefore put $p_g=0$ and $f_g\neq 0$.

The interaction of an oscillator with the thermostat can be described by adding to the Heisenberg equations of motion the term that takes the damping into account, and the operator of the random force (see, e.g., Ref. 8):

$$i\hbar\frac{da}{dt}=[a,H]-i\hbar\frac{\gamma}{2}a+i\hbar\theta. \qquad (3)$$

The constant $\gamma>0$ is connected with the relaxation time τ^* by the relation $\gamma^{-1}=\tau^*$. The random-force operator $\theta(t)$ satisfies the commutation relation $[\theta(t),\theta^+(t')]=\gamma\delta(t-t')$. The equation for a^+ is obtained from (3) by Hermitian conjugation.

Substituting in (3) the Hamiltonian (2) we obtain the equations of motion in explicit form

$$\frac{da}{dt}=-i\omega a-\omega pa^+e^{-i2\omega t}-i\omega fe^{-i\omega t}-\frac{\gamma}{2}a+\theta,$$
$$\frac{da^+}{dt}=i\omega a^+-\omega p^*ae^{i2\omega t}+i\omega f^*e^{i\omega t}-\frac{\gamma}{2}a^++\theta^+.$$

To solve them it is convenient to eliminate the free evolution by using the substitution

$$a(t)=e^{-i\omega t}e^{-\gamma t/2}A(t), \qquad a^+(t)=e^{i\omega t}e^{-\gamma t/2}A^+(t)$$

and carry out the Bogolyubov transformation

$$b(t)=e^{-i\psi/2}\operatorname{ch} rtA(t)+e^{i\psi/2}\operatorname{sh} rtA^+(t),$$
$$b^+(t)=e^{i\psi/2}\operatorname{ch} rtA^+(t)+e^{-i\psi/2}\operatorname{sh} rtA(t),$$

where $r=|p|\omega$. We then obtain for $b(t)$ the simple equation

$$db/dt=-i\omega e^{\gamma t/2}(f\operatorname{ch} rte^{-i\psi/2}-f^*\operatorname{sh} rte^{i\psi/2})$$
$$+e^{\gamma t/2}(e^{i(\omega t-\psi/2)}\operatorname{ch} rt\theta+e^{-i(\omega t-\psi/2)}\operatorname{sh} rt\theta^+).$$

The final solution for $a(t)$ is

$$a(t)=e^{-i\omega t}e^{-\gamma t/2}[m(t)+\Phi(t)+T(t)], \qquad (4)$$

where

$$m(t)=a_0\operatorname{ch} rt-a_0^+e^{i\psi}\operatorname{sh} rt,$$

$$\Phi(t)=-i\omega\int_0^t e^{\gamma\tau/2}[f\operatorname{ch} r(\tau-t)-f^*e^{i\psi}\operatorname{sh} r(\tau-t)]\,d\tau,$$

$$T(t)$$

$$=\int_0^t e^{\gamma\tau/2}[\theta(\tau)e^{i\omega\tau}\operatorname{ch} r(\tau-t)+\theta^+(\tau)e^{-i(\omega\tau-\psi)}\operatorname{sh} r(\tau-t)]\,d\tau.$$

An expression for $a^+(t)$ is obtained from (4) by Hermitian conjugation.

To calculate the mean values and the variances it is necessary to average using the density matrix. The complete oscillator + thermostat system is described by the direct product of the oscillator density matrix ρ and the thermostat density matrix ρ_T. The averaging of the operator $\theta(t)$ has the following properties[8] (the angle brackets $\langle\ \rangle$ denote averaging over the total density matrix, but the operator θ is in fact averaged over ρ_T):

$$\langle\theta(t)\rangle=\langle\theta^+(t)\rangle=0, \qquad \langle\theta^+(t)\theta(t')\rangle=\gamma n_\tau\delta(t-t'),$$
$$\langle\theta(t)\theta^+(t')\rangle=\gamma(n_\tau+1)\delta(t-t').$$

Here n_T is the average number of quanta in the thermostat at the frequency ω:

$n_T=[e^{\hbar\omega/kT}-1]^{-1}$.

The binary terms containing θ^2 and θ^{+2} yield zero on averaging.

When calculating the variance of the quantum-number operator $n=a^+a$ in the oscillator, use is made of fourth-order moments. Assuming that θ and θ^+ have Gaussian distributions, they reduce to second-order moments in accordance with the expansion[9]:

$$\langle\theta(t_1)\theta^+(t_2)\theta(t_3)\theta^+(t_4)\rangle=\langle\theta(t_1)\theta^+(t_2)\rangle\langle\theta(t_3)\theta^+(t_4)\rangle+\langle\theta(t_1)\theta^+(t_4)\rangle\langle\theta^+(t_2)\theta(t_3)\rangle.$$

We present expressions for the mean values of the operators X_1, X_2, and n and their variances, but do not specify concretely for the time being the initial value of the oscillator density matrix:

$$\langle X_1(t)\rangle=e^{-\gamma t/2}[(\operatorname{ch}rt-\cos\psi\operatorname{sh}rt)\langle X_1(0)\rangle-\sin\psi\operatorname{sh}rt\langle X_2(0)\rangle+l(\Phi(t)+\Phi^*(t)], \tag{5}$$

$$\langle X_2(t)\rangle=e^{-\gamma t/2}[(\operatorname{ch}rt+\cos\psi\operatorname{sh}rt)\langle X_2(0)\rangle-\sin\psi\operatorname{sh}rt\langle X_1(0)\rangle+il(\Phi^*(t)-\Phi(t))], \tag{6}$$

$$\langle n(t)\rangle=e^{-\gamma t}[\langle m^+(t)m(t)\rangle+\Phi(t)\langle m^+(t)\rangle+\Phi^*(t)\langle m(t)\rangle+|\Phi(t)|^2+\langle T^+T\rangle]. \tag{7}$$

We note that at $\sin\psi=0$ the mean values of X_1 and X_2 do not depend on the initial mean values X_2 and X_1, respectively.

We write down the variances of X_1 and X_2 by means of a single formula, in which the upper sign pertains to δX_1^2 and the lower to δX_2^2:

$$\delta X_{1,2}^2=\langle X_{1,2}^2\rangle-\langle X_{1,2}\rangle^2=e^{-\gamma t}[(\operatorname{ch}rt\mp\cos\psi\operatorname{sh}rt)^2\times\delta X_{1,2}^2(0)+\sin^2\psi\operatorname{sh}^2rt\,\delta X_{2,1}^2(0)-\sin\psi\operatorname{sh}rt(\operatorname{ch}rt\mp\cos\psi\operatorname{sh}rt)K(0)+l^2(\pm\langle T^+T^+\rangle\pm\langle TT\rangle+\langle T^+T\rangle+\langle TT^+\rangle)], \tag{8}$$

$$K(0)=\langle X_1(0)X_2(0)\rangle+\langle X_2(0)X_1(0)\rangle-2\langle X_1(0)\rangle\langle X_2(0)\rangle.$$

It can be seen that the variances δX_1^2 and δX_2^2 do not depend on the acting force. For the variance of the number of quanta we have the general formula

$$\begin{aligned}e^{2\gamma t}\delta n^2(t)=&[\langle(m^+m)^2\rangle-\langle m^+m\rangle^2]+\Phi[\langle m^+mm^++m^{+2}m\rangle-2\langle m^+\rangle\langle m^+m\rangle]+\Phi^*[\langle mm^+m+m^+m^2\rangle-2\langle m^+m\rangle\langle m\rangle]\\&+\Phi^2[\langle m^{+2}\rangle-\langle m^+\rangle^2]+\Phi^{*2}[\langle m^2\rangle-\langle m\rangle^2]\\&+|\Phi|^2[\langle m^+m+mm^+\rangle-2\langle m\rangle\langle m^+\rangle]+\langle T^2\rangle[\langle m^{+2}\rangle+2\Phi^*\langle m^+\rangle+\Phi^{*2}]+\langle T^{+2}\rangle[\langle m^2\rangle+2\Phi\langle m\rangle+\Phi^2]\\&+\langle TT^+\rangle[\langle m^+m\rangle+\Phi\langle m^+\rangle+\Phi^*\langle m\rangle+|\Phi|^2]\\&+\langle T^+T\rangle[\langle mm^+\rangle+\Phi\langle m^+\rangle+\Phi^*\langle m\rangle+|\Phi|^2]\\&+\langle(T^+T)^2\rangle-\langle T^+T\rangle^2.\end{aligned} \tag{9}$$

Expressions for the mean values containing products of T and T^+ are given in the Appendix.

If at the initial instant of time $t=0$ the oscillator was at equilibrium with the thermostat, it is described by the density matrix

$$\rho=[1-\exp(-\hbar\omega/kT)]\sum_{n=0}^{\infty}e^{-n\hbar\omega/kT}|n\rangle\langle n|,$$

and then

$$\langle X_1(0)\rangle=\langle X_2(0)\rangle=K(0)=0,\quad n(0)=n_T,$$
$$\delta X_1^2(0)=\delta X_2^2(0)=l^2(2n_T+1),\quad \delta n^2(0)=n_T(n_T+1).$$

Expressions for the mean values and the variances that arise under the action of f and p on an equilibrium oscillator are given in the Appendix.

Different aspects of the behavior of an oscillator in a thermostat under the action of a force and (or) parametric pumping were analyzed in Refs. 10 and 11.

§2. PRODUCTION OF SQUEEZED STATES

A decrease (squeezing) of the variance of the operator X_1 or X_2 is reached by a special choice of the phase ψ of the parametric generator. Assume that at $t=0$ the oscillator was in thermodynamic equilibrium with the thermostat. We put $\psi=0$. It follows then from (A3) that

$$\begin{aligned}\delta X_1^2(t)&=l^2(2n_T+1)(\gamma+2r)^{-1}(\gamma+2re^{-(\gamma+2r)t}),\\\delta X_2^2(t)&=l^2(2n_T+1)(\gamma-2r)^{-1}(\gamma-2re^{-(\gamma-2r)t}),\end{aligned} \tag{10}$$

i.e., in the variance of X_1 decreases with time, and the variance of X_2 increases, compared with the equilibrium value (we assume for the sake that $r>0$). The maximum squeezing of the variance of X_1 as $t\to\infty$ is always finite, and the equilibrium value $\delta X_1^2(0)$ decreases by a factor $\gamma/(\gamma+2r)$:

$$\delta X_1^2(t\to\infty)=l^2(2n_T+1)[\gamma/(\gamma+2r)]. \tag{11}$$

The increase of the variance of X_2 is finite if $2r<\gamma$, and increases exponentially with time if $2r>\gamma$. If the phase $\psi=\pi$ is chosen, the variances of X_1 and X_2 interchange roles (in (10) this is equivalent to replacing r by $-r$). At arbitrary ψ, the operators Y_1 and Y_2, which are certain linear combinations of X_1 and X_2, are subject to squeezing and to dilatation.

At arbitrary $2r\gg\gamma$, squeezing of the variance of X_1 to a value that practically reaches the limit takes place within a characteristic time

$$t_c=(2r)^{-1}\ln(2r/\gamma)\ll\gamma^{-1}.$$

Considerable squeezing is possible only at $2r$ comparable with γ or exceeding γ, and we shall therefore consider hereafter the cases $2r=\gamma$ and $2r\gg\gamma$.

The upper bound of the parameter $2r$ is 2ω. At this value $|p|=1$ and the Hamiltonian (2) would no longer be positive-definite. Consequently the oscillator would become unstable and the region of permissible values of the oscillator energy would range from $-\infty$ to $+\infty$.

As already noted, the variances of the operators X_1 and X_2 depend on the parameter r but not on f. The force enters only into the law that governs the mean values of X_1 and X_2. At $\psi=0$, as follows from (A.10), we obtain

$$\begin{aligned}\langle X_1(t)\rangle&=4l|f|\frac{\omega}{\gamma+2r}\sin\varphi[1-e^{-(r+\gamma/2)t}],\\\langle X_2(t)\rangle&=-4l|f|\frac{\omega}{\gamma-2r}\cos\varphi[1-e^{(r-\gamma/2)t}].\end{aligned} \tag{12}$$

We now turn to the mean value and to the variance of the number of quanta. Under a force generator and a parametric generator act jointly on an oscillator placed in a thermostat, $n(t)$ and $\delta n^2(t)$ vary in accordance with Eqs. (A2) and (A4). In contrast to δX_1^2 and δX_2^2, the variance δn^2 depends on f, so that the force increases not only n but also δn^2.

To observe a weak force (e.g., a gravitational wave) it is desirable to create states with low variance and with large number of the quanta. Large $\langle n(t)\rangle$ is desirable because in a squeezed state, just as in a coherent one, the response of the oscillator, i.e., the change Δn of the number of quanta under the action of the signal, increases in proportion to the square root of the number of quanta contained in the oscillator. Relegating the proof of this statement and a detailed analysis of the detection criteria to §3, we discuss the conditions under which the squeezing, i.e., the use of a parametric generator with $r\neq 0$, makes it possible to decrease the ratio $\delta n/n^{1/2}$ in the oscillator.

It can be seen from (A2) and (A4) that were we to have $r=0$ i.e., if a coherent state (plus thermal noise) were produced in the oscillator under the influence of a laboratory force, we would have by the instant of time $t=t_1$

$$\langle n(t_1)\rangle = n_T + |\alpha|^2, \tag{13}$$

$$\delta n^2(t_1) = n_T(n_T+1) + (2n_T+1)|\alpha|^2, \tag{14}$$

where

$$\alpha = (2\omega|f|/\gamma)(1-e^{-\gamma t/2})e^{i(\varphi-\pi/2)}.$$

The parameter α defines also the mean values of X_1 and X_2:

$$\langle X_1\rangle + i\langle X_2\rangle = 2l\alpha.$$

It can be seen therefore that even within a time exceeding the relaxation time $\tau^* = \gamma^{-1}$ it is impossible to obtain a better result than

$$\delta n/n^{1/2} \approx (2n_T+1)^{1/2}.$$

This quantity does not differ in practice from the equilibrium value

$$\delta n/n^{1/2} = (n_T+1)^{1/2}.$$

If, however, $r\neq 0$, the choice of the phase shift $\varphi - \psi/2$ becomes important. For the choice $\cos(\varphi-\psi/2)=0$ and under the assumption $2r\gg\gamma$, the joint action of the force and parametric generators during the time

$$t \gtrsim t_c = (2r)^{-1}\ln(2r/\gamma)$$

leads to

$$n(t_c) \approx \frac{|f|^2}{|p|^2}, \quad \delta n^2(t_c) \approx (2n_T+1)\frac{|f|^2}{|p|^2}\frac{\gamma}{2r}.$$

It was assumed here in the calculation that the deviation from the equilibrium state is appreciable, i.e., the terms containing $|f|$ predominate, and, concretely,

$$|f|^2/|p|^2 \gg (2n_T+1)(2r/\gamma)^3.$$

As a result we obtain a squeezed state with a value

$$\delta n/n^{1/2} \approx (2n_T+1)^{1/2}(\gamma/2r)^{1/2}, \tag{15}$$

which is better by a factor $(\gamma/2r)^{1/2}$ than in the coherent state. The obtained squeezed state can be used to record a weak force within a time interval that is short compared with τ^*, i.e., small compared with the decay time of this state.

Large deviations in the choice of the parameters used in the derivation of (15) make this estimate worse. The choice of the phase $\cos(\varphi-\psi/2)=0$ when considering $\langle n(t)\rangle$ and δn^2 follows the same purpose as the choice of the phases $\psi=0$ and $\cos\varphi=0$ when considering the most effective decrease of $\delta X_1^2(t)$ and the most effective increase of $\langle X_1(t)\rangle$.

In the derivation of (15) it was assumed that the force and parametric generators act jointly during the characteristic squeezing time t_c. A longer action of the generators is not advantageous, since it leads to dominance of terms that do not contain $|f|$, and then

$$\delta n/n^{1/2} \approx (2n_T+1)^{1/2}\exp[(r-\gamma/2)t].$$

At the same time, after a short time t_c the average number of the quanta does not increase strongly enough to permit it to grow under the influence of only the force generator in a time $\tau^* \gtrsim t \gg t_c$. Indeed, at $t\approx\tau^*$ we have

$$|\alpha|^2 \approx \frac{4\omega^2|f|^2}{\gamma^2} = \frac{|f|^2}{|p|^2}\left(\frac{2r}{\gamma}\right)^2 \gg \frac{|f|^2}{|p|^2}.$$

Under the experimental conditions it may be desirable to increase the oscillator response Δn that is proportional to the initial $\sqrt{n}$, with the preservation of the condition (15).

It is possible to obtain the same estimate (15), but with larger n, if the force and parametric generators act separately and in succession. The idea is to produce first with the aid of the force generator a large $\langle n(t)\rangle$, and then turn off the force action and turn on the parametric action. Then, at a suitable choice of the phases, after a short squeezing time t_c the variance δn^2 decreases strongly, and $\langle n(t)\rangle$ does not change so much within the same time.

Let us consider the proposed method in greater detail. Assume that an oscillator in equilibrium with the thermostat is acted upon by a force during a time t_1. Then by the instant t_1 we have

$$a(t_1) = e^{-i\omega t_1}e^{-\gamma t_1/2}[a_0 + \Phi(t_1) + T(t_1)]$$

and the Hermitian-adjoint expression for $a^+(t_1)$. The values of $\langle n(t_1)\rangle$ and $\delta n^2(t_1)$ are determined by Eqs. (13) and (14). At the instant t_1 the force is turned off and r is turned on. The subsequent evolution of the oscillator can be calculated from the general formulas (7) and (9) with the already known initial data. In this case $\Phi\equiv 0$ and it is convenient to reckon the time from the instant $t=t_1$. We then obtain for $\langle n(t)\rangle$

$$\langle n(t)\rangle = e^{-\gamma t}|\alpha|^2[\operatorname{ch} 2rt - \operatorname{sh} 2rt\cos(\psi-2\varphi_1)] + n_0,$$

where $\varphi_1 = \varphi - \omega t_1 - \pi/2$ and the term n_0 stands for expression (A2) in which we must put $|\Phi|^2=0$. For $\delta n^2(t)$, using the notation of the Appendix, we can obtain

$$\begin{aligned} e^{2\gamma t}\delta n^2(t) &= n_T(n_T+1)\operatorname{ch} 4rt \\ &+ |\alpha|^2(2n_T+1)[\operatorname{ch} 4rt - \operatorname{sh} 4rt\cos(\psi-2\varphi_1)] \\ &+ {}^1/_2\gamma|\alpha|^2(2n_T+1)\{e^{2rt}[1-\cos(2\varphi_1-\psi)](I_c-I_s) \\ &+ e^{-2rt}[1+\cos(\psi-2\varphi_1)](I_c+I_s)\} \\ &+ {}^1/_2[\operatorname{sh}^2 2rt - e^{\gamma t} + 1 + \gamma(2n_T+1)^2(I_c\operatorname{ch} 2rt - I_s\operatorname{sh} 2rt)]. \end{aligned}$$

The principal growing terms in $\langle n(t)\rangle$ and $\delta n^2(t)$ are eliminated by choosing the phase $\cos(2\varphi_1 - \psi) = 1$. We assume also that $2r \gg \gamma$ and

$$|\alpha|^2 \gg [n_T(n_T+1)/(2n_T+1)](2r/\gamma)^{1/2}.$$

By the instant of time t_c we then have

$$n(t_c) \approx |\alpha|^2 \frac{\gamma}{2r}, \quad \delta n^2(n_1, t_c) \approx |\alpha|^2 (2n_T+1) \left(\frac{\gamma}{2r}\right)^2, \quad (16)$$

i.e., $\delta n/\langle n\rangle^{-1/2}$ we return to Eq. (15) for, but now we have $n(t_c)$ larger by $2r/\gamma$ times than the value of n reached in the variant with joint action of f and r. We note that by that instant of time the average values of the operators a and a^+ are equal, apart from a phase factor, to the quantity $|\alpha|(\gamma/2r)^{-1/2}$, i.e., to $\langle n\rangle^{-1/2}$.

Worthy of special consideration is the case $2r = \gamma$. In Eqs. (12) and (10) for $\langle X_1(t)\rangle$ and $\delta X_1^2(t)$ this case is not at all remarkable, but in the expressions for $\langle X_2(t)\rangle$ and $\delta X_2^2(t)$ it leads to a singularity:

$$\langle X_2(t)\rangle = -2l|f|\omega t \cos\varphi \quad \delta X_2^2(t) = l^2(2n_T+1)(1+\gamma t). \quad (17)$$

If the experimenter can use time intervals that are long compared with the relaxation time, then at $t \gg \gamma^{-1}$ we can obtain (at $\cos\varphi = -1$)

$$\delta X_2/X_2 \approx [(2n_T+1)^{1/2}/2|f|\omega](\gamma/t)^{1/2},$$

i.e., $\delta X_2/X_2 \to 0$ at $t \to \infty$. We note that at $2r \gg \gamma$ and $t \to \infty$ we would obtain a nonvanishing and rather large quantity

$$\delta X_2/X_2 = (2n_T+1)^{1/2}(r/2|f|\omega).$$

For $\langle n(t)\rangle$ and $\delta n^2(t)$ at $2r = \gamma$, $\cos(\varphi - \psi/2) = \pm 1$ and $\gamma t \gg 1$ we have from (A2) and (A4)

$$\langle n(t)\rangle \approx |f|^2\omega^2 t^2, \quad \delta n^2 \approx (2n_T+1)|f|^2\omega^2\gamma t^3. \quad (18)$$

As will be shown in §3, the case $2r = \gamma$ can be used to improve the sensitivity if the signal can be accumulated during many relaxation times.

The variance δn of the number of quanta must be set in correspondence with the variance $\delta\hat{\varphi}$ of the phase operator, even though this operator is known to be defined subject to some stipulations. We present nevertheless illustrative arguments from which it can be seen that in squeezed states a decrease of δn is accompanied by an increase of $\delta\hat{\varphi}$ and an increase of δn is accompanied by a decrease of $\delta\hat{\varphi}$. We consider first coherent states. On a plane with coordinates $\langle X_1\rangle$ and $\langle X_2\rangle$ the coherent state $|\alpha\rangle$ is mapped by a circle with center at the points $2l\alpha$ in accordance with the equation $\langle X_1\rangle + i\langle X_2\rangle = 2l\alpha$. The diameter of the circle is determined by the variance $\delta X_1 = \delta X_2 = l(2n_T + 1)^{1/2}$. The uncertainty of the number of quanta at

$$|\alpha|^2(2n_T+1) \gg n_T(n_T+1)$$

is $\delta n \approx (2n_T + 1)^{1/2}|\alpha|$, i.e., $\delta n = S(m\omega/2\pi\hbar)$, where S is the area of a ring made up by rotating the circle around the origin (see Fig. 1). The phase uncertainty $\delta\hat{\varphi}$ is expressed in terms of the (doubled) angle from which the diameter is seen from the origin, so that

$$\delta\hat{\varphi} \approx (2n_T+1)^{1/2}/|\alpha|.$$

As a result we obtain

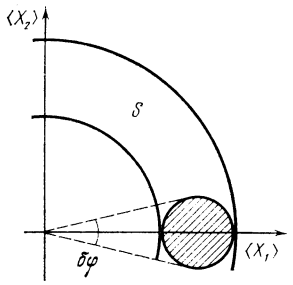

FIG. 1

$$\delta n\delta\hat{\varphi} \approx (2n_T+1).$$

In the squeezed state, the variance circle is transformed into an ellipse compressed along the axis for which the variance is a minimum. If the phases $\psi = 0$ and $\cos\varphi = 0$ are chosen, the ellipse is compressed along the X_1 axis, and its center is located on the X_1 axis; at $\psi = 1$ and $\cos\varphi = \pm 1$, the ellipse is compressed along the same axis, but its center is located on the X_2 axis (see Fig. 2). Accordingly, in the former case the area of the ring decreases, and the angle increases, so that [cf. (16)]

$$\delta n \approx (m\omega/\hbar)\langle X_1\rangle\delta X_1 \approx (2n_T+1)^{1/2}|\alpha|(\gamma/2r),$$
$$\delta\hat{\varphi} \approx 2\delta X_2/\langle X_2\rangle \approx (2n_T+1)^{1/2}|\alpha|^{-1}(2r/\gamma)$$

and

$$\delta n\delta\hat{\varphi} \approx (2n_T+1).$$

In the latter case δn increases and $\delta\hat{\varphi}$ decreases, so that again

$$\delta n\delta\hat{\varphi} \approx 2n_T+1.$$

§3. USE OF SQUEEZED STATES TO DETECT A WEAK FORCE

The possibilities of using squeezed states can be naturally separated into two versions, depending on whether the duration of the signal and other conditions of the experiment will permit accumulation of a signal during several relaxation times, or whether the accumulation time is much shorter than γ^{-1}. If $\gamma\tau \ll 1$, it is reasonable to first "prepare" the squeezed state, and then use it to observe the force before the variance of the measured quantity manages to increase substantially. The action of the signal itself in the course of preparation of the state is immaterial. We consider this technique for the measurement of $X_1(t)$ and of the number of quanta.

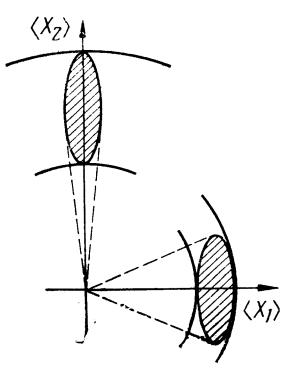

FIG. 2

Assume that at the instant when the laboratory generators are turned off (we choose this instant of time to be zero time) the squeezing reached (at $2r \gg \gamma$) is

$$\delta X_1^2(0) \approx l^2 (2n_\tau + 1)\,(\gamma/2r). \tag{19}$$

Subsequently $\delta X_1^2(t)$ increases in accordance with (8):

$$\delta X_1^2(t) = l^2(2n_\tau+1)\left[\frac{\gamma}{2r}e^{-\gamma t} + 1 - e^{-\gamma t}\right]$$

$$\approx l^2(2n_\tau+1)\left(\frac{\gamma}{2r} + \gamma t\right). \tag{20}$$

The expression (20), which is approximate at $\gamma t \ll 1$, makes it possible to refine the permissible observation time τ. It is desirable for this time to be such that the growing term in δX_1^2, i.e., the term proportional to γt, still has not exceeded the initial value $\delta X_1^2(0)$. In other words, if $\tau \lesssim (2r)^{-1}$, the variance did increase by not more than a factor of 2, but if $(2r)^{-1} \ll \tau < \gamma^{-1}$, the variance is still smaller than the equilibrium value, but comes close to it. The change of $\langle X_1(t)\rangle$ under the action of the gravitational force f_g to be observed proceeds in accordance with (5), where we must put $r = 0$, $f = f_g$, and $\varphi = \varphi_g$. This yields

$$\Delta X_1(t) = 4l|f_g|\frac{\omega}{\gamma}\sin\varphi_g(1 - e^{-\gamma t/2}) \approx 2l|f_g|\,\omega t \sin\varphi_g \tag{21}$$

Taking ΔX_1 to be the signal S and δX_1 the noise N and assuming also $\sin\varphi_g = 1$, we obtain within an observation time $\tau \lesssim 1/2r$

$$S/N \approx [2|f_g|\omega\tau/(2n_\tau+1)^{1/2}]\left(\frac{2r}{\gamma}\right)^{1/2} \tag{22}$$

and after a time $1/2r \ll \tau \lesssim 1/\gamma$

$$S/N \approx [2|f_g|\omega/(2n_\tau+1)^{1/2}]\left(\frac{\tau}{\gamma}\right)^{1/2}. \tag{23}$$

If the oscillator were to be in a coherent state, then after an observation time $0 < \tau \leqslant \gamma^{-1}$ we would obtain the estimate

$$S/N \approx 2|f_g|\,\omega\tau/(2n_\tau+1)^{1/2}, \tag{24}$$

which is worse by $(2r/\gamma)^{1/2}$ times than (22), and worse by $(\gamma\tau)^{-1}$ times than (23). Of course, if it is possible to accumulate a signal within a time on the order of γ^{-1}, the minimum observable force during that time is, according to (24),

$$f_{min} \approx (2n_\tau+1)^{1/2}\gamma/2\omega,$$

much better than the estimate

$$f_{min} \approx \frac{(2n_\tau+1)^{1/2}}{2\omega}(2r\gamma)^{1/2}$$

that follows from Eq. (22) at $\tau \approx 1/2r$, and somewhat better than the estimate that follows from (23). This is so because the time required to reach the maximum ΔX_1, as follows from (21), is γ^{-1} while the decay time of the squeezed state is also γ^{-1}. Thus, it is advantageous to use squeezed states that are prepared beforehand if the time of observation is strongly limited for some reason or another.

Perfectly analogous conclusions are obtained also by analyzing measurements of the number of quanta. The action of the force changes $\langle n(t)\rangle$ in accordance with (7):

$$\langle n(t)\rangle = n_0 e^{-\gamma t} + n_\tau(1 - e^{-\gamma t}) + \frac{2i\omega}{\gamma}e^{-\gamma t}(e^{\gamma t/2} - 1)$$

$$\times[\langle a_0\rangle f_g^* - \langle a_0^+\rangle f_g] + \frac{4\omega^2}{\gamma^2}|f_g|^2(1 - e^{-\gamma t/2})^2, \tag{25}$$

where n_0 is the initial average number of quanta.

Inasmuch as in the squeezed state $\langle a_0\rangle \neq 0$ and $\langle a_0^+\rangle \neq 0$, the term linear in the small quantity f_g is preserved, just as in the case of the coherent state (but not in the n-quantum or equilibrium state). We are interested in such squeezed states in which at a given average number of quanta the variance δn^2 is much less than in the coherent state with the same n. In such states, as can be seen from a discussion of Eqs. (16), $\langle a_0\rangle$ and $\langle a_0^+\rangle$ are equal, apart from phase factors, to $\sqrt{n_0}$. Thus, according to (25) the change of the number of quanta under the action of f_g and at $\gamma t \ll 1$ is

$$\Delta n(t) \approx 2|f_g|\sqrt{n_0}\,\omega t.$$

The variance δn^2 increases from an initial value δn_0^2, which we choose in accordance with (16) in the form

$$\delta n_0^2 = n_0(2n_\tau+1)\,\gamma/2r.$$

The law of variation of the variance is determined by the general formula (9) at $r = 0$, but we assume f_g to be so small that the increase of δn^2 is determined by the interaction with the thermostat and not with f_g. Then

$$\delta n^2(t) \approx n_0(2n_\tau+1)\,(\gamma/2r + \gamma t)$$

and for $\tau \lesssim (2r)^{-1}$ we have

$$\frac{S}{N} = \frac{\Delta n}{\delta n} \approx \frac{2|f_g|\,\omega\tau}{(2n_\tau+1)^{1/2}}\left(\frac{2r}{\gamma}\right)^{1/2}$$

which coincides with (22). At $1/2r \ll \tau \lesssim \gamma^{-1}$ we obtain a formula that coincides with (23).

We consider now the observation of prolonged signals with the aid of the variant $2r = \gamma$. As seen from (17) and (18), the mean values of X_2 and n and of their variances increase in the course of time, but the growth of the mean values is faster. The oscillator is acted upon jointly by the laboratory force f_l and by the gravitational f_g; i.e.,

$$f \equiv |f|e^{i\varphi} = |f_l|e^{i\varphi_l} + |f_g|e^{i\varphi_g}.$$

The increment of $\langle X_2(t)\rangle$ due to the force f_g is, if the phases are suitably chosen

$$\Delta X_2 \approx 2l|f_g|\,\omega t,$$

and the variance is

$$\delta X_2^2 \approx l^2(2n_\tau+1)\,\gamma t,$$

from which we obtain at an observation time $\tau \approx \gamma^{-1}$ or $\tau \gg \gamma^{-1}$

$$S/N = [2|f_g|\,\omega/(2n_\tau+1)^{1/2}]\,(t/\gamma)^{1/2}.$$

Exactly the same formula is obtained for $S/N = \Delta n/\delta n$. Thus, the minimum observable force decreases without limit with increasing observation time. The actual sensitivity limits will be determined by the accuracy with which the necessary relations between the phases and the parameters are satisfied.

§4. COMPARISON OF THE SQUEEZED-STATES TECHNIQUE AND QND MEASUREMENTS IN THE PROBLEM OF OBSERVING A WEAK FORCE

The squeezed-states technique and the use of QND measurements[1-3,12-14] have common features. In both cases one of the tasks of the method is to decrease the variance of the measured quantity. In QND measurements the decrease of the variance is reached by the very act of the first measurement, as a result of which a reduction of the wave function takes place, while in the squeezed-states technique the variance is decreased by specially chosen force and parametric action on the oscillator. Although the postulates of quantum mechanics permit the variance to be decreased after the measurement to zero, its actual value is determined by the coupling constants and by the measuring instrument, by the measurement time, etc. In addition, as already noted, the variance will inevitably increase with time as a result of the interaction of the system with the thermostat. In this sense, we lose the fundamental difference between the final variance obtained by squeezing, and that (final) dispersion which can be obtained after the first measurement performed in a realistic situation.

The initial requirement and theory of QND measurements is to choose quantities that can be measured with arbitrary accuracy without demolishing the state of the system. The system, by assumption is, after the first measurement in one of the eigenstates of the QNDF operator or of the QNDP operator, and it is precisely this quantity which is measured subsequently. The squeezed-states technique does not presuppose an obligatory measurement of the QND-variable. Prior to the arrival of the gravitational signal and during the time of its action, the oscillator is in a squeezed state and not, say, in an eigenstate $X_1(t)$ of the QNDF-operator. In this case the force can be detected, e.g., by the changes of the energy, i.e., of a quantity that is not a QNDF-variable. However, the experimenter must not claim too high an accuracy of the measurements and, consequently, too large a perturbation of the system. The accuracy of the measurements must not be better than the (*a priori*) variance of the measured quantity.

To compare the two considered methods, we assume that we measure the QNDF-variable $X_1(t)$. In accordance with the QND-measurement principle, we assume that at the initial instant of time an exact measurement of $X_1(t)$ was performed on the equilibrium oscillator, as a result of which the oscillator is brought to an eigenstate of the operator X_1 with a value $X_1(0)=0$; then $\delta X_1^2(0)=0$. Subsequently, the variance will increase in accordance with the general formula (8), and the average value will change under the influence of f_g in accordance with (5). The S/N ratio after a time τ of the action of the force will be

$$S/N=[2|f_g|\omega/(2n_T+1)^{1/2}](\tau/\gamma)^{1/2}. \tag{26}$$

We assume now that at the initial instant of time the oscillator is in a squeezed state. We measure again the quantity X_1, but not too accurately, within the limits of the variance. Then the S/N ratio is determined by Eqs. (22) and (23). We know that the measurement of the energy leads to similar equations. The difference from formula (26) takes place only at $0<\tau\lesssim 1/2r$. In this time interval the sensitivity of (26) is generally speaking better than that of (22). However, when $2r$ tends to a definite limit equal to 2ω, the difference vanishes, since the duration of the action of f_g is assumed at any rate to be not shorter than $2\pi/\omega$. Of course, as $r\to\omega$ the conclusions concerning the sensitivity are only qualitatively valid.

Summarizing, we can state that when account is taken of the inevitable damping in the oscillator ($\gamma\neq 0$, $n_T\neq 0$) the QND-measurement method loses its advantages to a considerable degree. At large squeezing parameters the state-squeezing technique is not inferior to that of QND measurements, having the advantage that the quantity measured must not necessarily be a QND variable.

The use of squeezed states can improve the realizability of laboratory experiments on the study and detection of gravitational waves. In Ref. 15 was considered a concrete scheme, in which the radiation and detection were proposed to be effected with electromagnetic fields. The estimate of the sensitivity started out with the fact that it is possible to observe the change of the number of quanta $\sqrt{n}$ against the background of the n quanta present in the cavity-detector. In other words, estimates were used for an oscillator in a coherent state. In this case the technical requirements on the facility are very stringent[15]: the total volume of the system $V=25\times 10^9$ cm^3, characteristic field intensity $E\sim H\sim 3\times 10^5$ G, signal frequency $\omega=2\times 10^{18}$ sec^{-1}, Q-factor of the cavity-detector $Q=\omega\tau^*=7\times 10^{13}$, time of signal accumulation (equal to the relaxation time) $\hat{\tau}=4\times 10^5$ sec. Were it possible to improve the Q of the resonator-detector, e.g., to $Q\approx 8\times 10^{15}$ and produced in it a squeezed state with value $2r/\gamma\approx 10^2$, the sensitivity could be increased during the same accumulation time by a factor of 10, and consequently relax the requirements on the other parameters of the system. These values of Q are apparently perfectly attainable.[16]

It is advantageous to use squeezed states also when detecting monochromatic cosmic radiation, e.g., from a pulsar in the Crab nebula. Experiment is being presently planned on detection of gravitational radiation from this pulsar.[17] The parameters of the resonant antenna are the following: $\nu=60$ Hz, $Q=2\times 10^8$ $M=1400$ kg, antenna length $L=1.65$ m, and the temperature at which the antenna will operate is $T=3\times 10^{-3}$ K. The signal accumulation time τ should amount to $\approx 5\times 10^5$ sec. At a frequency $\nu=60$ Hz, however, the Q of the antenna can possibly be raised to $Q\approx 10^{11}$ (Ref. 16). The relaxation time in such a system will be approximately 9 years. If the technique of squeezed states is used, the time of signal accumulation up to satisfaction of the observability criterion $S/N=1$ could be decreased to approximately 10^3 sec.

APPENDIX

We present first an expression for the quantities containing the operators T and T^+, which do not depend on the initial state of the oscillator. We introduce the notation

$$I_c=\int_0^t e^{\gamma\tau}\operatorname{ch}2r(\tau-t)\,d\tau,\quad I_s=\int_0^t e^{\gamma\tau}\operatorname{sh}2r(\tau-t)\,d\tau,$$

$$E=\int_0^t e^{\gamma\tau}\,d\tau.$$

Then

$$\langle T^+T\rangle=\gamma(n_\tau+{}^1/_2)I_c-{}^1/_2\gamma E,\quad \langle TT^+\rangle=\gamma(n_\tau+{}^1/_2)I_c+{}^1/_2\gamma E,$$
$$\langle T^+T^+\rangle=\langle TT\rangle^*=\gamma(n_\tau+{}^1/_2)e^{-i\psi}I_s,$$
$$\langle(T^+T)^2\rangle-\langle T^+T\rangle^2={}^1/_4\gamma^2[(2n_\tau+1)^2(I_c^2+I_s^2)-E^2].$$

We write out also the expression, which is used in the test for Φ:

$$\Phi(t)=2\omega|f|e^{i\psi/2}e^{\gamma t/2}\left\{-i\cos\left(\varphi-\frac{\psi}{2}\right)\frac{1-e^{(r-\gamma/2)t}}{\gamma-2r}\sin\left(\varphi-\frac{\psi}{2}\right)\times\frac{1-e^{-(r+\gamma/2)t}}{\gamma+2r}\right\}.$$

The general formulas (5)–(9) become simpler if at the initial instant of time the oscillator was at equilibrium with the thermostat. Then

$$\langle X_1(t)\rangle=le^{-\gamma t/2}[\Phi(t)+\Phi^*(t)],$$
$$\langle X_2(t)\rangle=le^{-\gamma t/2}i[\Phi^*(t)-\Phi(t)], \tag{A1}$$

$$\langle n(t)\rangle=e^{-\gamma t}\left[|\Phi(t)|^2+\frac{r}{2}(2n_\tau+1)\left(\frac{e^{-2rt}}{\gamma+2r}-\frac{e^{2rt}}{\gamma-2r}\right)\right]+\frac{n_\tau\gamma^2+2r^2}{\gamma^2-4r^2}. \tag{A2}$$

For the variances we have

$$\delta X_{1,2}(t)=l^2(2n_\tau+1)e^{-\gamma t}[\operatorname{ch}2rt\mp\cos\psi\operatorname{sh}2rt+\gamma(I_c\pm\cos\psi I_s)], \tag{A3}$$

$$\delta n^2(t)=e^{-2\gamma t}\left\{\frac{1}{4}(2n_\tau+1)^2\operatorname{ct}4rt-\frac{1}{4}e^{2\gamma t}+\frac{1}{4}\gamma(2n_\tau+1)^2[\gamma(I_c^2+I_s^2)+e^{2rt}(I_c-I_s)+e^{-2rt}(I_c+I_s)]+4(2n_\tau+1)|f|^2\omega^2\left[\cos^2\left(\varphi-\frac{\psi}{2}\right)\left(\frac{e^{\gamma t/2}-e^{rt}}{\gamma-2r}\right)^2\times(e^{2rt}+\gamma I_c-\gamma I_s)+\sin^2\left(\varphi-\frac{\psi}{2}\right)\left(\frac{e^{\gamma t/2}-e^{-rt}}{\gamma+2r}\right)^2(e^{-2rt}+\gamma I_c+\gamma I_s)\right]\right\}. \tag{A4}$$

Description

FIELD OF THE INVENTION

[0001] The present invention relates to a use of a high vacuum chamber and a device for generating and amplifying gravitational waves.

BACKGROUND OF THE INVENTION

[0002] Einstein theory of relativity and astronomical observation made by Taylor and Hulse have given convincing proof of the existence of gravitational waves, Taylor and Hulse obtained a Nobel prize for this discovery. In fact the orbital decay of a binary stars have been analyzed using the formalism of Einstein's General Relativity with the result that the stars emit Gravitational Waves because of their orbital motion, this phenomenon causes a predictable decay of the orbit that fits observations.

[0003] Efficient generation of Gravitational Waves (GWs) is a century long endeavor. In this field there is a large number of contributions, where we refer to Landau and Lifshits (1975), Misner, Thorne and Wheeler (1973), Pinto and Rotoli (1988) and Baker (2000, 2004) for a brief exemplification of various traditional approaches.

[0004] The laboratory generation of GW was discussed by Pinto & Rotoli in General Relativity and Gravitational Physics, 1998, World Scientific, Singapore. They found (page 560) terrestrial laboratory GW generation to be "... at the limit of the state of the art ... ", but they did not consider any mechanism of amplification both internal and external like those disclosed by the present document. The general concept of the laboratory generation of GW is to emulate GW generated by energizable celestial systems (rotating binary stars, star explosions, collapse to black holes, etc) as observed by astrophysicists by the use of micro, terrestrial energizable systems.

[0005] Robert M. L. Baker, Jr. in U.S. Pat. No. 6,417,597, shows that a third time derivative or jerk of a mass generates gravitational waves (GW) or produces a quadrupole moment and that the GW energy radiates along the axis of the jerk or if a harmonic oscillation, then radiates in a plane normal to the axis of the oscillation. The force producing the jerk or oscillation can be gravitational attraction, centrifugal, electromagnetic, nuclear, or, in fact, any force. The magnitude of the jerk or, more specifically, the magnitude of the third time derivative of the moment of inertia of the mass squared, determines the magnitude of the generated GW determined, for example by a quadruple approximation as reported in textbooks on General Relativity. The force energizing mechanism can be a particle beam. The particle-beam frequency is that resulting from chopping the particle beam into bunches. The magnitude of the GW power is approximately proportional to the square of the kernel according to the general theory of relativity as discussed for instance in patent U.S. Pat. No. 6,417,597.

[0006] US Pat No. 6,784,591 describes a generator of GW based on submicroscopic energizable elements that does not employ the amplification techniques that are disclosed by the present document.

SUMMARY OF THE INVENTION

[0007] It is an object of the present invention to improve the prior art.

[0008] According to a first aspect of the present invention, there is provided a use of a high vacuum chamber as an amplifier of a gravitational wave.

Further details according to the first aspect may be as follows:

[0009] The pressure in the high vacuum chamber may be below 10^{-3} mbar.

[0010] The ratio of a wavelength of the gravitational wave by a length of the amplifier in a propagation direction of the gravitational wave may be between 10^8 and 10^{16} wavelengths per meter.

[0011] The amplifier may amplify the gravitational wave by a factor of 10 and 10^8 per meter of the amplifier in a propagation direction of the gravitational wave

[0012] The high vacuum chamber may have a length between 0.5 and 1000 meter in a propagation direction of the gravitational wave.

[0013] A non-linear material for the gravitational wave may be disposed in the high vacuum chamber.

[0014] According to a second aspect of the present invention, there is provided a device for generating a gravitational wave, comprising a generator of an external energy; a primary vacuum chamber with window transparent for the external energy; a first vacuum pump connected to the primary vacuum chamber and configured to evacuate the primary vacuum chamber; a converting material for converting the external energy into a gravitational wave, the converting material being disposed inside the primary vacuum chamber such that the external energy illuminates the converting material; a second vacuum chamber used as an amplifier of the gravitational wave according to the first aspect of the invention; and a

second vacuum pump connected to the second vacuum chamber and configured to evacuate the primary vacuum chamber.

Further details according to the second aspect may be as follows:

[0015] The converting material may be excitable into an excited state by the external energy, wherein the excited state comprises a first oscillator of a first characteristic frequency comprising a mass and emitting the gravitational wave, and a second oscillator coupled with the first oscillator, and wherein a characteristic frequency of the second oscillator is smaller than the first characteristic frequency.

[0016] The first oscillator may be not electrically charged.

[0017] Each of the first and the second oscillator may comprise a subnuclear structure.

[0018] The material in a state other than the excited state may comprise a stable or metastable nucleus, and the external energy may include at least one of an electromagnetic wave and an elementary particle.

[0019] The electromagnetic wave may comprise at least one of X-ray and gamma ray, and wherein the elementary particle may comprise at least one of a neutron, a proton, an electron, a positron, and an antiproton.

[0020] A number of protons in the nucleus may be between 90 and 125.

[0021] The converting material may comprise Gadolinium.

[0022] The first oscillator may be one of a superconducting electron pair and a crystal or molecular excitation in a frictionless paired state, the second oscillator may be one of a molecular structure, an atom, and a crystal lattice, and the external energy may be at least one of an electromagnetic excitation, a thermal excitation, and an acoustic excitation.

[0023] The first and the second oscillator may be coupled by at least one further oscillator.

[0024] It is to be understood that any of the above modifications can be applied singly or in combination to the respective aspects to which they refer, unless they are explicitly stated as excluding alternatives.

[0025] Further details, features, objects, and advantages are apparent from the following detailed description of the preferred embodiments of the present invention which is to be taken in conjunction with the appended drawings, in which

Fig. 1 represents a detailed description of the nuclear model and the dynamical model;

Fig. 2 shows an apparatus for generating and amplifying gravitational waves.

FIG. 3 shows another apparatus for generating and amplifying gravitational waves; and

FIG. 4 shows still another apparatus for generating and amplifying gravitational waves.

DETAILED DESCRIPTION OF CERTAIN EMBODIMENTS

[0026] Herein below, certain embodiments of the present invention are described in detail with reference to the accompanying drawings, wherein the features of the embodiments can be freely combined with each other unless otherwise described. However, it is to be expressly understood that the description of certain embodiments is given for by way of example only, and that it is by no way intended to be understood as limiting the invention to the disclosed details.

[0027] Moreover, it is to be understood that the apparatus is configured to perform the corresponding method, although in some cases only the apparatus or only the method are described.

[0028] In a gravitational wave generating device, a material may be used in which external or internally produced energy is transferred from a main oscillator to other oscillators with different resonant frequencies coupled one another and with the main oscillator. Because of the interconnected cascade of oscillators and possible non linear coupling, the efficiency of the gravitational wave emission can be greatly increased.

[0029] At the atomic and subatomic scale, it is well known that all material particles may have mass or, alternatively, a combination of mass and electric charge.
Using particles with mass and charge, like protons, it is possible to excite those particles with external energy, like lasers and/or particle beams or with internal energy, like a chemical or nuclear reaction. As a consequence of the excitation the particles emit electromagnetic waves as a function of acceleration and emit gravitational waves as a function of the derivative (change in time) of acceleration, named jerk. Therefore the higher the frequency the higher is the emission of gravitational waves compared to the emission of electromagnetic waves. Because of the weakness of gravity with respect to electromagnetism, it is known from theory (Halpern and Laurent) that the emission of electromagnetic waves overwhelms the emission of gravitational waves in most, if not all, known situations.

[0030] For generating gravitational wave, the ideal approach is to use emitting particles that have large mass and no electric charge, they are neutral particles like neutrons, neutrinos, etc, they will emit gravitational waves and will not emit electromagnetic waves.

[0031] A method is disclosed that permit to put in motion massive neutral particles coupled to electrically charged particles with a great additional increment of the frequency, therefore obtaining an upgeared converter, which increases the emission of gravitational waves by many orders of magnitude respect to a direct, non upgeared, converter.

[0032] In addition to the above embodiment the disclosed concept includes all systems of coupled oscillators that are intended to emit gravitational waves using the same principles.

[0033] An embodiment of the invention relates to the generation and amplification of gravitational waves that can be modulated, directed, collimated and focused to be utilized for communications, space propulsion, air propulsion, near-ground propulsion, marine propulsion, sub-marine propulsion, through earth digging, material processing nuclear processes, including igniting nuclear fusion for energy production, testing physical-cosmological concepts and conjectures. More particularly an embodiment relates to the generation of gravitational waves (GW) by the interaction of elements (molecules, atoms, nuclei, nuclear particles, electrons, photons, antiprotons, etc.) through a dynamical process in which the different elements exchange energy through a process in which the final emitter of GW reaches a frequency higher than the input frequency or the frequency of the energy internally generated by the internal energy source, thus improving the emission of GW to a level that make this emission useable for practical applications. Because the improvement according to the embodiment may be over 20 orders of magnitude (10^{20}) with respect to previous techniques, the present invention is critical for the practical use of GWs.

[0034] An embodiment also relates to the use a non-linear solution of GWs propagation to obtain an amplification of the GWs produced by the above described generator to reach the amplitudes required for the cited practical applications. The present invention adopts two additional methods of amplification, one is the Holonomy, spin-orbit coupling, that realizes what is already known as parametric amplification using non-linear dynamics of coupled oscillator, the other is the non-linear dynamics of GWs themselves that is a consequence of General Relativity (GR) the best model of gravity developed till now. The amplification can be obtained by a tube or box in which a high vacuum is present to permit the undisturbed non-linear growth of the GW.

[0035] According to an embodiment of the present invention it is provided the generation of gravitational waves (GW) caused by the interaction of submicroscopic (molecules, atoms, nuclei, nuclear particles, electrons, alpha particles, neutrons, dineutrons, photons, etc.) energizing and energizable elements, nuclear cycles including instability cycles, chaos bifurcations, holonomy processes and non linear processes, in which a cascade of energy transfers ends on electrically neutral elements that emit the gravitational waves. This is the first generations and amplification mechanism. An embodiment includes a non linear propagation mode for gravitational waves that can provide further amplification of the amplitude of the wave. The combination of the different contribution enables reaching the amplitudes required for practical applications.

[0036] The weak point of all traditional approaches of generating gravitational waves is that the emitting system, whatever it is, operates at the same frequency of the excitation energy. The end result is that the frequency of the emitted GWs is twice the frequency of the excitation energy and the conversion efficiency is extremely low. For instance, for an electro-magnetic (EM) to GWs converter (Pinto and Rotoli, 1988), no practical cavity can have a sufficiently high Q or can host an EM field strong enough to produce detectable GWs according to traditional generator and detector configurations. Going back to the elementary basic formula of the power P emitted with gravitational waves by a "rod" with mass *m,* length *L,* rotating ω times a second, we have:

$$P = \frac{2}{45}\frac{m^2 L^4 \omega^6}{(c^5/G)}, \qquad (1)$$

where *c* is the speed of light and *G* is Newton's gravitational constant. In some embodiments we achieve that the power of gravitational waves excited is at the highest possible frequency, with the goal that future gravitational wave optics will permit collimation and focusing for technological applications (Baker, 2005) in which those parameters are most relevant.

[0037] Looking at the formula we observe that for identical systems, the power emitted is proportional to the sixth power of the frequency. Therefore a "gear-up" mechanism between electromagnetic excitation and the "rod" is what is required to increase the power emitted in GWs. Frequency multiplication can be obtained by using "gearboxes" like those we use in cars. Nano-mechanical gearboxes could be made, but all of them still have electromagnetic coupling at the "fast" pinion, and they need a torque reaction coupling to operate. Both limitations need to be addressed to define a new converter that is highly efficient and capable of enabling new technologies.

[0038] The main requirements for such an elementary converter are:

1. Small size and highly reproducible structure with highest possible operating frequency leading to GWs,

2. Nuclear density GWs emitter for best impedance matching to space-time,

3. Capability to be used in large numbers and in synchronized modes,

4. High frequency multiplication ratio,

5. Electrically charged low frequency interface for easy energization,

6. Electrically neutral high frequency interface to avoid re-emission of EM waves,

7. Massive and with high gravitational quadrupole moment high frequency interface for GWs emission,

8. Capability to be used without external torque reaction (it should be based on autonomous coupled oscillators and spin-orbit coupling).

[0039] The requirements point to nuclear or molecular systems as the preferred choice. We therefore recall that the spheron model of the nucleus (Pauling, 1965) may suggest that some nuclei do indeed provide the full spectrum of features that is required to practically build an efficient EM to GWs converter. The spheron model of the nucleus has been proposed by the two times Nobel Laureate Linus Pauling in 1965 (Pauling, 1965) as a simple model capable of explaining many properties of the different nuclei. The spheron model was proposed after the drop model and the shell model and is probably the most practical and intuitive model of the nucleus capable of producing realistic predictions as an alternative to brute force quantum mechanical calculations.

[0040] Figure 1 represents a detailed description of the nuclear model and the dynamical model. Reference number **6** indicates the core of the nucleus that is composed by one or more spherons **1** and **5**. Each spheron can be a proton, a neutron, a dineutron **8** a triton or an alpha particle like in the specific spheron **5.** The alpha particle α is composed by two neutron **3** and two protons **4.** In the discolsesd invention the dineutron **8** orbits on the surface of the core of nucleus along an orbit **7,** the dineutron **8** orbits and spins **2** around its own axis producing gravitational waves **9.** Those subnuclear elements can be present as a real particle or as a hole for the device to operate properly.

[0041] The spheron model is characterized by clusters of protons and neutrons in the nucleus named spherons, that are alpha particle (helions), tritons and dineutrons: they are aggregates of protons and neutrons in localized 1*s* orbitals. Spherons may be present in the nucleus as "particles" and also as "holes".

[0042] Pauling shows that concentric layers of spherons allow the simple derivation of a subsubshell occupancy diagram and explanation of magic numbers (Pauling, 1965). The effective existence of dineutrons was discussed by Kamal and Parker (1991) and other authors with the clear conclusion that dineutrons are real objects.

[0043] Two qualities of the spheron model are of great relevance for GWs generation. The first one is that heavy isomers with high angular momentum are represented by a central core with magic number of protons and neutrons that does not rotate plus one or more spherons orbiting the core (Pauling, 1990). As the dynamics is driven by the strong nuclear force, the process is a proper gliding in an orbit. In one of his papers Pauling also suggests that $^{204}_{80}Hg_{124}$ has an α particle hole revolving in the sphere of the doubly magic $^{208}_{82}Pb_{126}$, and $^{206}_{82}Pb_{124}$ has a dineutron hole revolving in the sphere (Pauling, 1990).

[0044] The second quality of the spheron model is that each orbiting spheron may have its own rotational state that can be excited while gliding the magic number core. This is relevant if the spheron is a dineutron. In fact the dineutron obviously has nuclear density, it is electrically neutral and the two magnetic moments of the component neutrons are antiparallel, making it an ideal emitter of GWs, possibly the best microscopic emitter found so far.

[0045] Quantum mechanical analysis of nuclei is simpler for nuclei with less than ten nucleons, and various efforts are ongoing to produce detailed models. Itagaki et al. (2002) have studied the nuclear configuration of ^{10}Be, that has a couple of neutrons orbiting the α-α core; a lower energy state is found that has a bound neutron *n*-*n* (dineutron) structure orbiting the core, a higher energy state has the two neutrons separately orbiting the core in opposite directions (see page 044302-4 of Itagaki, 2002). Modem quantum mechanical analysis confirms the Pauling's view about the existence of nuclear substructures (Pauling, 1990). Nuclear substructures clearly have a rich dynamics and with our interdisciplinary view, we recognize that the dineutron rotational state excited by its orbital angular momentum around the core may enable a very efficient mechanism for the generation of GWs. Energy is transferred from orbital motion to the spin of the dineutrons by relativistic spin-orbit coupling. The interaction is mostly dynamical in nature, not involving nuclear reactions, and following the rules of nonlinearly coupled dynamical systems.

[0046] If the excitation energy is external, it can be a particle and/or electromagnetic and/or gravitational radiation that hit the nucleus and make it oscillate at some frequency; as a consequence the dineutron/s orbit the nucleus and also spins at a much higher frequency respect to the excitation one. As the emission of gravitational waves if proportional to the sixth power of frequency there will be a great increase in emitted power. Being electrically neutral the dineutrons will

not emit electromagnetic waves.

[0047] By adopting a collection of converting nuclei excited by coherent radiation a beamed coherent emission is possible, with additional gain due to coherence.

[0048] If the excitation energy is mostly internal, an external trigger particle, for example a proton is injected in the selected nucleus. According to theoretical analysis by Binder (2008), some heavy nuclei can enter a regime of dynamical instability related to chaos by a small increase of proton number Z; let's choose for example, but not limited to, Z=115. With the additional proton Z=115 may become a nucleus in the range Z=116, entering a region of instability, becoming unstable and highly energized trough Zero Point electromagnetic Fluctuations (ZPF). Afterwards a proton of the nucleus becomes a neutron plus a positron, following the usual beta+ decay channel. The positron is emitted and the neutron participates to the efficient emission of Gravitational Waves like we have in the externally excited converter. The emission of Gravitational Waves de-energizes the nucleus, the neutron is then released and the nucleus is ready for another cycle.

[0049] A vacuum enclosure permits further amplification because of non-liner phenomena related to Gravitational Waves, as determined by Fontana (2008).

[0050] A material according to an embodiment comprises one or more sets of coupled oscillators. Each set has a low frequency mode, which is excited/depleted by internal or external energy or by the high frequency mode, and a high frequency mode that is excited/depleted by internal energy, external energy or by the low frequency mode, being this last one the most relevant excitation path. The low frequency mode may couple to all known forces and fields to some degree, the high frequency mode couples mostly only to Gravitational Waves.

[0051] With external excitation an embodiment operates as converter from electromagnetic waves (EMW) to Gravitational Waves (GW); with internal excitation an embodiment operates as a generator of Gravitational Waves.

[0052] The invention is based on interdisciplinary application of nuclear dynamics within the Spheron model of the nucleus, non-linear dynamics of coupled oscillator, parametric amplification, holonomy, holonomy and nuclear instability in chaos theory, non-linear propagation of Gravitational Waves. It is based on the mainstream theories and on nuclei, nevertheless the same principles may be applied to similar systems of different nature like paired electrons in crystals, superconductors, polarons and other excitations in the solid state or plasmas that could manifest properties that may allow the here described phenomena to manifest as described in this document.

[0053] **Figure 2** shows a device for generating GW according to an embodiment of the present invention. The target plurality of nuclei **12** is excited or driven into instability by an external wave or exciting particles **11** produced by the generator **10.** The gravitational wave generating material **12** produces gravitational waves **13, 14, 15.** The gravitational wave **15** is amplified by the gravitational wave amplifying device **16** and emitted as high amplitude gravitational wave **17.**

[0054] More details of such an embodiment are shown in **Figure 3.** In the embodiment, an X-ray laser **18** sends a beam of X-ray electromagnetic radiation through an X-ray transparent window **19** inside a primary vacuum chamber **20** evacuated by the vacuum pump **21**. The X-ray illuminates the converting material **22** that as a consequence produces the gravitational waves. Gravitational waves enter the second vacuum chamber **23** whose pressure and/or gas content can be controlled by pump **24**. amplified gravitational waves **25** are emitted along the main axis of the vacuum chamber **23**. The selection of the window material of the second vacuum chamber is not critical because many known materials are transparent to gravitational waves.

[0055] The pressure in the primary and second vacuum chamber is below 10^{-3} mbar, preferably below 10^{-6} mbar, more preferably below 10^{-10} mbar. The x-ray energy is between 0.1 and 120 keV, preferably between 1 and 100 keV, more preferably between 30 and 70 keV.

Figure 4 shows another embodiment. Compared with the embodiment of Figure 3, the X-ray laser is replaced by a particle accelerator 26 which is in the same vacuum chamber as the converting material 22.

[0056] According to Binder (2008), that determined some general rules for spin-orbit coupling in nuclei, the spinning frequency of the dineutrons is about 8939 times higher than the excitation frequency of the core of the nucleus. The frequency ratio between electromagnetic waves and emitted Gravitational Waves is 2*8939=17878 times higher than the excitation frequency of the core of the nucleus. Thus we have defined a $8939^{GW}/1^{EMw}$ converter. According to the calculations of Halpern and Laurent (1964) The net gain in power emitted respect to a traditional $1^{GW}:1^{EMW}$ converter is therefore $8939^6=5*10^{23}$, with an additional gain of $2*10^7$ that can be obtained by a synchronized operation of coherent oscillators or by a high Q resonator, the unitary energy balance and 100% conversion efficiency, can be obtained. Please observe that the energy balance for the $1^{GW}:1^{EMW}$ converter is 10^{31} in favor to the electromagnetic interaction, which means that with the $1^{GW}:1^{EMW}$ converter a "graviton" is emitted every 10^{31} "photons" as described by Halpern and Laurent (1964). Instead with the disclosed invention $8939^{GW}/1^{EMw}$ converter, a "graviton" is emitted every $2*10^7$ "photons".

[0057] An ensemble of $2*10^7$ or more nuclei is required to operate with unitary (100%) conversion efficiency, that is about fractions of a picogram of a suitable element. According to Pauling and the periodic table of the elements a suitable element could be Gadolinium.

Coherent emission is possible by exciting the nuclei with coherent radiation, for instance in the X-ray frequency range and letting the stimulated emission of GW to build-up as described by Halpern and Laurent (1964). Frequency multipli-

cation in non linear coupled oscillators can be described as follows:

SPINNING AT HIGH HARMONIC FREQUENCIES IN NUCLEAR APPLICATIONS

[0058] Rolling, gliding, and revolving in the sphere provides for holonomy effects. In classical mechanics we have holonomy effects (Marsden, 1973), especially if the solid-body rotation angle is connected to the actual solid angle that the body-fixed axis describes as the body performs a conical motion (Ishlinskii, 1952, Malykin, 1999). There are mechanical toys modeling the dynamics of spin-precession coupling: the function of the Gyrotwister or Powerball (Mishler, 1973) is based on a mechanical gear-type coupling between precession and spin phase: if the spin axis rolls in the bearing (on the rim of the groove by friction) and the device has enough spin, the onset of linear spin-precession coupling enables to control spin by precession. If the conic motion of the external stimulation is such, that the number N of axis rotations for one precession period is reduced by j, the device auto-tunes recurrently and follows the external holonomy change. Now it can be powered-up to high spin frequencies with precession frequency multiplier N/j. Near dynamic equilibrium we get curves of constant precession (Darboux) in the Frenet description, which are rolling cone paths showing the dynamics of a precession axis pendulum.

[0059] "Magic Angle Precession" (MAP) (Binder, 2008) describes a special chaotic behavior in the precession angle of a precessing rotor (gyroscope), where the rotor angular velocity is linearly coupled by (an)holonomy to the precession angular velocity and angle. In the mechanical picture a linear coupling between spin and precession angular velocity provides for rolling cone paths and allows spinning up and controlling the rotor simply by forcing precession at special quantum magic precession angles. The principle can be experimentally verified with devices, where spin and precession of a rotor are coupled by a conic rolling mechanism. This linear relation models a recurrent chaotic holonomy, where precession as the effect of holonomy is also a cause of holonomy linearly related to the rotator spin. Gravitational waves can be regarded as a modulated holonomy signals obeying a hyperbolic wave equation. In a more recent approach, it is shown that a pure geometric attractor can promote a local hyperbolic (vortex) geodesic flow on a rotating spherically curved surface, where the vortex angular velocity is considerably higher than the angular velocity on the sphere (Binder, 2008). Here, we regard an ideal system of rotated rotations, where spherical harmonics store angular momentum while hyperbolic harmonics (traveling waves) extract or support angular momentum. Due to different curvature signs we have at the boundary a holonomy discontinuity, which could provide from a signal theoretic point of view for impedance jumps capsulating the spherical harmonics and reflecting external waves.

[0060] From referenced papers we know about magic angle precession constellations reducing the mismatch to zero and allowing for a lossless external angular momentum exchange. At special precession angles it is possible to inject and extract angular momentum from precession to and from the rotor spin, allowing spinning up the rotator to very high frequencies controlled by a slow precession frequency. Due to the apparent coupling between spin and precession it is a strictly nonlinear dynamics supporting fast auto-tuning and self-stabilization capabilities. The recurrent situation balances the linear coupling by a transcendental holonomy spin coupling effect. The emerging magic precession/nutation angle/phase patterns are singularities given by the intersections between linear and transcendental couplings. Near these points very strong and lossless angular momentum currents crossing the boundary between hyperbolic precession space and the spherical rotator space are observed. The strange attractor balancing the linear and holonomy spin-currents living on the tangential cone connects the sphere with the hyperbolic space, where the resulting precession or twister dynamics can be modeled.

[0061] With synergetic effects given by a neural-type recursive network based on coupled MAP elements, a strong long range spin-network synchronization dynamics should be possible (Binder, 2008). It has been proposed that this holonomy attractor could integrate a large number of quantum spins from Hopf fibrations and correspondent magnetic monopoles into one global higher-dimensional spin, where the local coupling network provides for electroweak and strong interactions (Binder, 2008).

[0062] With three or six MAP elements we get a rational exact solution without chaotic transcendental part and SU(3) symmetry, where the Dirac monopole charge condition $NM = \pm 1/\alpha$ fits very well to $Z = j/J = \pm 1/3, \pm 2/3$, the quark charge (Binder, 2008). This spin has some serious support in literature (Franklin, 1969). Finally, more complex networks near Z=115 could explain the heavy nuclei instability (Binder, 2003, 2009).

[0063] With the support of the Spheron model and MAP dynamics it is possible to identify a nucleus that could convert EMW radiation to GWs with high efficiency such as nuclei with a heavy core with highly relativistic dineutrons capable of strong spin-orbit coupling.

[0064] In the following analysis we compare the GWs emission properties of dineutrons dynamically coupled to a suitable core to a similar (according to Equation 1) GWs source that is the deuterium nucleus. The dineutron will be coupled to the electromagnetic field via the core and MAP dynamics, the deuterium nucleus will be directly coupled to the electromagnetic field.

NON LINEAR DYNAMICS OF DINEUTRONS

[0065] After recognizing that a nuclear model is suitable for producing GWs through angular frequency high order harmonics interplay between a charged body (the core) and an electrically neutral "dumbell" (the dineutron) a quantum mechanical relationship between the two frequencies, applicable to heavy nuclei, must be found. At STAIF 2008 Bernd Binder described MAP (Magic Angle Precession) dynamics for nuclei (Binder, 2008). The study of MAP dynamics applied to nuclei has provided values for some critical parameters capable of describing the efficiency of the EMW to GWs converter. Bernd's analysis is a powerful tool that we here apply to the spheron - core/dineutron model of suitable nuclei. The method involves non-linear dynamics of coupled oscillators. Coupled oscillators with non-linear terms exhibit a complex dynamics that goes from "regular motion" through "star patterns" to "chaotic motion" as a function of excitation energy. The "start pattern" dynamics is very peculiar for our approach because energy goes back and forth from a high frequency oscillation to a low frequency oscillation on different linear combination of physical coordinates. The model has widespread applications, for instance Earth atmosphere may be modeled by such a system of coupled oscillators (Lynch, 2002). Energy transfer between modes is also an example of parametric amplification and de-amplification. In such case the traditional approach is based on the Manley and Rowe equations (Brown, 1965). With a set of frequencies in the source and in the sink written as $f_{mn}=mf_1+nf_2$, with m, n integers and f_2/f_1 irrational, being P_{mn} the power at f_{mn}, positive if it enters the system and negative if it leaves the system, the Manley-Rowe equations are:

$$\sum_{m,n}\frac{mP_{m,n}}{mf_1+nf_2}=\sum_{m,n}\frac{nP_{m,n}}{mf_1+nf_2}=0 \qquad (1)$$

[0066] As a particular case, if two oscillators at frequency f_0 and Nf_0, where N can be irrational, are coupled by a non-linear non-dissipating element, such as a non-linear elastic constant, it is possible that energy goes from one oscillator to the other periodically, the direction of the energy transfer depends on the phase relationship between the phase of the higher frequency oscillator and the respective harmonic of the lower frequency oscillator, a changing phase is determined by the fact that N can be irrational, i.e. it is the nearest rational number plus a small irrational frequency difference (a changing phase). This is what Lynch describes as the star-pattern phenomenon. It is a form of degenerated parametric amplifier in which the mode at f_1 amplifies the mode at f_2 at the expense of its own energy, until is completely depleted, then the energy flows the other direction if no other mechanism can remove it. Usually, the physical coordinates of the system are linear combination of the orthogonal coordinates of the two modes. With higher initial energy the same system may enter the regime of chaotic motion. Chaotic motion is usually disruptive for nuclear systems because as soon as some binding energies are overcome the nucleus is interested by fission, which destroys the mechanism.

[0067] Another interesting example of parametric coupling applied to gravitating systems is satellite librations (Klemperer and Baker, 1957), in this case the time-scale of the phenomenon is much longer.

[0068] As soon as a dynamical system exhibits these properties (like non-linear or relativistic spin-orbit coupling), the periodic energy exchange takes place. In suitable nuclei, when energy peaks on the high frequency spinning dineutron, it can be emitted as GWs. The emission of a quantum of GWs removes power from the system and a new cycle can begin, thus partially depleting the "star pattern", whose dynamics do indeed operate to keep the system synchronized. If energy input is kept below some threshold, the converter can safely operate. With Binder's notation, parameter N is the integral number of nutations, or orbital waves (dineutron rotations on its axis) for one rotation of the base plane (one glide-orbit around the core, induced by EMW excitation of the core). Analyzing the Sommerfeld spin-orbit fine structure coupling conditions for M=137, best fit is obtained by averaging results with N about equal to 8939. N=8939 has been primarily applied to the numerical study of heavy nuclei bifurcation (Binder, 2008). For the analysis of the "gear up" mechanism in heavy nuclei we adopt N=8939 as gear ratio i.e. the "frequency ratio", an addition factor of 2 is required for the GWs frequency.

ESTIMATION OF THE CONVERSION EFFICIENCY

[0069] To estimate the conversion efficiency of the arrangement, the nucleus can be treated like a quantum system for which a ratio r between the emission probability for gravitons and photons from equal structures can be computed. Halpern and Laurent computed in their seminal paper (Halpern, 1964) the above mentioned ratio for electrons $r\sim10^{-43}$, for protons $r\sim10^{-36}$, and for larger molecular structures or heavy nuclei that are only slightly ionized $r\sim10^{-31}$.

[0070] If we introduce the concept that the EM excitation frequency is lower than the frequency of the high frequency GWs (HFGW) emission and the HFGWs emitting subsystem is "geared-up" by an electrically neutral mechanism, according to equation (1) r is increased by the sixth power of the frequency ratio, that is $8939^6=5*10^{23}$. Therefore for heavy

nuclei that are only slightly ionized and for which the MAP coupling effect ends on neutron structures $r \sim 5 \cdot 10^{-8}$.

[0071] To increase the interaction of the nucleus with the EMW field without affecting the emission of GWs, it is possible to adopt an EMW resonator tuned on the EMW absorption frequency of the nucleus. In an embodiment, a superconducting cavity with $Q=2 \cdot 10^{7}$, capable of accumulating energy till dissipation makes it leak to the external environment, makes unitary, which is the goal of any efficient converter from electromagnetic radiation to GWs. High power superconducting cavities with intrinsic Q exceeding 10^{10} are described by Padamsee, 2005, therefore nuclei designed to provide MAP coupling effect to dineutrons are excited with EM waves obtaining nearly complete conversion of EM energy to GWs. In some other embodiments photons may interact with sequences of many converting nuclei, to enhance the conversion probability, see Fontana and Baker (2006). In an embodiment, the traveling-wave converter is designed to perform coherent conversion, thus maintaining the spatial and temporal coherence of the EM excitation, mimicking the operation of non-linear crystals employed for optical frequency multiplication of Laser light. Discrepancies between the phase velocities of the two kinds of radiation are minimized by the geometry of the converter (Fontana and Baker, 2006).

[0072] The process can be described as a continuous excitation of the rotational state of the dineutron; alternatively it can be described as a transition to a higher energy state with unbound neutrons to a lower energy state with bound neutrons (pairing-condensation) (Itagaki et al., 2002).

ESTIMATION OF THE MAXIMUM OUTPUT POWER

[0073] In this section the maximum permissible output power in GWs per unit of converting material is estimated under a number of reasonable conditions. In an embodiment analyzed herinafter the dineutrons do not dissociate, therefore no nuclear reaction takes place. The estimate will be based on maximum centrifugal force counteracted by the strong nuclear force to determine the maximum angular velocity and therefore the power emitted in GWs. The classical approximation should be sufficient for an order of magnitude estimate. In some embodiments, the power is limited without overcoming the limit. Overcome the limit is possible by the usual fission phenomenon.

[0074] The measured binding energy of the deuteron nucleus is 2.226 MeV, for dineutrons the binding energy depends on the structure of the α-cluster core, because no binding is possible in isolated n-n systems. The early calculations made by Pauling himself give values of about 1.4 MeV (Pauling, 1967) for dineutrons belonging to heavy nuclei. The distance between the two neutrons of the couple is 2-3 fm, as reported by recent studies in neutron rich light nuclei (Kanada-En'yo, 2007), which also suggest that the α-cluster core is a Bose condensate of α-particles, the same kind of condensation apply to dineutrons for nuclei that have more than one dineutron orbiting the core. Adopting equation 1, the maximum power emitted by a single dineutron as GW is of the order of 10^{-33} W at frequencies of the order of 10^{22} Hz, that belong to the γ-ray region of the spectrum. A kilogram of dineutrons consists of $N \approx 3 \cdot 10^{26}$ dineutrons and the power emitted with incoherent summation (only applicable to spontaneous emission) is of the order of microwatts. In an embodiment with coherent amplitude summation is possible, the (Number of Emitters)2 factor pushes the maximum power to about 10^{20} W per kilogram of dineutrons, therefore the converter produces powerful beams of GWs according to the degree of coherence that can be achieved experimentally and the geometric configuration of the converter. The effective output power will be obviously less than the input power, that for the internally energized converter, includes Zero Point electromagnetic Fluctuations (ZPF).

[0075] The here presented concept of EM wave to GW converter with high order harmonic generation exploits the quantum relationship between the frequency excitation of EM energy and the frequency of the generated GWs. The process can be made coherent for GW output, with space and time coherent excitation in the X-ray region of the EM spectrum. In an embodiment, the excitation system is an X-ray laser.

[0076] If the excitation energy is mostly internal, with an external trigger particle, for example a proton, which is injected in the selected nucleus, some heavy nuclei can enter a regime of dynamical instability by a small increase of Z, let's choose for example, but not limited to, Z=115. With the additional proton Z=115 may become a nucleus in the range Z=116, entering a region of instability, becoming unstable and highly energized trough Zero Point electromagnetic Fluctuations (ZPF). Afterwards an energetic proton of the nucleus becomes a neutron plus a positron and a neutrino, following the usual beta+ decay channel. The positron and the neutrino are emitted and the neutron participates to the efficient emission of Gravitational Waves like we have in the externally excited converter. The emission of Gravitational Waves de-energizes the dineutron, the neutron is then released according to the core/dineutron energy balance already disclosed, and the nucleus is ready for another cycle.

AMPLIFICATION OF GRAVITATIONAL WAVES

[0077] When a strong GW propagates undisturbed in high vacuum it may grow to higher amplitude because of the following considerations:

[0078] As a simple rewriting of the metric of a GW of General Relativity it is possible to show that Gravitation can be easily modeled by resorting to the analogy to optical propagation in a three-space and introducing a gravitational refractive

index of the Hyperspace named *n* (Almeida, 2001):

$$c^2(dt)^2 = n^2\left[(d\tau)^2 + (dx)^2 + (dy)^2 + (dz)^2\right], \quad n \neq 0, \tag{2}$$

after switching to spherical coordinates with $d\varphi=0$ and $d\theta=0$, writing $ds^2=n(d\tau^2)$ and substituting:

$$\frac{1}{n} = \left(1 - \frac{2Gm}{r}\right), \tag{3}$$

we find the Schwarzschild's metric of General Relativity (Almeida, 2001), with G the gravitational constant, *m* is mass and *r* distance. Therefore there exist a formal link between General Relativity and the Theory of Gravity for the Hyperspace that is called Four Dimensional Optics (4DO).

[0079] For the wave described by Equation (2), with $a<<1$ we express Equation (2) as:

$$c^2(dt)^2 = n_\tau^2(d\tau)^2 + n_x^2(dx)^2 + n_y^2(dy)^2 + n_z^2(dz)^2, \tag{4}$$

Comparing Equation (1) with Equation (4), it is obvious that the weak gravitational wave is a wave of refractive index of the Hyperspace, which propagates at the speed of light in four dimensions. More generally, assuming isotropic propagation, a generic wave equation for weak waves traveling at speed c can be written:

$$\frac{1}{c^2}\frac{\partial^2 n}{\partial t^2} = \nabla^2 n, \tag{5}$$

Equation (5) is characterized by time *t* defined as an evolution variable as in the equations of electrodynamics and by having four space dimensions.

[0080] The linear wave Equation (5) can be integrated with results that will have integration constants. In fact in the flat background, the refractive index is unitary; this value must be added to the solutions of Equation (5). If the background value can be ignored in the derivatives, it must be included in the expression of speed. The nonlinear wave equation that includes the effect of the refractive index on speed is therefore:

$$\frac{(n+1)^2}{c^2}\frac{\partial^2 n}{\partial t^2} = \nabla^2 n, \tag{6}$$

whose nonlinear behavior expresses the non-linearity of gravitational waves (Christodoulou, 1991). The background value of *n* must be added to the solutions of Equation (6).

[0081] Equation (5) has the usual wave solutions for any value of *n*, instead Equation (6) has the usual wave solutions if $n^2 <<1$.

[0082] The solutions for weak waves in a unitary background may come from separations of variables in spherical (hyperspherical) coordinates. Writing the solutions of Equation (5) in the form $n(r, t)= T(t) R(r)$, the individual equations are:

$$r\frac{d^2R}{dr^2} + (i-1)\frac{dR}{dr} + k^2 rR = 0; \qquad \frac{d^2T}{dt^2} + \omega^2 T = 0, \tag{7}$$

where *i* is the space dimensionality of the problem, *k* has units of 1/distance and ω has units of 1/time. With *i*=4, they are waves in four dimensions. Please note that with odd dimensionality (*i*=1, 3, 5, ...) the traveling wave solutions have speed *c*; instead for even dimensionality the traveling wave solutions have a spread of speeds from zero to a maximum (Brown, 2007). This last result applies to gravitational waves in the Hyperspace.

[0083] Qualitatively, according to Equation (6), if a beam of gravitational waves is more intense at the center respect to the periphery, then the central part of the beam travels at lower four-speed, leading to self-focusing, in agreement with the classical GW treatment of the problem (Corkill and Stewart, 1983; Ferrari,1988).

[0084] The unitary background refractive index of Equation (6) needs some explanation as it could be attributed to a background gravitational wave that cosmologically supports our space-time. In fact removing the background the non-linear wave equation is:

$$\frac{n^2}{c^2}\frac{\partial^2 n}{\partial t^2} = \nabla^2 n\,, \tag{8}$$

[0085] Starting from the wave equation in *i* space dimensions (*i*=4 for the Hyperspace) and adopting again *n(r, t) = T (t) R(r)*:

$$T\frac{d^2R}{dr^2} + (\frac{i-1}{r})T\frac{dR}{dr} = R\frac{R^2T^2}{c^2}\frac{d^2T}{dt^2}\,, \tag{9}$$

we separate the variables:

$$\frac{1}{R^3}\frac{d^2R}{dr^2} + \frac{1}{R^3}(\frac{i-1}{r})\frac{dR}{dr} = \kappa = \frac{T}{c^2}\frac{d^2T}{dt^2}\,, \tag{10}$$

rewriting, the left hand equation is:

$$r\frac{d^2R}{dr^2} + (i-1)\frac{dR}{dr} - \kappa\, r\, R^3 = 0\,, \tag{11}$$

while the right hand equation gives:

$$\frac{d^2T}{dt^2} = \frac{\kappa c^2}{T}\,, \tag{12}$$

that is a case of the Emden-Fowler (EF) nonlinear ordinary differential equation with $A=\kappa c^2$ (Sachdev, 1991). Equation (12) has no known explicit solution in the form *T(t)=f(t),* instead it is possible to write:

$$t = \int \left(2A\ln T + C_2\right)^{-1/2} dT + C_1\,. \tag{13}$$

[0086] With $\kappa \neq 0$, Equation (12) can be integrated numerically with the approximate result: $T(t) \approx C_1 + C_2 t^{\alpha}$, with C_1 and C_2 real constants and α slightly larger than 1 ($\alpha \approx 1.03$). The solutions of Equation (11) are oscillating, while the solution of Equation (12) can be continuously increasing with time, which is the feature of our interest for amplification. Materials with nonlinear gravitational properties may enhance the amplification phenomenon.

[0087] With $\kappa \neq 0$, Equation (12) can be integrated numerically with the approximate result:

$$T(t) \approx C_1 + C_2 t^{\alpha}, \qquad (14)$$

with C_1 and C_2 real constants and α slightly larger than 1 ($\alpha \approx 1.03$). The solutions of Equation (11) are oscillating, while the solution of Equation (12) can be continuously increasing with time, which is the feature of our interest for amplification.

[0088] Materials with nonlinear gravitational properties may enhance the amplification phenomenon.

[0089] For calculating the physical dimensions of the amplifier it is necessary to consider the effect of the nonlinearity of GW propagation on gravitons emitted by the converter and propagating in high vacuum. Considering the time component of the refractive index, we can put it in the Schwarzschild's metric obtaining:

$$\frac{1}{C_1 + C_2 t^{\alpha}} = \left(1 - \frac{2Gm}{r}\right), \qquad (15)$$

[0090] In which the gravitational field associated to the wave is represented by *m,* which increases as time passes because the term in parentheses is positive when t=0.

With the proposed externally excited converter the reference peak power of the impulse is comparable to the peak power of the exciting X-ray laser and can be according to present technology about .6 MW at a typical wavelength of 47 nm. This power will be converted to gamma ray GWs by the converter at a typical wavelength of 5.2 pm by the N=8936 frequency relationship.

[0091] In an amplifier length of 1 m, the amplifier contains $1/5.2*10^{-12}$ wavelengths, that is $1.9*10^{11}$ wavelengths. More general, the ratio of the wavelength of the GW by a length of the amplifier in a propagation direction of the GW is usually between 10^6 and 10^{20} wavelengths per meter, preferably between 10^8 and 10^{16} wavelengths per meter. As C_2 of equation 14 represents the non-linearity of propagation in time and assuming an overall contribution of the order of 10^{-7} per wavelength for typical configurations, a high vacuum chamber with a 1 m length gives appreciable amplification of the order of $10^{4,}$ or more general of 10 to 10^8, preferably between 10^3 and 10^8.

[0092] In some embodiments, the amplifier may have a length between 0.5 and 1000 meter.

[0093] Implementations of any of the above described blocks, apparatuses, systems, techniques or methods include, as non limiting examples, implementations as hardware, software, firmware, special purpose circuits or logic, general purpose hardware or controller or other computing devices, or some combination thereof.

[0094] It is to be understood that what is described above is what is presently considered the preferred embodiments of the present invention. However, it should be noted that the description of the preferred embodiments is given by way of example only and that various modifications may be made without departing from the scope of the invention as defined by the appended claims.

[0095] Hereinafter is a short summary of the most important features relevant for generating gravitational waves according to some embodiments of the present invention:

[0096] A Gravitational Wave Generating device comprising:

One or a plurality of dynamical systems, each composed by two or more coupled oscillators with different characteristic frequencies. One of the oscillators is coupled to input energy and another emits Gravitational Waves, and a device for sending electromagnetic waves or excitation energy to the low frequency oscillator.

[0097] A method for avoiding the emission of electromagnetic energy from the high frequency oscillator by using electrically neutral and massive emitting particles, thus promoting the emission of Gravitational waves.

[0098] An amplification stage composed by a volume of ultra high vacuum and/or non-linear material for enhancing and/or guiding non-linear propagation and amplification of gravitational waves.

An optional excitation/triggering stage applicable to some specific oscillators near the chaotic instability region.

An optional particle accelerator to cycle the oscillators through the instability region.

[0099] A device in which the coupled oscillators are subnuclear structures like spheron cores or central fraction of

nuclei for coupling to external electromagnetic excitation and dineutrons for the emission of gravitational waves.
A device in which the oscillators are a stable or metastable nucleus that is made more unstable and/or excited by external energy.
A device in which the external energy is X-ray
A device in which the external energy is gamma-ray
A device in which the external energy is an elementary particle like a neutron, proton, electron, positron, antiproton or any subatomic particle.
A device in which the external energy is a generic electromagnetic wave.
A device in which, after the generation of a pulse of gravitational waves because the emitting nucleus has been hit the external energy, the nucleus returns to its original state.
A device in which, after the generation of a pulse of gravitational waves because the emitting nucleus has been hit the external energy, the nucleus does not return to its original state because of the nuclear reaction.
A device in which the coupled oscillators are molecular structures like atoms and/or crystal lattices for coupling to external electromagnetic excitation and superconducting electron for the emission of gravitational waves.
A device in which the coupled oscillators are molecular structures like atoms and/or crystal lattices for coupling to external thermal and/or acoustical excitation and superconducting electron for the emission of gravitational waves.
A device in which the coupled oscillators are molecular structures like atoms and/or crystal lattices for coupling to external electrical and/or thermal and/or acoustical excitation and crystal/molecular excitations in a frictionless paired state for the emission of gravitational waves.
A device in which a box with ultra high vacuum inside allows the amplification of the gravitational wave.
A device in which a box with non-linear material inside allows the amplification of the gravitational wave.
A device where the chaotic instability region is the Z=115 to Z=116 boundary.
A device where the chaotic instability region is the Z=X to Z=X+1 boundary. Where X is a number between 1 and 200.
A device where the chaotic instability region is the Z=X to Z=X+2 boundary. Where X is a number between 1 and 200.

Claims

1. Use of a high vacuum chamber as an amplifier of a gravitational wave.

2. The use of claim 1, wherein the pressure in the high vacuum chamber is below 10^{-3} mbar.

3. The use of any of claims 1 to 2, wherein the ratio of a wavelength of the gravitational wave by a length of the amplifier in a propagation direction of the gravitational wave is between 10^8 and 10^{16} wavelengths per meter.

4. The use of any of claims 1 to 3, wherein the amplifier amplifies the gravitational wave by a factor of 10 and 10^8 per meter of the amplifier in a propagation direction of the gravitational wave

5. The use of any of claims 1 to 4, wherein the high vacuum chamber has a length between 0.5 and 1000 meter in a propagation direction of the gravitational wave.

6. The use of any of claims 1 to 5, wherein a non-linear material for the gravitational wave is disposed in the high vacuum chamber.

7. A device for generating a gravitational wave, comprising a generator (10, 18) of an external energy;
a primary vacuum chamber (20) with window (19) transparent for the external energy;

a first vacuum pump (21) connected to the primary vacuum chamber (20) and configured to evacuate the primary vacuum chamber (20);
a converting material (22, 12) for converting the external energy into a gravitational wave, the converting material being disposed inside the primary vacuum chamber (20) such that the external energy illuminates the converting material (22);
a second vacuum chamber (16, 23) used as an amplifier of the gravitational wave according to any of claims 1 to 6; and
a second vacuum pump (24) connected to the second vacuum chamber (16, 23) and configured to evacuate the primary vacuum chamber (16, 23).

8. A device according to claim 7, wherein the converting material is excitable into an excited state by the external energy, wherein the excited state comprises a first oscillator of a first characteristic frequency comprising a mass and emitting the gravitational wave, and a second oscillator coupled with the first oscillator, and wherein a characteristic frequency of the second oscillator is smaller than the first characteristic frequency.

9. The device according to claim 8, wherein the first oscillator is not electrically charged.

10. The device according to any of claims 8 to 9, wherein each of the first and the second oscillator comprises a subnuclear structure.

11. The device according to any of claims 8 to 10, wherein the converting material in a state other than the excited state comprises a stable or metastable nucleus, and the external energy includes at least one of an electromagnetic wave and an elementary particle.

12. The device according to claim 11, wherein the electromagnetic wave comprises at least one of X-ray and gamma ray, and wherein the elementary particle comprises at least one of a neutron, a proton, an electron, a positron, and an antiproton.

13. The device according to claim 11 or 12, wherein a number of protons in the nucleus is between 90 and 125.

14. The device according to any of claims 7 to 12, wherein the converting material comprises Gadolinium.

15. The device according to any of claims 8 to 12, wherein the first oscillator is one of a superconducting electron pair and a crystal or molecular excitation in a frictionless paired state, the second oscillator is one of a molecular structure, an atom, and a crystal lattice, and the external energy is at least one of an electromagnetic excitation, a thermal excitation, and an acoustic excitation.

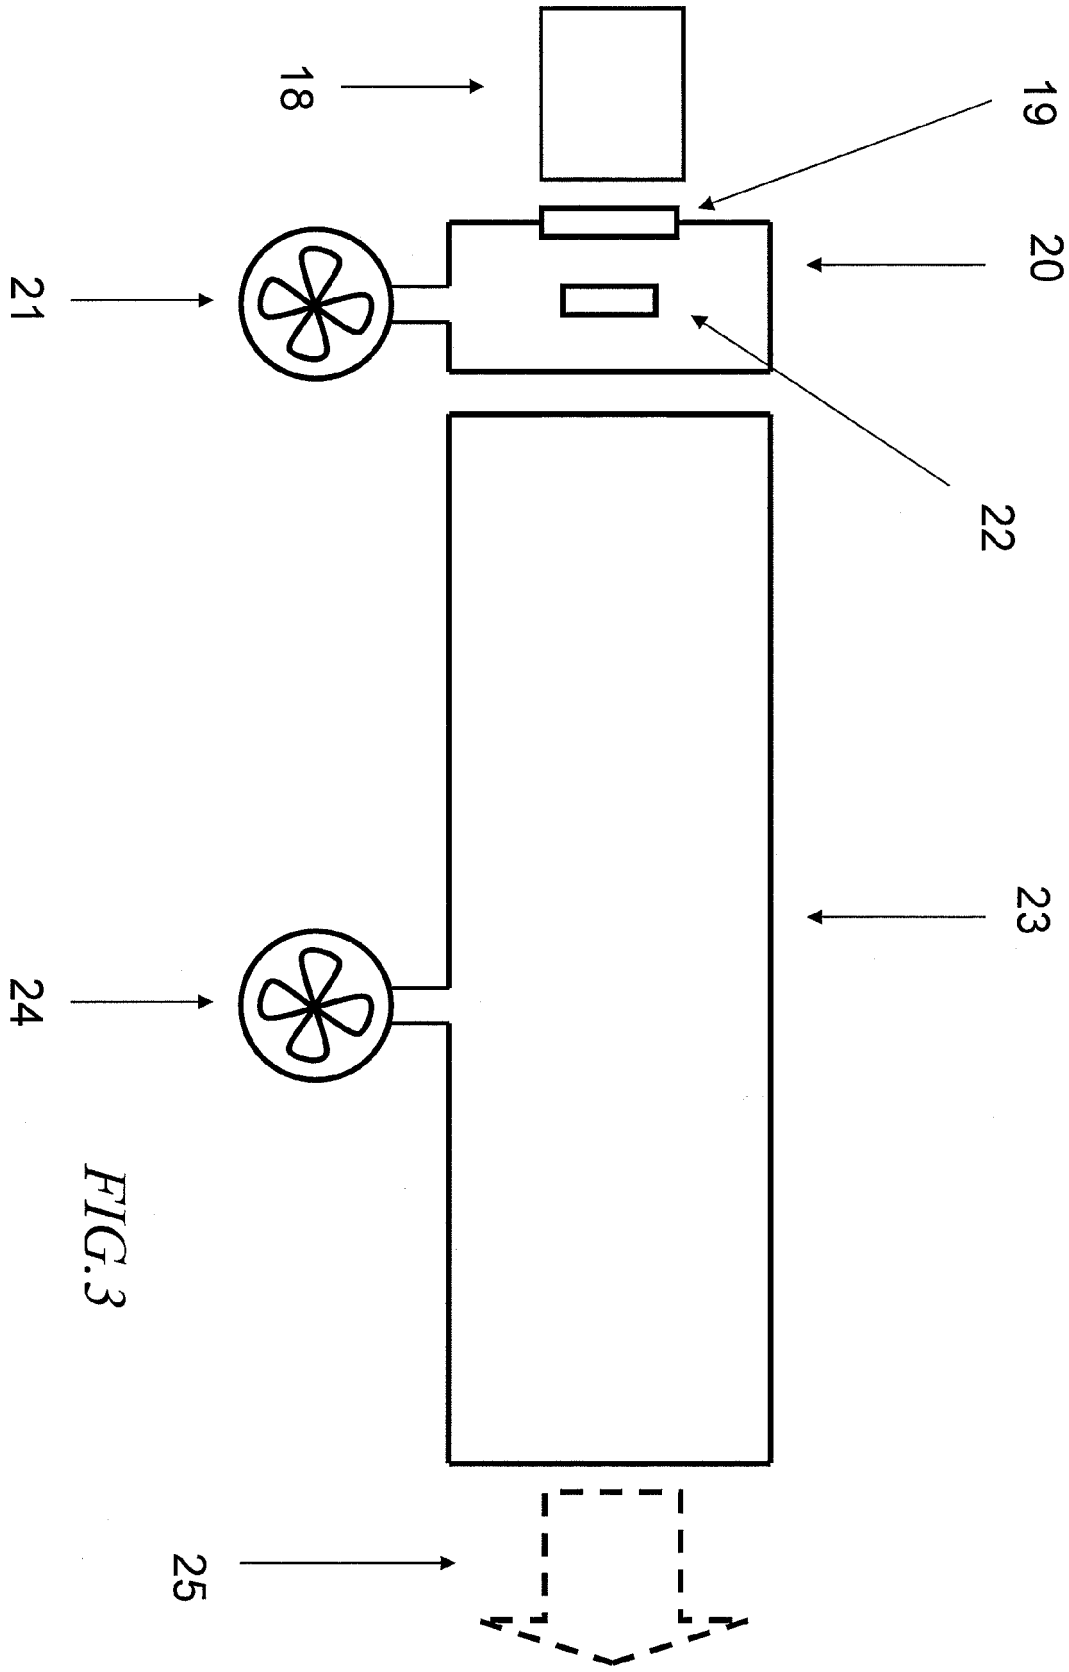

FIG.3

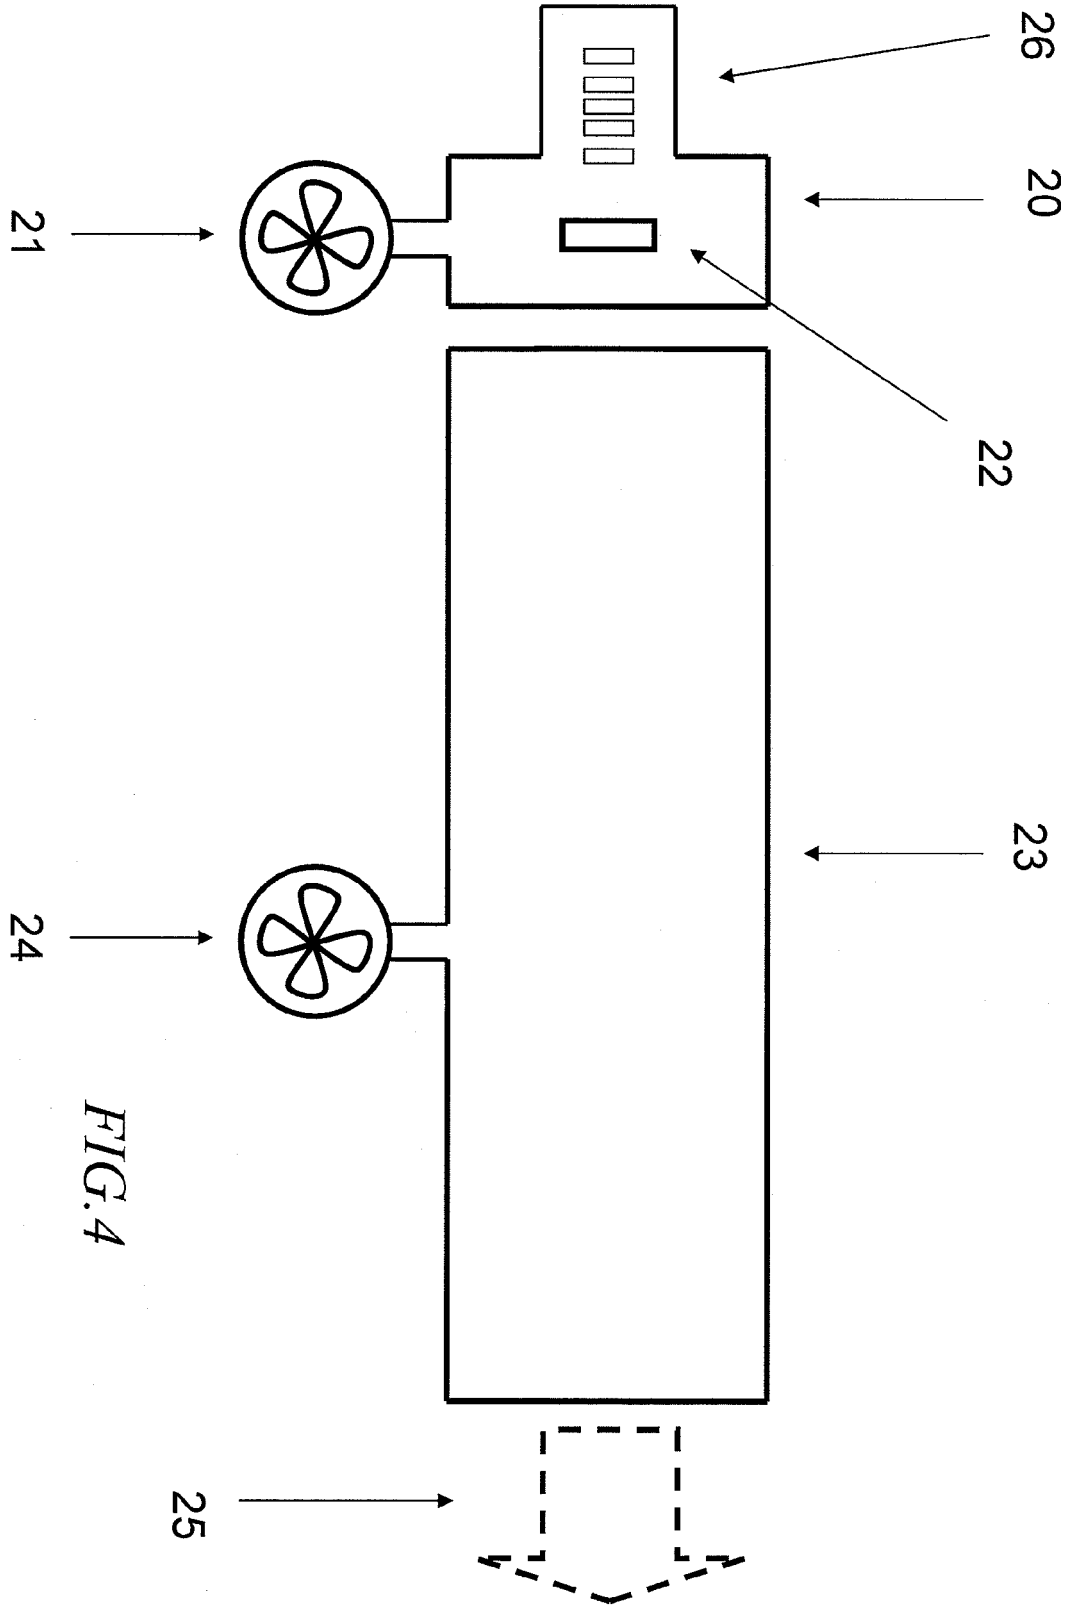

FIG.4

Europäisches Patentamt
European Patent Office
Office européen des brevets

DECLARATION

which under Rule 63 of the European Patent Convention shall be considered, for the purposes of subsequent proceedings, as the European search report

Application Number EP 09 15 6549

The Search Division considers that the present application, does not comply with the provisions of the EPC to such an extent that it is not possible to carry out a meaningful search into the state of the art on the basis of all claims

Reason:

All claims of the application include "amplification of gravitational waves". The possibility of amplification has so far not generally been recognized, prior art discusses amplification in combination with black holes. The application apparently targets amplification of gravitational waves by means of laboratory scale devices.
In the description, no clear description of an embodiment is present, only statements which say that certain materials or configuration may be used. In particular, the amplification is said to be made in a vacuum chamber, possibly by means of a nonlinear material (to gravitational waves). However no example of such a material is given in detail.
Further, reference is made to masses of nucleons, sometimes as nucleus of Gadolinium, but as well as a nucleus with Z=115, and a mass consisting of 10^7 nucleons. NB that the generation of the latter two has not yet been reported, yet confirmed.
Further, in one configuration an exciting coherent X-ray beam is to be used, and the description makes reference to and X-ray laser with energies preferable between 30 and 70 keV. Such an laser has not yet been realised.
In consequence, the application concerns entirely subject matter, which does not comply with the requirements of Art 83 EPC, and therefore a meaningful search is not possible.

The applicant's attention is drawn to the fact that a search may be carried out

Abstract We present a new kind of generator of internal waves which has been designed for three purposes. First, the oscillating boundary conditions force the fluid particles to travel in the preferred direction of the wave ray, hence reducing the mixing due to forcing. Second, only one ray tube is produced so that all of the energy is in the beam of interest. Third, temporal and spatial frequency studies emphasize the high quality for temporal and spatial monochromaticity of the emitted beam. The greatest strength of this technique is therefore the ability to produce a large monochromatic and unidirectional beam.

1 Introduction

Stratified fluids are nowadays a field of paramount importance in fluid mechanics and are carefully studied theoretically, experimentally and numerically by a large and always increasing scientific community. The underlying reason is, of course, the identification of many crucial phenomena appearing in the oceanic and atmospheric environments, where the stratification cannot be overlooked. The possibility to reproduce in a laboratory experiment conditions close to theoretical hypotheses is, of course, a very important way to validate theoretical ideas developed in the last decades. Indeed, if one will always rely on in situ observations for the final decisive tests, new fundamental ideas are usually derived within an oversimplified framework that cannot be reproduced in a real environment. Among many difficulties, let us mention just a few. The linear stratification hypothesis is almost always used in theoretical works despite the complicated oceanic or atmospheric stratification (Thorpe 2005). Internal waves are also often considered as monochromatic plane waves, while oceanic measurements usually report a beam-like structure, with a width smaller than a wavelength (Lam et al. 2004; Gerkema et al. 2004). The paradox of internal waves impinging onto topography (Dauxois and Young 1999) was solved for a linear oblique slope which can only be a poor description of a real seamount (Eriksen 1998). It is not satisfactory to test this last theoretical example by considering a *beam* impinging onto a *curved* topography in a fluid with a *real and complicated* stratification (exponential, thermocline, mixed layer,...). Indeed, possible disagreements between theoretical and experimental results might always be attributed to one of these three hypothesis which are not fulfilled in the experimental test. Controlled experiments in a simplified framework are therefore of paramount importance.

In a laboratory experiment, one can identify three main difficulties: the preparation of a stratified fluid with a controlled *stratification*, the *generation* and the

visualization of internal waves propagating within this fluid. The first difficulty was rapidly solved thanks to the well-known double bucket method and its improved versions (Oster 1965; Hill 2002; Benielli and Sommeria 1998). The visualization difficulty has been nicely solved in the last decade by two different techniques: the Schlieren method, on the one hand, later improved into the modern quantitative synthetic Schlieren method (Dalziel et al. 2000), gives time resolved density fields; on the other hand, the particle image velocimetry (PIV) technique provides time resolved velocity fields (Fincham and Delerce 2000). However, the generation of monochromatic plane waves remains a crucial problem from the experimental point of view. We propose in this article a new experimental set-up that is able to provide a single monochromatic and unidirectional large beam.

The paper is organized as follows. In Sect. 2, we briefly review existing generation methods, with a special emphasis on their limitations. In Sect. 3, we present the new internal waves generator. In Sect. 4, we analyze the internal waves which are generated with a particular emphasis on its temporal, and spatial properties. Section 5 concludes the paper.

2 Review of existing generation methods

2.1 Important properties of internal gravity waves

Internal waves in a continuously stratified fluid are shear waves that propagate with a phase velocity perpendicular to their group velocity. The density stratification allows the propagation of such waves by generating a restoring force. This latter is characterized by the Brunt–Väisälä frequency N, which corresponds to the vertical oscillation frequency of water masses in a local density gradient. It is defined as $N^2 = -(g/\rho)(\mathrm{d}\rho/\mathrm{d}z)$ where g is the gravity, ρ the density and z the vertical coordinate. The frequency N will be kept constant in the remainder of the paper.

In such a stratified fluid, it is well-known that the dispersion relation for linear internal gravity waves is

$$\omega = N \sin\theta, \tag{1}$$

where ω is the temporal frequency and θ the angle of the wave vector with the vertical direction. This dispersion relation emphasizes that for a fixed frequency, the direction in which the shear propagates is fixed and is denoted σ. This direction is also found to be orthogonal to the direction of propagation of the energy, denoted s.

The study of internal waves generation must therefore take into account these very unusual and restrictive geometrical conditions. Moreover, it is very important to notice that the spatial wavelength of the wave does not appear in the dispersion relation (1). There is no mechanism of wavelength selection other than the physical boundary conditions imposed by the forcing technique. This last point will be of first importance in the following.

2.2 Oscillating bodies

The simplest experiments on internal waves emission use oscillating bodies as radiation sources and, more precisely, in a two-dimensional set-up, a vertically oscillating cylinder (see the sketch in Fig. 1a). The first experiment was performed by Görtler (1943) in a two-dimensional setup. Nonetheless, as this experiment is often forgotten, one usually refers to the seminal experiment by Mowbray and Rarity (1967). This is nowadays a simple laboratory set-up, often used in laboratory tutorials at the undergraduate level. In the simplified two-dimensional set-up, these generators emit four beams of internal waves, making a constant angle with the horizontal. A typical resulting pattern is presented in Fig. 1b. Recent three-dimensional experiments with an oscillating sphere have reported striking double cones (Peacock and Weidman 2005).

As the wavelength does not enter the dispersion relation (1) of internal waves, it is absolutely non trivial, a priori, to predict the spatial structure of the beam. This question has been at the origin of several theoretical studies (Thomas and Stevenson 1972; Hurley 1997; Hurley and Keady 1997; Hurley and Hood 2001; Voisin 2003) which have proposed a non-trivial scaling of the beam spatial structure by the size of the object, the viscosity of the fluid and the emission frequency. In all cases, the beam envelope does not contain a full wavelength. Therefore, it is difficult to use these sources to study spatial properties of internal waves.

2.3 Paddle-like generators

It has also been proposed to generate directly a shear motion in the stratified fluid by using a multi-bladed folding paddle (McEwan 1973; Cacchione and Wunsch 1973; Teoh et al. 1997; Silva et al. 1997; Ivey et al. 2000; Gostiaux et al. 2006): see the sketch in Fig. 1c. The flow generated by such a device corresponds to the superposition of two shear waves propagating in opposite directions along the zig-zag paddle, each one being independently solution of the internal waves'

equations. Such a set-up thus generates two beams propagating symmetrically leftwards and rightwards (resp. upwards and downwards) when the paddle is set horizontally (resp. vertically) as in Teoh et al. (1997). Locating a vertical wall close to the paddle (see vertical black thick line in Fig. 1d) allows to avoid a second beam: moreover, because of the reflection of the leftward beam on this wall, one may increase artificially the width of the rightward beam.

The energy transmission is proportional to the sine of the angle between the paddle and the along-direction of the beam. To gain in amplitude, one might therefore propose to tilt the paddle orthogonally to the desired beam. One realizes immediately, however, that the generated shear is no more the superposition of two internal wave beams. Consequently it will excite strong nonlinearities. Intermediate position between the horizontal and this inclination can be proposed, this method, however, still generates higher harmonics. As shown in Fig. 1d (see Gostiaux et al. 2006 for additional details), the main part of the energy is transmitted to a beam of internal wave of frequency ω, while higher harmonics $n\omega$ are also excited by the oscillating paddle. Their frequencies being higher, their propagation angles are also larger (see Fig. 1d) and a screen can therefore be located appropriately to remove most harmonics (Gostiaux et al. 2006). Fortunately, in Ivey et al. (2000), this effect was avoided since the excitation frequency ω was larger than half of the Brunt–Väisälä. In conclusion, as avoiding harmonics generation is of primary importance for energy fluxes measurements and comparisons with theoretical predictions, especially for low frequency ratios ω/N, such a method is not ideal.

2.4 Tidal-like excitation

Finally, a third way of generating internal waves has been proposed and realized in a form of a global excitation of internal waves. A vertical periodic motion of the fluid container (see the sketch in Fig. 1e) acts as a perturbation of the gravity force on the whole fluid. Tidal-like excitations by barotropic forcing (Ivey and Nokes 1989; Gostiaux and Dauxois 2006) also excite globally the fluid. Resonant modes are selected and can be focused on internal waves attractors. This excitation

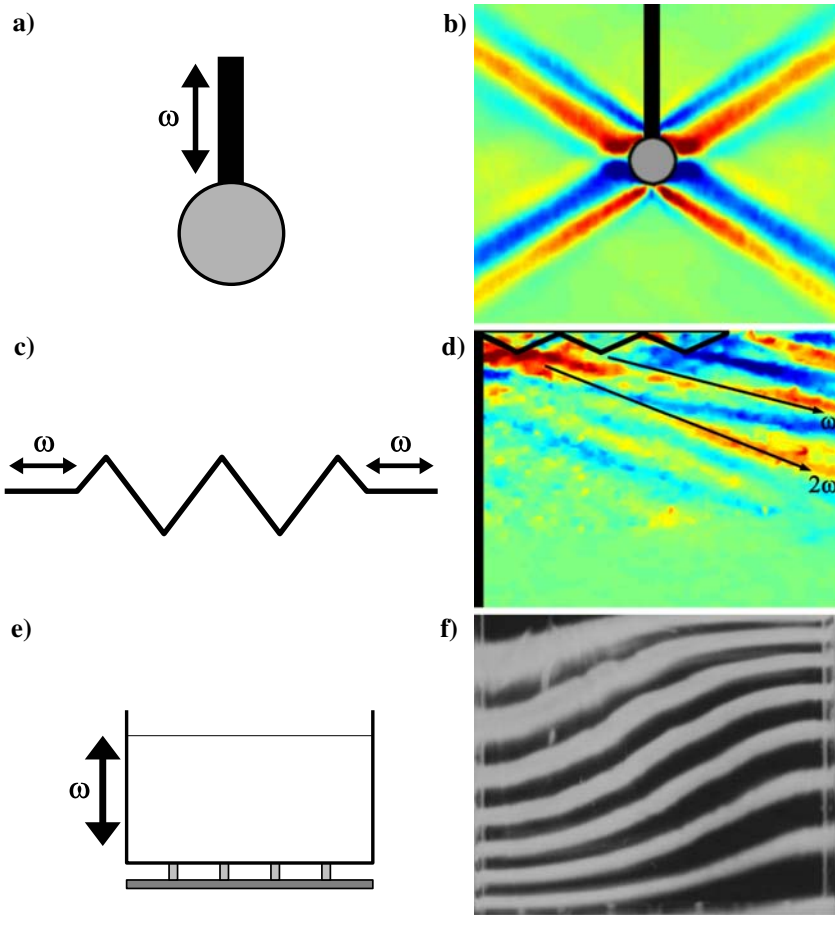

Fig. 1 Principles and internal waves patterns for the three previous internal gravity wave generators. **a** Presents the sketch of a vertically oscillating cylinder. **b** Shows the resulting four rays as captured with a synthetic Schlieren technique. **c** Presents the paddle-like generator, while **d** shows a typical instantaneous PIV measurement. Note harmonic waves propagating in different directions. **e** Presents the parametric excitation principle while **f** shows the resulting internal wave pattern (Benielli 1995)

is highly dependent of the size and shape of the fluid domain, and relies on resonances of the enclosed geometry itself (Maas et al. 1997) as shown in Fig. 1f.

The first very limitation is that oscillating vertically a large tank is, of course, very difficult and cannot be easily performed. In addition, the whole stratified fluid is thus excited so that it is not possible to discern how internal waves, generated in one part of the tank, might encounter independently a topography, or another internal wave, in another part of the tank.

3 The new solution for internal waves generation

As briefly motivated in the previous section, a new principle for internal wave generation has to be proposed, if a *monochromatic plane wave* is necessary for laboratory experiments. The key idea is to create physical boundary conditions that effectively propagate within the fluid interior, instead of a stationary forcing.

3.1 Mechanism of the generator

The generator consists of a pile of 24 expanded PVC sheets ($2 \times 36 \times 150$ cm) enclosed in a parallelepiped half-opened box and free to slip one over the other. The plates are weighted with thin lead sheets so that they are buoyantly neutral in water; it minimizes friction forces between plates. They are thus separated by 2.2 mm one from the other. Two rectangular holes in each plates allow two identical camshafts (see Fig. 2a)

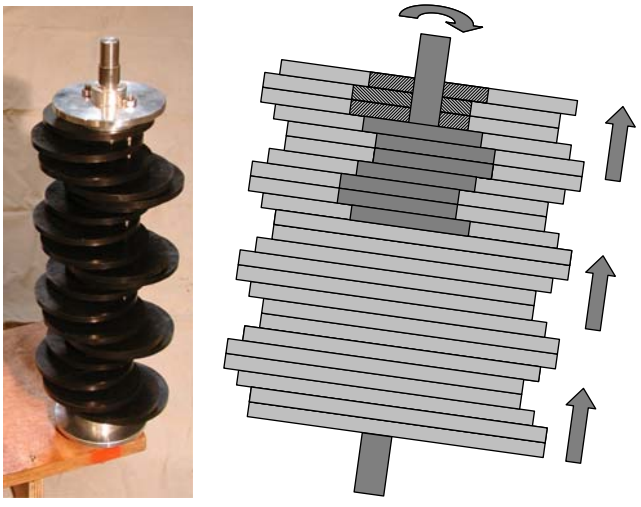

Fig. 2 Internal wave generator mechanism. The *left panel* presents one of the two identical camshafts, while the *right* one shows the cross section of the generator. One clearly identify the plates (*light grey*) and one of the camshafts (*dark grey*)

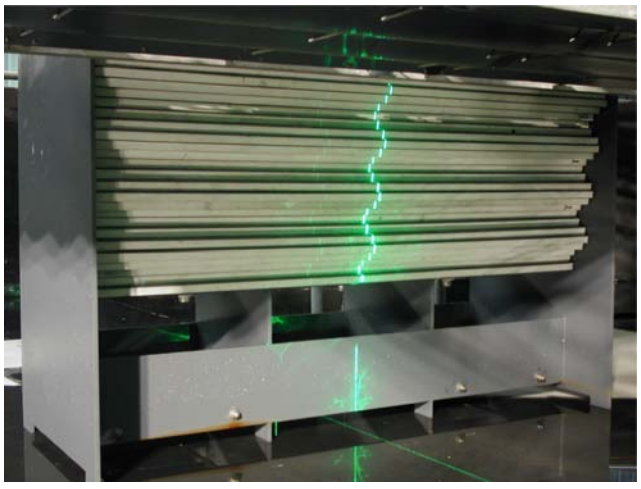

Fig. 3 Perspective view of the wave generator before the filling of the tank. The *thin vertical line* in the *middle* of the plates is the impact of the laser sheet, used for the PIV visualization. We can see the two *vertical* sidewalls of the generator that hinder to view the field very close to the generator

to go through the pile, imposing the relative position of the plates. At rest, the plates are sinusoidally shifted, due to the helicoidal repartition of the cams (see Fig. 2b). The rotation of the camshafts applies a periodic motion to the plates which propagates upward (resp. downward) for a clockwise (resp. anti-clockwise) rotation. The eccentricity of the camshafts defines the amplitude of oscillation of the plates, namely 6 cm peak to peak. A perspective view of the generator can be seen in Fig. 3.

To optimize the emission process, the generator is slightly tilted in direction of the emitted beam, i.e. the direction of shear propagation. In the following, we generate a downward propagating beam (defined by the direction of the group velocity) corresponding to an upward propagating shear (direction of the phase velocity). As anticipated, the device can easily generate upward propagating beams by inverting the sign of rotation of both camshaft.

3.2 Flow visualization

We performed experiments in the 13 m diameter circular tank of the Coriolis Plateform in Grenoble, filled with 90 cm of linearly stratified fluid at 3% corresponding to a Brunt–Väisälä period of $T_{\mathrm{BV}} = 11.7 \pm 0.2$ s. A vertical laser sheet illuminates the wavemaker (visible in Fig. 3) and the 400 μ diameter particles polystyrene beads seeded in the stratified fluid. PIV measurements of the velocity field were performed in order to characterize the waves generated by the new device. All experiments discussed in

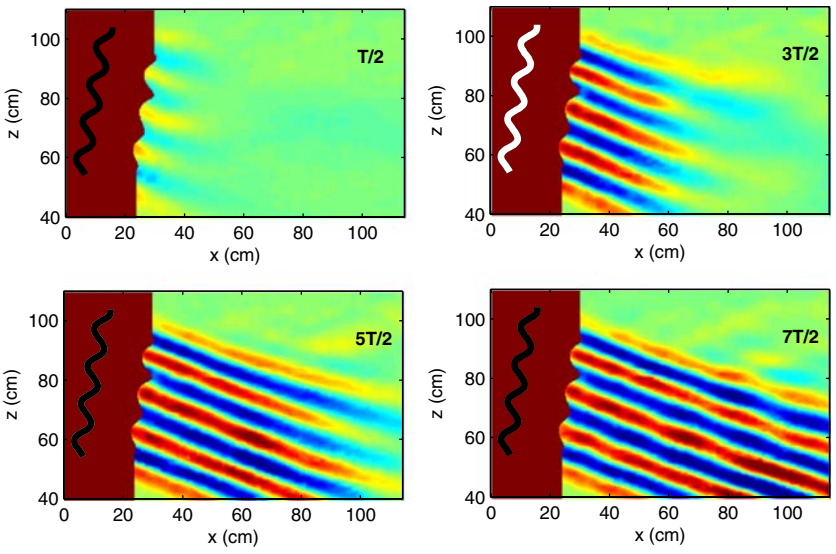

Fig. 4 Horizontal velocity pattern in the vertical plane after 1, 2, 3 and 4 periods T of excitation. The position of the wavemaker is indicated by the oscillating and *tilted white line*. On the *left* of each panel, the *shadowed region* corresponds to the invisible region hidden by the sidewalls of the generator

this paper were carried out with a period of excitation $T = 36$ s. It corresponds to an angle of emission $\theta = 19°$. Snapshots of the flow every 600 ms were recorded using a 12 bits $1{,}024 \times 1{,}024$ pixels camera. Subsequently, we compiled the CIV correlation algorithms (Fincham and Delerce 2000) between successive frames to get the velocity field induced by the wavemaker. Results are reported and analyzed in the next section.

4 Analysis of the emanating internal waves

4.1 Qualitative analysis

Figure 4 present four successive images of the emitted wave. Colors show the horizontal velocity which is the strongest component in this configuration since the angle of propagation is rather small. As can be seen, only one downward propagating beam is emitted: this is the first important improvement of this new generator. These four pictures clearly emphasize the generation of the internal plane waves propagating towards the fluid interior.

The transversal wave structure perfectly fits also the profile of the wavemaker, with four wavelengths emitted. It is the largest beam ever generated in a laboratory experiment. It is however important to stress that there is no theoretical limitation to have a larger beam. This is of crucial importance for experiments designed to test plane waves properties.

Figure 5 shows the velocity field. As expected, it is parallel to the direction of emission, emphasizing nicely the pure shear structure. Moreover, it clearly attests that iso-phase lines are propagating perpendicularly to the energy propagation. The maximal velocity value measured in that case is 1.8 mm/s, while amplitude displacements are of the order of 1 cm.

4.2 Temporal chromaticity

As stated in Sect. 1, *monochromatic* internal gravity waves are highly desirable for studying, for example, the role of nonlinearities involved in collisions with topography (Ivey and Nokes 1989; Dauxois and Young 1999; Gostiaux and Dauxois 2006) or with other internal waves (Teoh et al. 1997): the chromaticity quality of the incident beam is therefore of primary importance. With the present device, as the forcing is itself solution of the wave equation, no harmonics are measurable in the flow. To attest this result, Fig. 6a shows a temporal evolution of the horizontal velocity at a point situated in the centerline of the beam, 29 cm away from the generator.

First, note that the signal is vanishingly small before starting to increase at $t = 30$ s. This remark allows to compute the group velocity of the beam. As the generation and measurement points are distant by 29 cm, one gets a group velocity $c_g \simeq 0.97$ cm/s. This value has to be compared with the theoretical one, $c_g = \lambda/(T \tan\theta)$, where T is the excitation period, λ the wavelength of the internal beam and θ the angle of propagation. With $\lambda = 13.2$ cm, $T = 36$ s and $\theta = 19°$, the expected value $c_g = 1.06$ cm/s compares well with the measurement.

Moreover, one can notice that the transient regime is almost invisible as the wave reaches the measurement area. This allows to consider the forcing of such a wave as a suddenly switched on sinusoid (sinus function convoluted with a Heaviside distribution), which

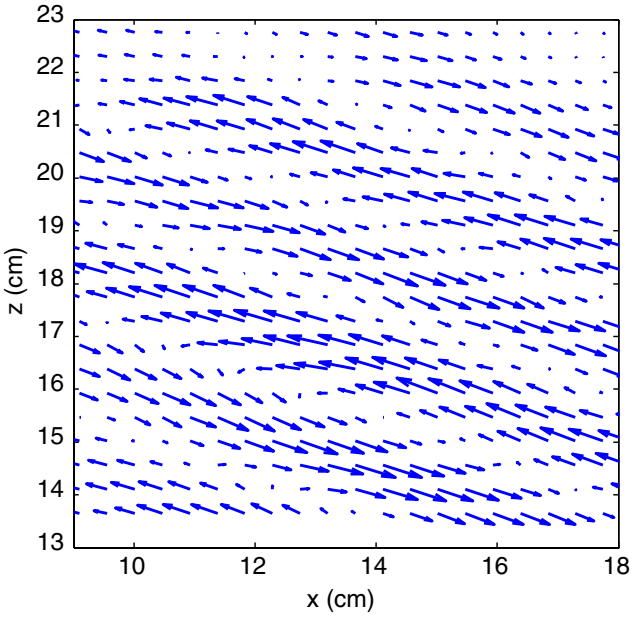

Fig. 5 Zoom of the velocity field generated by the generator

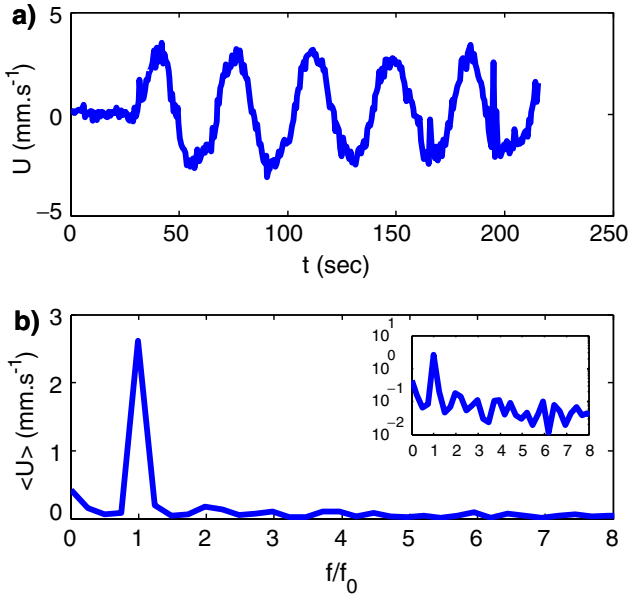

Fig. 6 Temporal analysis of the internal waves beam in a point located at 29 cm from the wavemaker and in the middle of the beam. **a** Presents the time evolution of the horizontal velocity field, while **b** shows the Fourier transform of this signal. Frequencies are renormalized with the excitation one, $f_0 = 1/T$. The *inset* in **b** presents the spectrum in logarithmic scale

allows fine comparisons with analytical results using such a forcing (Dauxois and Young 1999).

Once the beam reaches the measurement point, the velocity oscillates at a well defined frequency. The temporal spectrum of the wave, plotted in Fig. 6b, confirms that the frequency signal is, as expected, imposed by the generator. Moreover, it shows that amplitudes of higher harmonics (see the inset in logarithmic scale) are at least one order of magnitude smaller than the fundamental one. The emitted beam is thus highly temporally monochromatic. The latter characteristic allows to filter the velocity field at the excitation frequency in order to reduce measurement noise. The filtering technique is used in Figs. 7 and 8 which present spatial properties of the beam.

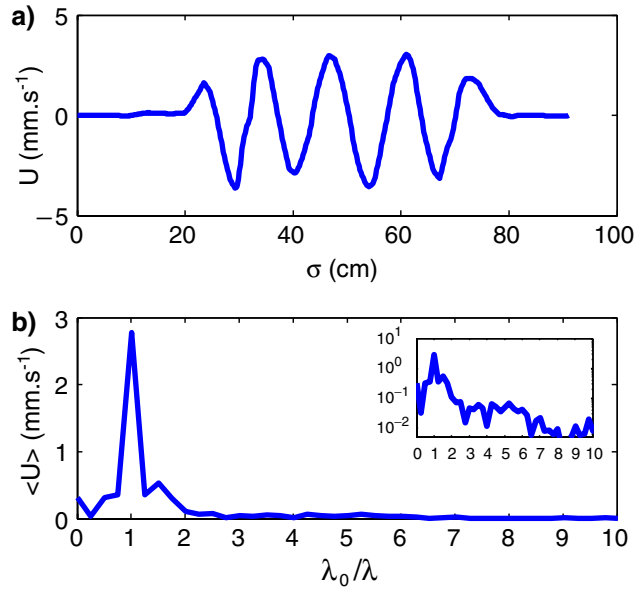

Fig. 7 Transversal structure of the internal waves beam, 29 cm from the wavemaker. **a** Presents the spatial evolution of the horizontal velocity field, while **b** shows the Fourier transform of this signal. Wavelengths are renormalized with the excitation one λ_0. The *inset* in **b** presents the spectrum in logarithmic scale

4.3 Spatial structure of the beam

Contrary to optical or acoustic waves, and owing to the unusual dispersion relation (1) of internal waves, temporal monochromatism does not imply any spatial monochromatism: it is necessary to study them separately. Figure 7a presents a cross section of the horizontal velocity field at 29 cm from the wavemaker. One may easily distinguish slightly more than four wavelengths. Its corresponding wavelength spectrum is shown in Fig. 7b. The spatial monochromatism of the produced beam is attested by the very well defined peak of the spectrum. Note that a careful study shows that end effects in the horizontal y-direction have very little, if no, consequences: one can only detect a very small transverse component of the velocity field.

Finally, Fig. 8 emphasizes that the viscous damping of the beam along its propagation is extremely weak.

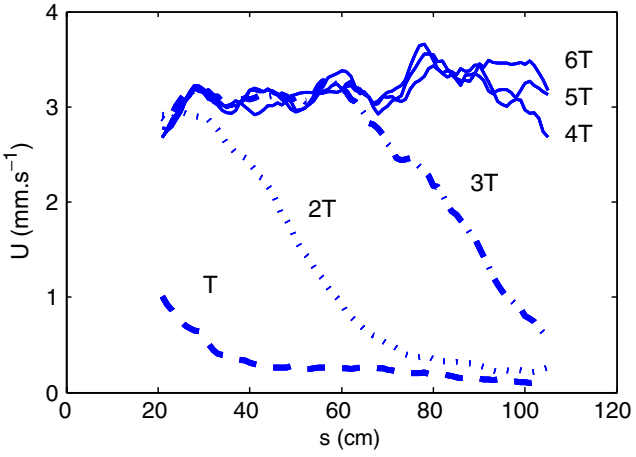

Fig. 8 Superposition of successive longitudinal profiles of the horizontal velocity after 1, 2, 3, 4, 5 and 6 excitation periods

One can notice the non-dispersive profile of the wave front: the beam does not disperse since it is spatially monochromatic. From this picture, it is possible to get another reliable estimate of the group velocity. Indeed, by measuring the location difference of the appearance of the velocity $U = 1$ mm/s or by trying to superpose the first three profiles, one gets $c_g \simeq 38$ cm per period i.e. 1.06 cm/s: the precise theoretical value derived previously.

This generator was used to excite waves up to 1.5 m away from the region of interest, no appreciable damping was measured at this point. The absence of nonlinear losses may explain this remarkable constancy of the wave amplitude.

5 Conclusion

We have reported the design of a new kind of internal waves generator that imposes a rigid boundary condition compatible with the equations governing the propagation of plane internal waves. By generating a propagating shear, we select a single direction of emission of the waves. The waves emitted are purely monochromatic, both spatially and temporally, which is of first importance for the study of nonlinear processes involved in internal waves dynamics.

Finally, it is important to emphasize that this experimental setup allows to generate any kind of wave form. Not only sinusoidal, but also gaussian beams or more complicated shapes can be easily generated, by modifying the camshafts eccentricity appropriately. This possibility opens new perspective for future studies of the dynamics of internal waves in stratified fluids.

Acknowledgments We warmly thank J. Sommeria for helpful discussions and S. Viboud for help during the experiments. Figure 1f was obtained by D. Benielli and J. Sommeria. Comments to the manuscript by Denis Martinand are deeply appreciated. This work has been partially supported by 2005-ANR Project TOPOGI-3D and by the 2006-PATOM CNRS program.

GRAVITY WAVE DYNAMICS AND EFFECTS IN THE MIDDLE ATMOSPHERE

David C. Fritts and M. Joan Alexander
Colorado Research Associates Division
Northwest Research Associates
Boulder, Colorado, USA

Received 6 July 2001; revised 29 August 2002; accepted 6 November 2002; published 16 April 2003.

[1] Atmospheric gravity waves have been a subject of intense research activity in recent years because of their myriad effects and their major contributions to atmospheric circulation, structure, and variability. Apart from occasionally strong lower-atmospheric effects, the major wave influences occur in the middle atmosphere, between ~ 10 and 110 km altitudes because of decreasing density and increasing wave amplitudes with altitude. Theoretical, numerical, and observational studies have advanced our understanding of gravity waves on many fronts since the review by *Fritts* [1984a]; the present review will focus on these more recent contributions. Progress includes a better appreciation of gravity wave sources and characteristics, the evolution of the gravity wave spectrum with altitude and with variations of wind and stability, the character and implications of observed climatologies, and the wave interaction and instability processes that constrain wave amplitudes and spectral shape. Recent studies have also expanded dramatically our understanding of gravity wave influences on the large-scale circulation and the thermal and constituent structures of the middle atmosphere. These advances have led to a number of parameterizations of gravity wave effects which are enabling ever more realistic descriptions of gravity wave forcing in large-scale models. There remain, nevertheless, a number of areas in which further progress is needed in refining our understanding of and our ability to describe and predict gravity wave influences in the middle atmosphere. Our view of these unknowns and needs is also offered. *INDEX TERMS:* 3319 Meteorology and Atmospheric Dynamics: General circulation; 3334 Meteorology and Atmospheric Dynamics: Middle atmosphere dynamics (0341, 0342); 3379 Meteorology and Atmospheric Dynamics: Turbulence; 3384 Meteorology and Atmospheric Dynamics: Waves and tides; *KEYWORDS:* gravity waves; middle atmosphere dynamics; wave-mean flow interactions; wave-wave interactions; gravity wave instability; turbulence

1. INTRODUCTION

[2] Considerable progress has occurred in our understanding of middle atmosphere gravity waves in the four decades since the pioneering study by *Hines* [1960]. Indeed, interest in the field continues to expand as the many effects of gravity waves become better understood. Early results were reviewed extensively by *Fritts* [1984a], while subsequent reviews addressed specific aspects of gravity wave instability [*Fritts and Rastogi*, 1985], saturation [*Dunkerton*, 1989; *Fritts*, 1989], or climatologies and effects [*Vincent*, 1984a; *Schoeberl*, 1987; *Hamilton*, 1996; *McLandress*, 1998]. Arguably, the greatest quantitative advances in our understanding have been the most recent and have accompanied equally dramatic advances in observational and computational techniques and capabilities. This review will span middle atmosphere gravity wave dynamics and effects but will emphasize results subsequent to the review by *Fritts* [1984a].

[3] In retrospect, our understanding of middle atmosphere gravity waves in 1984 was quite limited. We had recognized the role of gravity waves in transporting energy and momentum, in contributing turbulence and mixing, and in influencing the mean circulation and thermal structure of the middle atmosphere, based on limited theoretical, numerical, and observational studies [*Lindzen*, 1981; *Holton*, 1982, 1983; *Vincent and Reid*, 1983]. However, we had little or no understanding of the characteristics of the gravity wave spectrum and of its behavior with altitude, of the variability imposed by sources and variable mean and low-frequency motions, of the global climatology of gravity waves and their effects, or of the processes and interactions that constrain wave amplitudes, effect spectral energy transfers, and account for turbulence, fluxes, and mixing. We also had explored only the most rudimentary schemes for describing gravity wave effects in large-scale models [*Lindzen*, 1981; *Holton*, 1982; *Matsuno*, 1982; *Dunkerton*, 1982a] and had no appreciation for the rich range of

behaviors accompanying gravity waves throughout the middle atmosphere.

[4] More recent studies have yielded a more detailed understanding of middle atmosphere gravity waves on many fronts. In situ, ground-based, and space-based observational studies have contributed greatly to our knowledge of gravity wave scales, amplitudes, fluxes, and spectra. They have also addressed instability dynamics, vertical propagation, variations with altitude, and seasonal and geographic variability. Recent theoretical and numerical studies have addressed source characteristics and scales, spectral character, evolution, and energy transfers, instability dynamics, wave–wave and wave–mean flow interactions, and the implications of various parameterizations for atmospheric circulation and structure.

[5] Our purpose here is to review the contributions since 1984 that have led to our more advanced understanding of middle atmosphere gravity waves and their effects. In doing so, it will be impossible to cite all of the work that has been published. Instead, we will restrict ourselves to what we consider to be the more significant contributions in each area. We also will note, on occasion, where errors in interpretation have occurred and where debate over observational or theoretical implications continues to allow the reader to steer clear of mistakes and identify topics of current interest.

[6] We begin by reviewing the linear inviscid theory of gravity wave propagation as well as departures due to nonlinearity, dissipation via wave breaking, transience, localization, and variable environments, in section 2. Sources, propagation, and scales relevant to the middle atmosphere will be addressed in section 3. Spectral character and evolution, including evidence for and against universality, are reviewed in section 4. Section 5 summarizes what is known of gravity wave climatologies and their implications for sources and effects. Gravity wave interactions, instability dynamics, and wave-breaking or saturation processes are examined in section 6. Sections 7 and 8 describe efforts to parameterize gravity wave effects to date and their implementation and effects on the large-scale circulation and structure of the middle atmosphere. Our summary and recommendations are presented in section 9.

2. EQUATIONS OF MOTION

[7] Atmospheric gravity waves can frequently be described with a simple linear theory that treats them as small departures from a stably stratified background state varying only in the vertical. The restoring force for gravity wave oscillations is the buoyancy that results from the adiabatic displacements of air parcels characteristic of these disturbances. Here we outline a general gravity wave solution to the linearized forms of the fundamental conservation equations. We then discuss the simpler forms of the dispersion and polarization relations that result when limited portions of the possible gravity wave spectrum are considered.

2.1. Linear Theory

[8] We begin with the fundamental fluid equations in Cartesian coordinates (x, y, z) that follow from conservation of momentum, mass, and energy [e.g., *Holton*, 1992]:

$$\frac{du}{dt} - fv + \frac{1}{\rho}\frac{\partial p}{\partial x} = X\,, \tag{1}$$

$$\frac{dv}{dt} + fu + \frac{1}{\rho}\frac{\partial p}{\partial y} = Y\,, \tag{2}$$

$$\frac{dw}{dt} + \frac{1}{\rho}\frac{\partial p}{\partial z} + g = 0\,, \tag{3}$$

$$\frac{1}{\rho}\frac{d\rho}{dt} + \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0\,, \tag{4}$$

$$\frac{d\theta}{dt} = Q\,, \tag{5}$$

where d/dt represents a total, or advective, derivative; (u, v, w) is the fluid velocity vector; and the terms X, Y, and Q represent unspecified forcings that could include wave-driven forces and diffusive mixing effects accompanying wave dissipation. The remaining symbols have the usual meanings: p is pressure, ρ is density ($\rho = \rho_0 \exp[-(z - z_0)/H]$ with $\rho_0 = \rho(z_0)$ the density at reference level z_0 and H the scale height), and $f = 2\Omega sin\phi$ is the Coriolis parameter (where Ω is the Earth rotation rate and ϕ is latitude). These five equations plus the definition of potential temperature θ,

$$\theta = \frac{p}{\rho R}\left(\frac{p_0}{p}\right)^{\kappa}\,, \tag{6}$$

define a complete set describing inviscid fluid motions. Here $p_0 = p(z_0)$, R is the ideal gas constant, and $\kappa = c_p/c_v$ is the ratio of specific heats at constant pressure and constant volume. Here θ represents the temperature a parcel of air would have if lowered adiabatically from p to p_0.

[9] The unforced forms of equations (1)–(6) linearized about a horizontally uniform hydrostatic basic state with background wind ($\bar{u}$, $\bar{v}$, 0), potential temperature $\bar{\theta}$, pressure $\bar{p}$, and density $\bar{\rho}$ varying only in z are

$$\frac{Du'}{Dt} + w'\frac{\partial \bar{u}}{\partial z} - fv' + \frac{\partial}{\partial x}\left(\frac{p'}{\bar{\rho}}\right) = 0\,, \tag{7}$$

$$\frac{Dv'}{Dt} + w'\frac{\partial \bar{v}}{\partial z} + fu' + \frac{\partial}{\partial y}\left(\frac{p'}{\bar{\rho}}\right) = 0\,, \tag{8}$$

$$\frac{Dw'}{Dt} + \frac{\partial}{\partial z}\left(\frac{p'}{\bar{\rho}}\right) - \frac{1}{H}\left(\frac{p'}{\bar{\rho}}\right) + g\frac{\rho'}{\bar{\rho}} = 0\,, \tag{9}$$

$$\frac{D}{Dt}\left(\frac{\theta'}{\bar{\theta}}\right) + w'\frac{N^2}{g} = 0\,, \tag{10}$$

$$\frac{D}{Dt}\left(\frac{\rho'}{\bar{\rho}}\right) + \frac{\partial u'}{\partial x} + \frac{\partial v'}{\partial y} + \frac{\partial w'}{\partial z} - \frac{w'}{H} = 0\,, \quad (11)$$

$$\frac{\theta'}{\bar{\theta}} = \frac{1}{c_s^2}\left(\frac{p'}{\bar{\rho}}\right) - \frac{\rho'}{\bar{\rho}}\,. \quad (12)$$

Here the derivative D/Dt is the linearized form of the time derivative,

$$\frac{D}{Dt} = \frac{\partial}{\partial t} + \bar{u}\,\frac{\partial}{\partial x} + \bar{v}\,\frac{\partial}{\partial y}\,, \quad (13)$$

primed quantities are perturbations to the background state, and $N = (g\partial \ln\theta/\partial z)^{1/2}$ is the buoyancy frequency.

[10] We now neglect the background shear terms in equations (7) and (8) by assuming $(\bar{u}, \bar{v})$ and N vary only slowly over a wave cycle in the vertical (the WKB approximation [e.g., *Gill*, 1982]). We also assume the gravity wave solutions have the form

$$\left(u',\, v',\, w',\, \frac{\theta'}{\bar{\theta}},\, \frac{p'}{\bar{\rho}},\, \frac{\rho'}{\bar{\rho}}\right) = (\tilde{u}, \tilde{v}, \tilde{w}, \tilde{\theta}, \tilde{p}, \tilde{\rho}) \cdot \exp\left[i(kx + ly + mz - \omega t) + \frac{z}{2H}\right]. \quad (14)$$

These describe a monochromatic wave perturbation with wave number components (k, l, m) and ground-relative (Eulerian) frequency ω. Substitution into equations (7)–(12) yields a set of six algebraic equations for $(\tilde{u}, \tilde{v}, \tilde{w}, \tilde{\theta}, \tilde{p}, \tilde{\rho})$:

$$-i\hat{\omega}\tilde{u} - f\tilde{v} + ik\tilde{p} = 0\,, \quad (15)$$

$$-i\hat{\omega}\tilde{v} + f\tilde{u} + il\tilde{p} = 0\,, \quad (16)$$

$$-i\hat{\omega}\tilde{w} + \left(im - \frac{1}{2H}\right)\tilde{p} = -g\tilde{\rho}\,, \quad (17)$$

$$-i\hat{\omega}\tilde{\theta} + (N^2/g)\tilde{w} = 0\,, \quad (18)$$

$$-i\hat{\omega}\tilde{\rho} + ik\tilde{u} + il\tilde{v} + \left(im - \frac{1}{2H}\right)\tilde{w} = 0\,, \quad (19)$$

$$\tilde{\theta} = \tilde{p}/c_s^2 - \tilde{\rho}\,, \quad (20)$$

where $\hat{\omega} = \omega - k\bar{u} - l\bar{v}$ is called the intrinsic frequency, i.e., the frequency that would be observed in a frame of reference moving with the background wind $(\bar{u}, \bar{v})$. The above equations can be combined to form a single equation for the perturbation vertical velocity amplitude. Demanding the imaginary coefficients of this equation go to zero gives,

$$\frac{g}{c_s^2} = \frac{1}{H} - \frac{N^2}{g}\,, \quad (21)$$

$$\hat{\omega}^2\left(k^2 + l^2 + m^2 + \frac{1}{4H^2} - \frac{(\hat{\omega}^2 - f^2)}{c_s^2}\right) = N^2(k^2 + l^2) + f^2\left(m^2 + \frac{1}{4H^2}\right). \quad (22)$$

The second equation is fourth-order in $\hat{\omega}$ and supports both acoustic and gravity waves. By letting the sound speed $c_s \to \infty$ we retain the compressibility term related to the background density gradient and obtain the gravity wave dispersion relation,

$$\hat{\omega}^2 = \frac{N^2(k^2 + l^2) + f^2\left(m^2 + \frac{1}{4H^2}\right)}{k^2 + l^2 + m^2 + \frac{1}{4H^2}}\,, \quad (23)$$

or alternatively for the vertical wave number as

$$m^2 = \frac{(k^2 + l^2)(N^2 - \hat{\omega}^2)}{(\hat{\omega}^2 - f^2)} - \frac{1}{4H^2}\,. \quad (24)$$

The dispersion relation relates the wave frequency to the wave's spatial characteristics (wave numbers) and to the background atmosphere properties N and $(\bar{u}, \bar{v})$. The gravity wave solutions above admit waves with a broad range of properties. For vertically propagating waves, (k, l, m) are real, and the intrinsic frequency is confined to the range $N > \hat{\omega} > |f|$. All parts of this spectrum can be important to middle-atmosphere dynamics. Because of this wide range of properties and because the intrinsic frequency and vertical wave number can vary strongly as a wave propagates vertically through background shear and stability gradients, models describing their propagation across a wide range of conditions may need to retain all terms in equation (23) in their analysis. Simpler forms representing waves in certain limited regions of this spectral space, however, provide considerable insight and will be summarized below.

[11] The wave group velocity describes energy transport and wave packet propagation and is written as

$$(c_{gx}, c_{gy}, c_{gz}) = \left(\frac{\partial\omega}{\partial k}, \frac{\partial\omega}{\partial l}, \frac{\partial\omega}{\partial m}\right) = (\bar{u}, \bar{v}, 0) + \frac{[k(N^2 - \hat{\omega}^2), l(N^2 - \hat{\omega}^2), -m(\hat{\omega}^2 - f^2)]}{\hat{\omega}\left(k^2 + l^2 + m^2 + \frac{1}{4H^2}\right)}. \quad (25)$$

Our sign convention here assumes that $\hat{\omega}$ is positive definite. The vector (k, l) defines the direction of horizontal propagation. Then m is negative for upward group velocity and positive for downward. Thus, for eastward $(k > 0)$ and upward $(m < 0)$ energy propagation relative to the wind, intrinsic phase speeds are eastward $(\hat{c}_x = \hat{\omega}/k)$ and downward $(\hat{c}_z = \hat{\omega}/m)$ relative to the wind. Note that the phase speed is not a vector quantity, although wave phase propagation has a direction given by the vector (k, l, m).

[12] Polarization relations relating perturbation amplitudes of the different variables to one another can also be derived from equations (15)–(20). Some useful examples are

$$\tilde{u} = \left(\frac{i\hat{\omega}k - fl}{i\hat{\omega}l + fk}\right)\tilde{v}, \tag{26}$$

$$\tilde{p} = \left(\frac{\hat{\omega}^2 - f^2}{\hat{\omega}k + ifl}\right)\tilde{u} = \left(\frac{\hat{\omega}^2 - f^2}{\hat{\omega}l - ifk}\right)\tilde{v}, \tag{27}$$

$$\tilde{w} = \frac{\left(m - \frac{i}{2H}\right)\hat{\omega}}{N^2 - \hat{\omega}^2}\tilde{p}, \tag{28}$$

and equation (18).

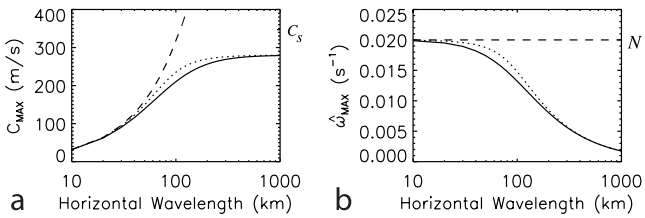

Figure 1. Analytical solutions derived from linear theory for the (a) maximum intrinsic phase speed (c_{MAX}) and (b) maximum intrinsic frequency (ω_{MAX}) at the point of total internal reflection, also known as the turning level. The dashed and solid lines are the incompressible and fully compressible solutions, respectively. The dotted line shows the approximation given by equation (29).

2.1.1. High-Frequency Waves: $\hat{\omega} \gg f$

[13] The dispersion relation (23) is derived by neglecting acoustic wave solutions, but the terms proportional to $1/4H^2$ retain one of the larger compressibility effects associated with gravity wave motions. These arise when the vertical wave number m becomes small so that $1/2H$ is a nonnegligible factor. With $H \sim$ 7 km in the middle atmosphere, this term becomes significant for waves with vertical wavelengths of ~30 km or longer, where the change in background density becomes significant over the vertical wavelength of the wave. This compressibility effect is important in the interpretation of airglow images of gravity wave perturbations near the mesopause [e.g., *Swenson et al.*, 2000]. As the vertical wavelength grows very large and $m \rightarrow 0$, the wave will undergo total internal reflection where the vertical group velocity can change sign (called a turning level). Above this level, the wave is evanscent. If turning levels occur both above and below, the wave is said to be ducted. Observational and modeling studies associated with these effects will be described further in section 3.2.2.

[14] Neglecting rotation effects but retaining the scale-height compressibility term and setting $m = 0$ in equation (23) yields an equation describing the maximum horizontal intrinsic phase speed $\hat{c}_{max}$ prior to total internal reflection as a function of horizontal wavelength:

$$|\hat{c}_{max}| = N\left(k^2 + l^2 + \frac{1}{4H^2}\right)^{-1/2}. \tag{29}$$

This gives a useful approximation to the fully compressible solution [*Marks and Eckermann*, 1995]. Figure 1 compares solutions for $\hat{c}_{max}$ and the corresponding maximum intrinsic frequency $\hat{\omega}_{max}$ versus horizontal wavelength for the fully compressible, incompressible, and approximate equation (29) solutions.

[15] Figure 1a shows that short horizontal wavelengths are much more easily reflected and will likely remain trapped at lower altitudes. Thus only waves with horizontal wavelengths >10 km are generally considered important to middle-atmosphere dynamics. Although the vertical wavelength theoretically goes to infinity at the turning level (and therefore the WKB approximation should be violated), the theory embodied in equation (29) appears to provide a good approximation even for waves observed near this theoretical limit [*Swenson et al.*, 2000].

[16] For high-frequency waves for which the Coriolis force can be neglected and for which $m^2 \gg 1/4H^2$, the dispersion relation simplifies to

$$\hat{\omega}^2 = \frac{N^2(k^2 + l^2)}{k^2 + l^2 + m^2} = N^2\cos^2\alpha, \tag{30}$$

where α is the angle between lines of constant phase and the vertical. These are simple plane waves with zero velocity perturbations perpendicular to the plane of propagation. Group velocity simplifies to

$$(c_{gh}, c_{gz}) = (\bar{u}_h, 0) + \frac{Nm}{k_h^2 + m^2}\frac{(m, -k_h)}{(k_h^2 + m^2)^{1/2}}, \tag{31}$$

where c_{gh} is the horizontal component of group velocity, $\bar{u}_h$ the horizontal wind in the direction of propagation, and $k_h = \sqrt{k^2 + l^2}$ is the horizontal wave number. Note that phase propagation is downward ($m < 0$) for upward group velocity. In this form it can be seen that group velocity is parallel to lines of constant phase and perpendicular to phase propagation.

[17] High intrinsic frequency waves are observed not only in mesopause airglow image data [*Swenson and Espy*, 1995; *Taylor and Garcia*, 1995; *Gardner et al.*, 1996; *Taylor et al.*, 1997; *Isler et al.*, 1997; *Hickey et al.*, 1998; *Haque and Swenson*, 1999] but also in sublimb viewing infrared and microwave satellite observations in the stratosphere [*Wu and Waters*, 1996a, 1996b; *Alexander*, 1998; *Dewan et al.*, 1998; *Picard et al.*, 1998; *McLandress et al.*, 2000] and in middle-atmosphere radar data [*Reid et al.*, 1988; *Fritts et al.*, 1990a, 1992; *Fritts and Wang*, 1991; *Hoppe and Fritts*, 1995; *Mitchell and Howells*, 1998].

2.1.2. Medium-Frequency Waves: $N \gg \hat{\omega} \gg f$

[18] For gravity waves with midrange intrinsic frequencies, very simplified relationships emerge that lend valuable insight into gravity wave properties and the effects due to changes in the background wind and stability. Letting c_h represent the horizontal phase speed and $k_h = \sqrt{k^2 + l^2}$, the dispersion relation then simplifies to

$$\hat{\omega} = N\left|\frac{k_h}{m}\right|, \tag{32}$$

and the vertical wave number can now be very simply related to the background wind and stability:

$$|m| = \frac{N}{|\hat{c}_h|}. \tag{33}$$

Note that $k_h > 0$ for $\hat{c}_h = (c_h - \bar{u}_h) > 0$, and $k_h < 0$ for $\hat{c}_h < 0$. Equations (32) and (33) demonstrate that vertical wavelength and intrinsic frequency are both proportional to the intrinsic phase speed $\hat{c}_h = c_h - \bar{u}_h$. The level where $c_h = \bar{u}_h(z)$ is a critical level for the wave where vertical wavelength shrinks to zero. This theoretical limit is never achieved in the real atmosphere because a host of instability and dissipation mechanisms become more likely as a wave approaches a critical level.

[19] The group velocity for medium-frequency gravity waves becomes

$$(c_{gh}, c_{gz}) = (\bar{u}_h, 0) + \left(\frac{\hat{\omega}}{k_h}, \frac{-\hat{\omega}}{m}\right) \tag{34}$$

and has the same magnitude as the phase propagation but opposite sign in the vertical. The time-dependent ray equations [*Lighthill*, 1978] show that a wave packet requires an infinite time to reach a critical level (with $m \to \infty$), implying that time-dependent and nonlinear effects will become important as a critical level is approached. Note, however, that wave transience and time dependence of the background flow can allow different interactions near the critical level. Departures from linear theory due to transience and nonlinearity are discussed in section 6.

[20] The polarization relations under the medium-frequency approximation take simple forms:

$$\tilde{p} = c_{gz}\tilde{w}, \tag{35}$$

$$\tilde{w} = -\frac{k_h}{m}\tilde{u}_h = \frac{k_h\hat{c}_h}{N}\tilde{u}_h = \frac{\hat{\omega}}{N}\tilde{u}_h. \tag{36}$$

Note that group velocity, vertical wavelength, and intrinsic frequency increase as a wave propagates "upshear," defined as an altitude region where the intrinsic phase speed $|\hat{c}_h|$ is increasing. These simplified forms demonstrate that vertical velocity will grow proportionately larger than the horizontal velocity perturbations in these conditions, and pressure perturbations become increasingly important. The opposite is true for waves propagating "downshear" such as those approaching a critical level ($|\hat{c}_h| \to 0$). In fact, it is the tendency for $\tilde{u}/|\hat{c}_h|$ to increase as the wave approaches a critical level that drives the tendency for instability and turbulence generation. These approximations for waves with midrange frequencies are inappropriate for most detailed analyses, but the set of very simple relationships that results provides an extremely valuable intuitive view of gravity wave properties and their relationship to background winds and stability.

2.1.3. Low-Frequency Waves: $\hat{\omega} \sim f$

[21] Low-frequency gravity waves, or inertia-gravity waves, are those for which the rotation of the Earth has an important influence. These wave perturbations have an interesting three-dimensional helical structure. Velocity perturbations in the direction perpendicular to the direction of propagation are no longer zero but grow proportionately larger as intrinsic frequency decreases toward f. For a zonally propagating wave the meridional velocity amplitude $\tilde{v}$ is

$$\tilde{v} = -i\frac{f}{\hat{\omega}}\tilde{u}. \tag{37}$$

An approximation to the dispersion relation appropriate for both low- and medium-frequency gravity waves is

$$\hat{\omega}^2 = N^2\frac{k_h^2}{m^2} + f^2. \tag{38}$$

Any wave nearing a critical level (where the background wind speed approaches the horizontal phase speed and $m \to \infty$) will move toward lower intrinsic frequency where rotation effects become important. The true critical level is therefore where $\hat{\omega} \to f$, somewhere below the critical level described for medium-frequency waves ($c_h = \bar{u}_h$).

[22] Because the ratio of vertical to horizontal group velocity,

$$\left|\frac{c_{gz}}{c_{gh}}\right| = \left|\frac{k_h}{m}\right| = \frac{(\hat{\omega}^2 - f^2)^{1/2}}{N}, \tag{39}$$

becomes quite small for inertia-gravity waves relative to their higher-frequency counterparts, they can be found at large horizontal distances from their sources [*Dunkerton*, 1984; *Eckermann*, 1992]. They are very commonly seen in lower stratosphere observations.

[23] A number of observational techniques are sensitive to inertia-gravity waves. Balloon-borne measurements of horizontal wind profiles in the lower stratosphere enable inertia-gravity wave hodograph and rotary spectral analyses [*Kitamura and Hirota*, 1989; *Barat and Cot*, 1992; *Tsuda et al.*, 1994a; *Ogino et al.*, 1995, *Hamilton and Vincent*, 1995; *de la Torre et al.*, 1996; *Sato et al.*, 1994; *Sato and Dunkerton*, 1997; *Shimizu and Tsuda*,

1997; *Vincent and Alexander*, 2000]. Limb viewing satellite measurements can also be sensitive to inertia-gravity waves [*Fetzer and Gille*, 1994, 1996; *Eckermann and Preusse*, 1999; *Tsuda et al.*, 2000], and they are prominent signals in stratospheric radar and lidar observations [*Sato*, 1994; *Mitchell et al.*, 1994; *Sato et al.*, 1997; *Riggin et al.*, 1997] and middle-atmosphere rocket sounding data [*Hirota and Niki*, 1985; *Hamilton*, 1991; *Tsuda et al.*, 1992; *Eckermann et al.*, 1995; *Fritts et al.*, 1997a].

2.2. Conservative Propagation and Departures

[24] Gravity waves conserve wave pseudomomentum flux if they propagate without dissipation through a background atmosphere that varies only in the vertical. The vertical flux of horizontal pseudomomentum

$$(F_{Px}, F_{Py}) = \bar{\rho} c_{gz} \frac{E}{\hat{\omega}} (k, l) \tag{40}$$

is related to the Reynolds stress and vertical flux of horizontal momentum under these assumptions as

$$(F_{Px}, F_{Py}) = \bar{\rho}(1 - f^2/\hat{\omega}^2)(\overline{u'w'}, \overline{v'w'}). \tag{41}$$

Dissipation results from processes such as radiative damping [*Fels*, 1984; *Zhu*, 1994], wave–wave and wave–mean flow interactions [*Broutman and Grimshaw*, 1988; *Sutherland*, 2000, 2001], and wave breaking and instability processes (see section 6). We note here only that nonlinearity and time dependence usually prevent the attainment of amplitudes anticipated by linear, inviscid, steady wave theory.

[25] Viscosity and molecular diffusion are generally not important dissipation mechanisms except in the thermosphere where the exponentially decreasing density and growth of kinematic viscosity with altitude ultimately allow these to dominate over other dissipation processes. (We note here that the "viscosity waves" proposed by *Hocking et al.* [1991] are, in reality, the viscous solutions of the Orr-Sommerfeld equation [e.g., *Fritts and Geller*, 1976]. They do not propagate, and they do not have a dispersion relation. Thus their role is to eliminate, not create, the artificial singularities that occur in the linear inviscid equations, and they cannot play the role proposed by *Hocking et al.* [1991] accounting for enhanced radar backscatter.) This growth of kinematic viscosity with altitude accounts for the turbopause at an altitude typically ~110 km.

[26] The negative of the zonal mean pseudomomentum flux is the gravity wave contribution to the more general Eliassen-Palm flux (EP flux) that is commonly used to describe planetary-scale wave effects [*Edmon et al.*, 1980; *Miyahara et al.*, 1986]. The divergence of the EP flux is proportional to the force exerted on the mean flow. In the case of gravity waves, the zonal average is replaced by an average over some smaller, but still large, area such as a GCM grid scale, and the force on the background wind on that scale becomes

$$(\bar{X}, \bar{Y}) = -\frac{\varepsilon}{\bar{\rho}} \frac{\partial}{\partial z} (F_{Px}, F_{Py}). \tag{42}$$

This is the wave driving (or wave-induced force) [*Andrews and McIntyre*, 1976] that would be used for studying wind evolution in the momentum conservation equation for the background flow as in equations (1) and (2). The force is a vector quantity such that the direction and sign of the force are always the direction and sign of the horizontal phase propagation in the frame of reference moving with the wind (i.e., the horizontal intrinsic phase speed of the wave).

[27] The factor ε has been called an efficiency [*Holton*, 1982] or intermittency [*Alexander and Dunkerton*, 1999] factor, and it can be thought of as describing the fractional coverage of the wave dissipation event within the larger-scale space- and/or time-averaging interval. The intermittency factor is a necessary ingredient in gravity wave parameterization estimates of $(\bar{X}, \bar{Y})$ when the input parameters are describing mean gravity wave properties. We note, however, that for observational estimates of (F_{Px}, F_{Py}) and $(\bar{X}, \bar{Y})$, such as derived from time-averaged radar data, the ε factor is already included.

[28] Gravity waves also have an associated energy flux, so departures from conservative propagation will lead to energy dissipation and local heating of the atmosphere. If wave dissipation involves turbulence generation, then mixing and turbulent heat, momentum, and constituent transport will also occur. Direct heating has been neglected in most GCMs that parameterize gravity wave effects. Models of the middle atmosphere, however, generally require parameterized vertical mixing that is commonly called eddy diffusion. Such mixing could, for example, result from convective overturning of material surfaces and subsequent turbulence following gravity wave breaking (see section 6.2.1).

[29] A momentum eddy diffusion coefficient associated with gravity wave dissipation may be approximated for a single wave [*Lindzen*, 1981; *Holton*, 1982] as

$$D_M = \frac{\hat{c}|(\bar{X}, \bar{Y})|}{N^2}. \tag{43}$$

This coefficient is related to the thermal eddy diffusion coefficient via the Prandtl number. The value of the Prandtl number associated with gravity wave breaking is poorly defined at present and may vary with height. It is expected to be large and highly variable based on numerical and theoretical models of gravity wave convective instability [*Chao and Schoeberl*, 1984; *Fritts and Dunkerton*, 1985; *Coy and Fritts*, 1988; *McIntyre*, 1989]. Assessments of turbulent thermal diffusion required to account for observed atmospheric structure in global models likewise imply large turbulent Prandtl numbers and smaller thermal diffusion coefficient than the momentum diffusion coefficient predicted by equation (43) [*Strobel et al.*, 1985, 1987; *Holton and Schoeberl*, 1988; *Smith and Brasseur*, 1991; *Huang and Smith*, 1991].

While equation (43) with an arbitrary scaling factor is very commonly applied, this relation remains to be confirmed and extended to multiple waves by direct numerical simulation.

[30] Departures from linear theory also occur because of the time dependence of the background flow and the spatial and temporal variations in wave activity (i.e., wave packets). In the case of a gravity wave packet that is localized in space and/or time, the result is a spread of horizontal and/or vertical wave numbers and a corresponding spread of intrinsic frequencies. A gravity wave packet in a shear flow may achieve large amplitudes, but it never attains a singular critical level solution. Spatial localization of a wave packet is also now understood to have some surprising effects. Gravity waves due to local topography comprise a continuous spectrum of wave numbers and propagation directions. When such a spectrum of gravity waves is incident on a veering wind, the result is a monotonic decrease in momentum flux and a turning of the direction of wave drag with altitude as successive portions of the spectrum are removed by critical levels [*Hines*, 1988a; *Shutts*, 1995, 1998; *Broad*, 1995, 1999]. At larger wave amplitudes, localization of a wave packet in the vertical can result in its penetration via nonlinear "self-acceleration" beyond its linear critical level [*Fritts and Dunkerton*, 1984], while localization horizontally and vertically can enable penetration through a turning level [*Sutherland*, 2000] (see section 6.2.3).

[31] Time dependence of the flow in which a gravity wave propagates also influences wave characteristics, enabling the formation of caustics, inducing wave number transport, and either accelerating or retarding the approach toward unstable local wave amplitudes [*Broutman and Young*, 1986; *Bruhwiler and Kaper*, 1995; *Eckermann*, 1997; *Buckley et al.*, 1999; *Walterscheid*, 2000]. Given the importance of (or lack of) these processes in the spectral evolution of gravity waves in the middle atmosphere and the current debate within the community over these issues, this topic will be reviewed more fully in section 6.

3. SOURCES AND PROPAGATION

3.1. Gravity Wave Sources

[32] A complete survey of the gravity wave sources important for the middle atmosphere is beyond the scope of this paper. Indeed, such a survey is beyond our current state of knowledge based on the extensive theoretical, modeling, and observational efforts to date. Instead, the purpose of this section is to identify the dominant sources, their spatial and temporal variability, and the general characteristics of gravity waves arising from them as we understand them at present. The most obvious sources include topography, convection, and wind shear, although other sources may also be significant at preferred sites or in association with specific larger-scale dynamics. Examples of other sources that are likely to be important statistically include adjustment of unbalanced flows in the vicinity of jet streams and frontal systems, body forcing accompanying localized wave dissipation, and wave–wave interactions. Less significant sources which may, nevertheless, be important at higher altitudes include auroral heating and eclipse cooling.

3.1.1. Topographic Generation

[33] Mountain waves have been studied extensively over the past three decades using theoretical, numerical, and observational methods. As a result, idealized two-dimensional (2-D) responses to 2-D topography are reasonably well understood in terms of nonlinear wave dynamics and hydraulic theory [*Long*, 1955; *Smith*, 1985; *Durran and Klemp*, 1987; *Nance and Durran*, 1998; *Lott*, 1998; *Farmer and Armi*, 1999]. Responses to three-dimensional (3-D) topography have also been quantified increasingly in a number of measurement programs and numerical studies, yielding estimates of mountain wave scales, amplitudes, and momentum fluxes. Horizontal wavelengths for vertically propagating waves are typically tens to hundreds of kilometers, while amplitudes vary from small to breaking [*Lilly and Kennedy*, 1973; *Nastrom and Fritts*, 1992; *Chan et al.*, 1993; *Dörnbrack et al.*, 1999; *Leutbecher and Volkert*, 2000]. Horizontal and vertical cross sections of a wave structure anticipated over northern Scandinavia in a 3-D mesoscale simulation by *Dörnbrack et al.* [1999] are shown in Figure 2 and exhibit the large-scale thermal structure (areas of low temperature in Figure 2) believed to trigger polar stratospheric clouds (PSC) and ozone depletion. Such simulations, however, do not yet capture the responses often observed over smaller-scale topography [*Nastrom and Fritts*, 1992].

[34] Momentum fluxes likewise vary greatly but are typically in the range of ~0.1 to a few $m^2\ s^{-2}$ (per unit mass, or ~0.01–0.5 Pa) in the upper troposphere and lower stratosphere based on in situ aircraft and radar measurements and large-scale cross-mountain pressure distributions [*Lilly and Kennedy*, 1973; *Lilly and Lester*, 1974; *Smith*, 1978; *Kennedy and Shapiro*, 1979; *Shutts et al.*, 1988; *Fritts et al.*, 1990b; *Sato*, 1994]. Momentum fluxes are also preferentially associated with the smaller horizontal scale waves that are vertically propagating because of their larger vertical velocities. Maximum (generally negative in Figure 2) momentum fluxes were inferred at horizontal wavelengths between ~10 and 100 km by *Nastrom and Fritts* [1992] (see Figure 3).

[35] The Global Atmospheric Sampling Program (GASP) and more recent aircraft observations also enabled assessments of the statistical importance of mountain waves over rough and smooth terrain and relative to other significant sources. These showed horizontal velocity and temperature variances to be ~2–3 times higher over significant topography compared to plains and oceans, independent of other sources [*Nastrom et*

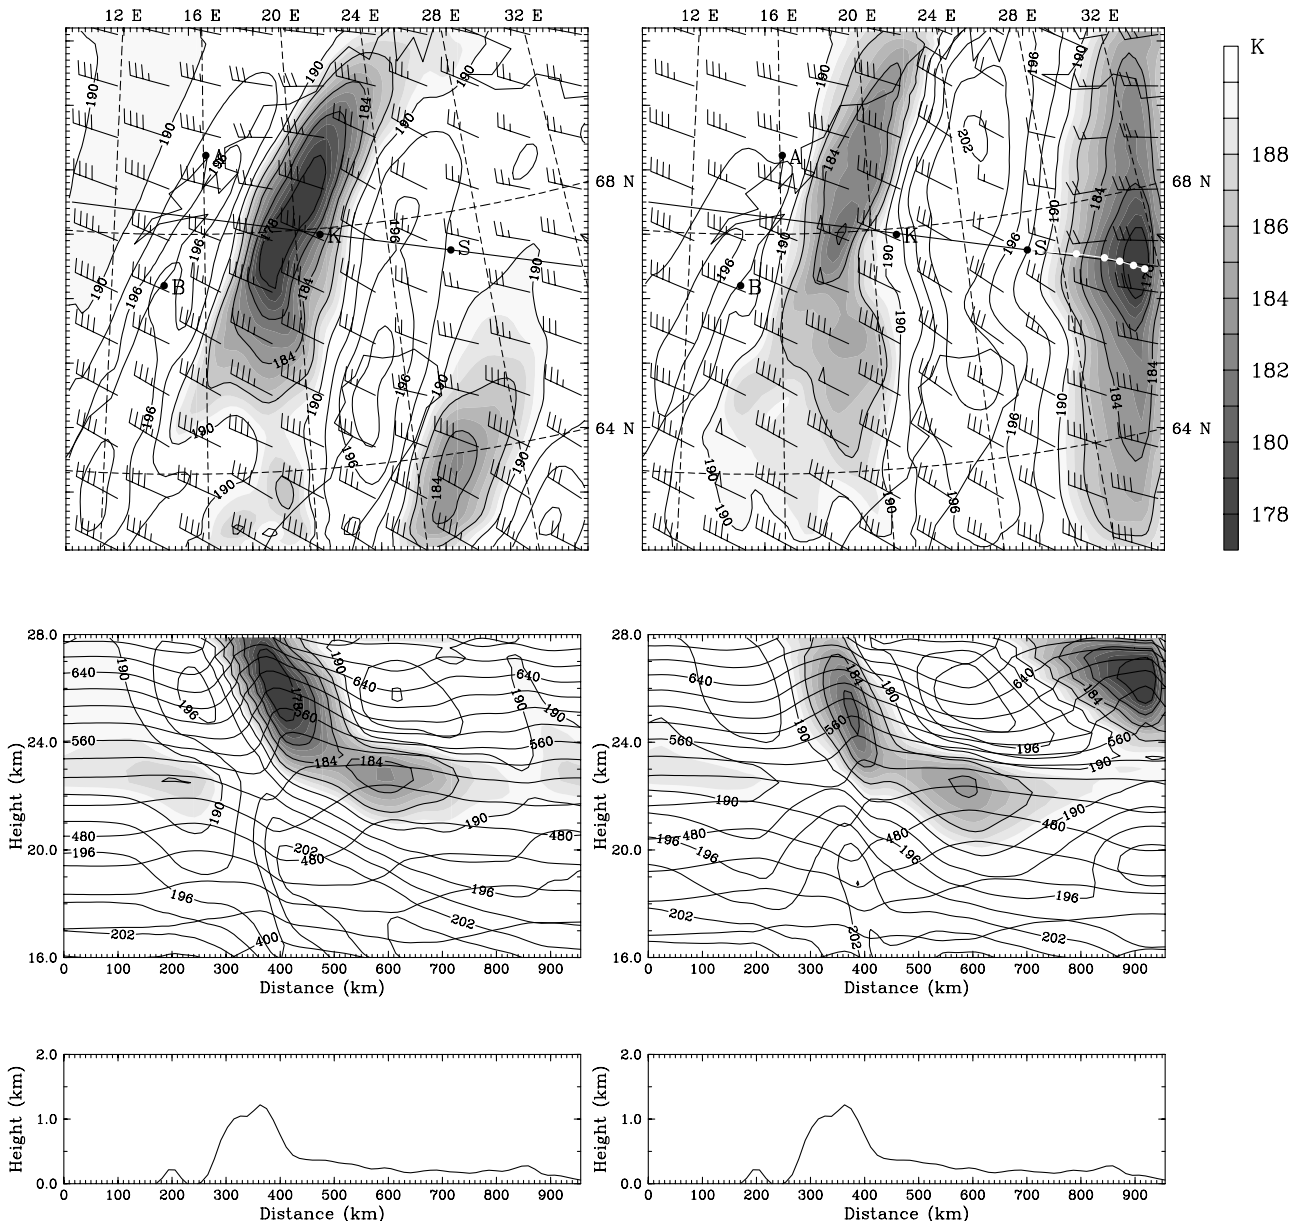

Figure 2. (top) Horizontal and (middle) vertical cross sections of temperature and horizontal wind in a 3-D mesoscale simulation of flow over northern Scandinavia. (bottom) Terrain height beneath the vertical cross section. Modified after *Dörnbrack et al.* [1999].

al., 1987; *Jasperson et al.*, 1990; *Bacmeister et al.*, 1990a] and ~5 times higher than regions having no obvious meteorological sources [*Fritts and Nastrom*, 1992]. Because of the importance of such waves for mean circulations a number of authors have attempted to parameterize their specific effects in large-scale models (see section 7). The importance of mountain waves relative to other significant sources is discussed further in section 5.

[36] Of relevance to the middle atmosphere, then, mountain waves have dominant scales (in terms of momentum fluxes) of ~10–100 km, phase speeds near zero and vertical wavelengths dictated by the local static stability and mean wind in the plane of wave propagation [*Bacmeister et al.*, 1990b]. Indeed, *Bacmeister* [1993] has argued that mountain waves likely account for a large fraction of zonally averaged wave-induced force (wave drag) in the mesosphere, although this result is based on predictions of Lindzen-type parameterizations (see section 7) and remains to be demonstrated observationally.

3.1.2. Convective Generation

[37] Although it has been known for decades that convection can excite gravity waves, it has only been in more recent years that observations and models have begun to characterize the waves generated by this source and the mechanisms within convection responsible for their generation. In fact, there is at the time of this

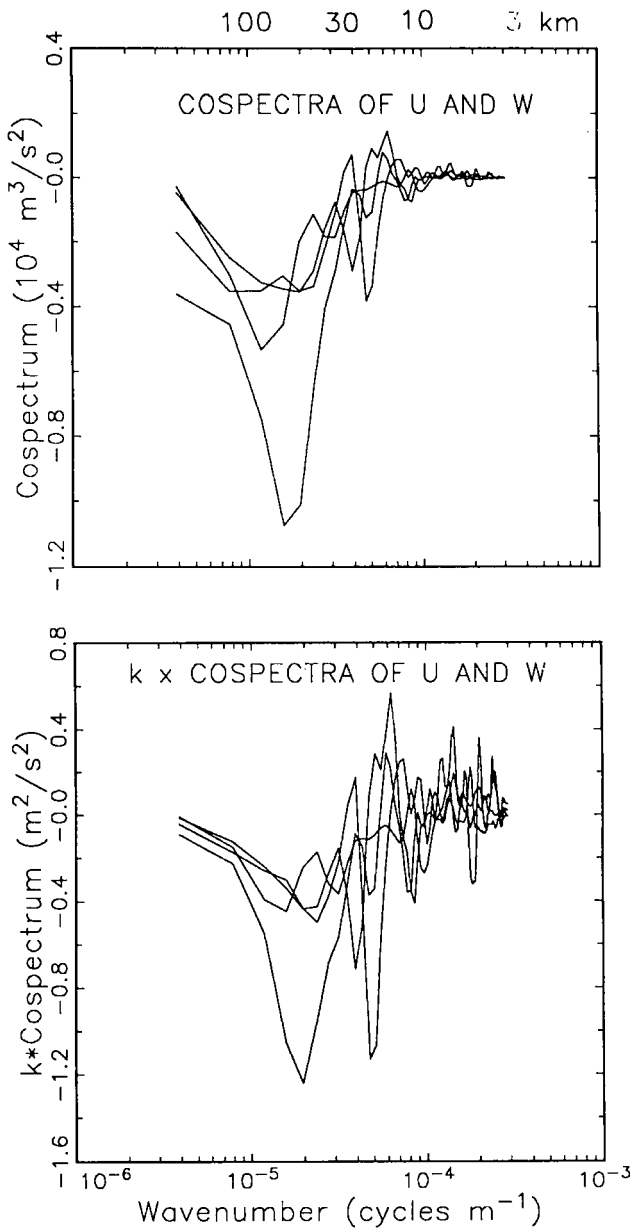

Figure 3. Spectra of momentum flux in (top) standard and (bottom) variance content forms computed for four flights over the central Rockies. Note that the dominant fluxes in each case are largely at horizontal scales between 10 and 100 km. After *Nastrom and Fritts* [1992] (reprinted with permission of the American Meteorological Society).

review still considerable controversy and ongoing research aimed at understanding this wave generation mechanism.

[38] One of the difficulties in characterizing this source is its inherent intermittency. Observations of high-frequency waves in the stratosphere have shown a close correspondence with deep convective clouds (see Figure 4) [*Sato*, 1992, 1993; *Alexander and Pfister*, 1995; *Sato et al.*, 1995; *Dewan et al.*, 1998; *McLandress et al.*, 2000; *Alexander et al.*, 2000]. Observational estimates of momentum flux are fewer but show significant variability. Local magnitudes range up to ~0.03–0.2 Pa [*Sato*, 1993; *Alexander and Pfister*, 1995; *Alexander et al.*, 2000], and longer-term averages peak at $\sim 1\text{–}5 \times 10^{-3}$ Pa [*Sato and Dunkerton*, 1997; *Sato et al.*, 1997; *Vincent and Alexander*, 2000].

[39] Waves generated by convection are not characterized by a single prominent phase speed or frequency as is the case for topographic waves. Instead, convection can generate waves throughout the full range of phase speeds, wave frequencies, and vertical and horizontal scales. The low-frequency waves, in particular, may be observed in the middle atmosphere at large horizontal distances from the convective source, making correlation with clouds or other indicators of convection more difficult. In the tropics, however, far from topography and regions of baroclinic instability, the occurrence of inertia-gravity waves has been linked to convection as the source [*Pfister et al.*, 1986; *Tsuda et al.*, 1994a; *Karoly et al.*, 1996; *Shimizu and Tsuda*, 1997; *Wada et al.*, 1999; *Vincent and Alexander*, 2000].

[40] Model studies of waves generated by convection (Figure 5) have greatly enhanced our understanding of these phenomena. Convection involves a time-varying thermal forcing associated with latent heat release that can interact with overlying stable layers and shear in complex ways that are not fully understood. Three simplified mechanisms have been proposed to describe convective generation: (1) pure thermal forcing, (2) an "obstacle" or "transient mountain" effect, and (3) a "mechanical oscillator" effect.

[41] For pure thermal forcing in the absence of strong shear the heating depth and the vertical wavelength of the gravity waves generated are surprisingly approximately equal [*Alexander et al.*, 1995; *Piani et al.*, 2000]. This relationship (demonstrated by *Salby and Garcia* [1987] for larger-scale waves) arises because the heating projects most strongly onto a wave with vertical wavelength twice the depth of the heating, but the wave is then refracted to half that vertical wavelength as it propagates across the twofold increase in buoyancy frequency at the tropopause (see equation (33)). *Bergman and Salby* [1994] used global cloud imagery at tropical latitudes to estimate the planetary-scale and long-wavelength, low-frequency gravity wave responses with this model, and the far-field effects of the waves generated have been extended through the mesosphere by *Garcia and Sassi* [1999]. The linear mechanism used in these studies has been validated for tropical planetary-scale waves, but the amplitudes are generally larger than those in corresponding nonlinear models [*Manzini and Hamilton*, 1993]. The gravity wave momentum fluxes derived from these cloud data sets are still highly uncertain. *Pandya and Alexander* [1999] further describe how the local mesoscale environment surrounding the storm can modify the smaller-scale gravity wave response in the stratosphere from a latent heat source. Observational evidence for the thermal forcing mechanism of gravity wave generation is given by *McLandress et al.* [2000]

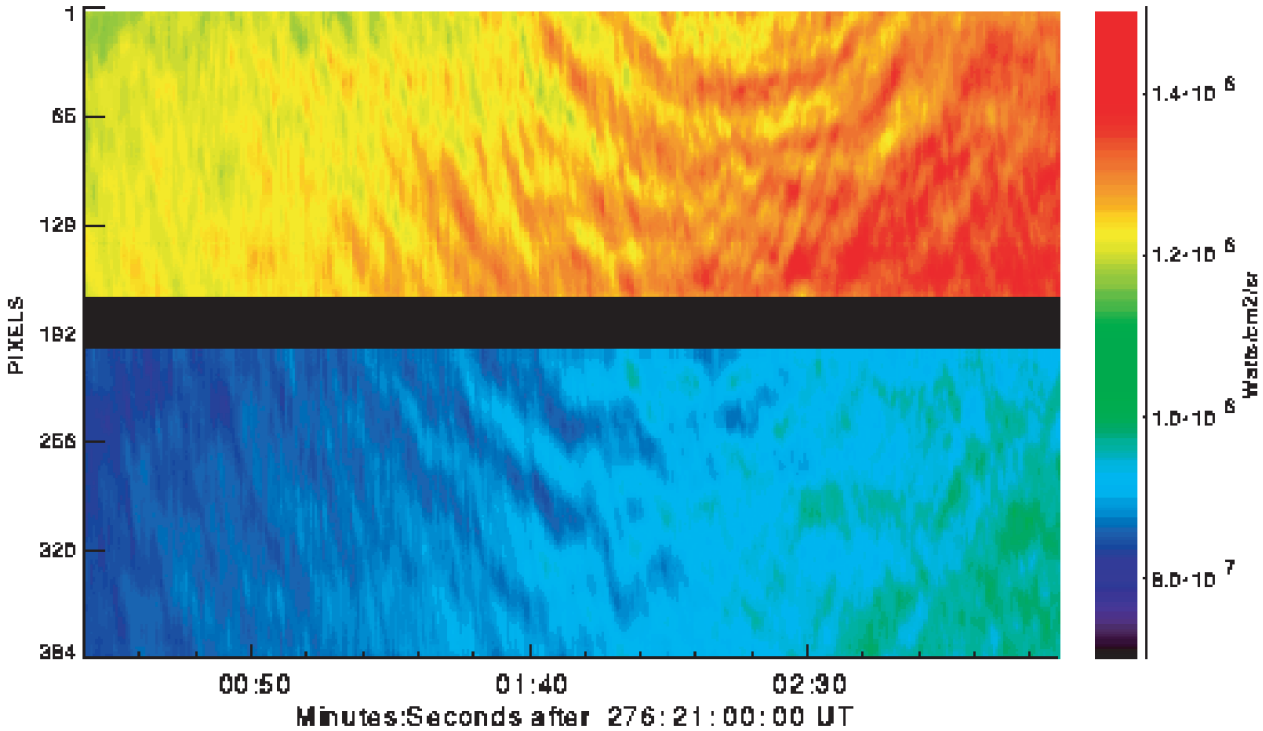

Figure 4. Images of infrared emissions from the stratosphere observed by the SPIRIT III radiometer from the MSX satellite. Circular phase fronts of waves with horizontal wavelength ~25 km can be seen in these images that were centered around a deep convective cloud below in the troposphere. After *Dewan et al.* [1998, Figure 1].

(Figure 6), although its importance relative to other mechanisms could not be quantified. Pure thermal forcing would be expected to generate an isotropic wave field, with anisotropies occurring primarily via background wind filtering effects.

[42] The obstacle effect was descibed by *Clark et al.* [1986] for short horizontal wavelength waves in the troposphere generated by boundary layer convection [*Kuettner et al.*, 1987], but the ideas developed in their study have also contributed to understanding the larger horizontal scale waves in the middle atmosphere generated by convection. The obstacle effect can be thought of as analogous to topographic wave generation where the convective heating modifies the shape of isentropes at the bottom of a stable layer which is moving relative to the convective obstacle. *Clark et al*. [1986] found that both the pure thermal forcing and the obstacle effect produced gravity waves in the overlying stable layer but that the obstacle effect generated much larger amplitude waves. *Pfister et al.* [1993a, 1993b] explicitly modeled a linear version of this mechanism and found evidence for it in stratospheric aircraft observations over convection. *Pfister et al.* [1993b] also described how the time dependence of the obstacle (or transient mountain) affects the phase speed spectrum of the waves that are generated. Observational evidence for the obstacle effect has appeared in radiosonde analyses of low-frequency waves [*Vincent and Alexander*, 2000; *Alexander and Vincent*, 2000]. This mechanism is associated with an anisotropic wave spectrum with a preference for generating waves propagating opposite to the mean wind relative to the obstacle.

[43] *Fovell et al.* [1992] described the "mechanical oscillator" mechanism as a periodic and localized momentum source term that generates waves with a frequency equal to the oscillation frequency. This mechanism is not distinct from the time-varying thermal source when that source oscillates with a regular period [*Clark et al.*, 1986; *Alexander et al.*, 1995; *Pandya and Alexander*, 1999]. *Lane et al.* [2001] describe a similar mechanism acting in their 3-D model that had little or no shear in the forcing region, with some added constraints. In their conceptual model the parcel oscillates about its level of neutral buoyancy at the local tropospheric buoyancy frequency which limits this mechanism to generating only very high frequency gravity waves in the upper troposphere at altitudes above any lower minima that occur in the N profile. For the mechanical oscillator mechanism, anisotropies in the wave spectrum can result from background wind effects in a manner similar to the obstacle effect [*Fovell et al.*, 1992].

[44] In summary, the three simplified excitation mechanisms that have been proposed may all be important, depending strongly upon the local shear and the vertical profile and time dependence of the latent heating. In reality, the three mechanisms are not distinct but cou-

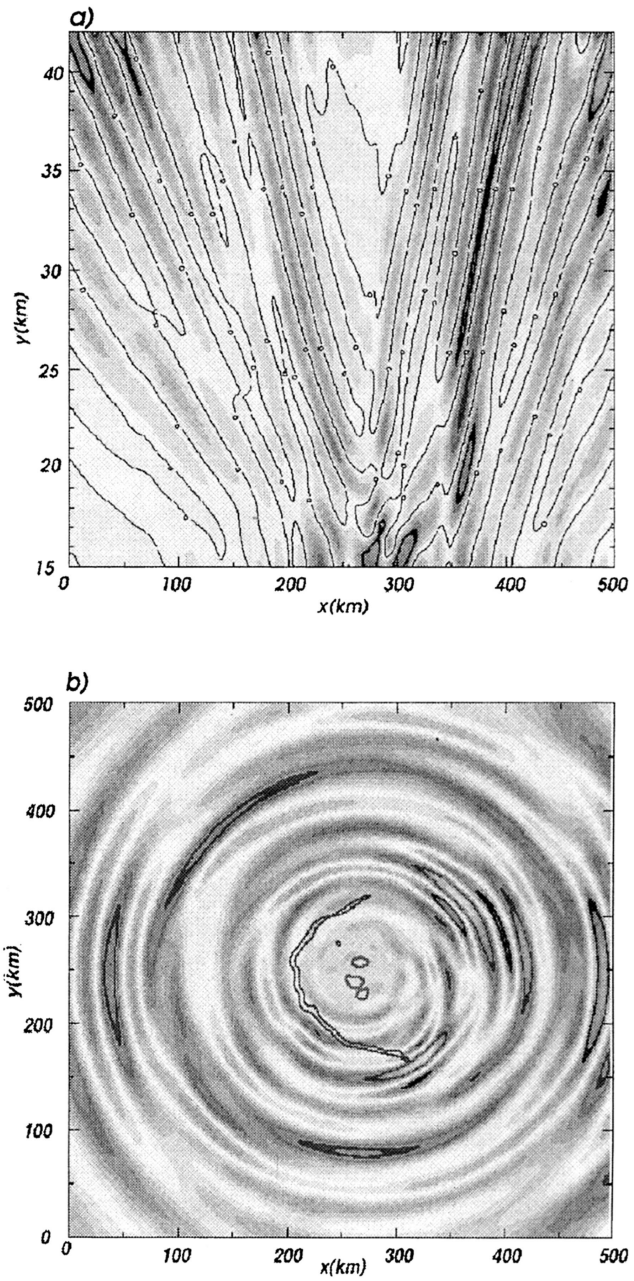

Figure 5. Three-dimensional study of gravity waves generated by convection in a mesoscale model with parameterized microphysics. (a) Vertical velocity patterns in a cross section in the vertical (z) and zonal (x) plane at $y = 250$ km. (b) The $x - y$ cross section of vertical velocity at $z = 40$ km. Also shown in Figure 5b are the surface gust front (arc-shaped solid line) and regions of strong latent heating in the troposphere (small solid contours). pled. However, one mechanism or another may serve to largely explain a set of observations with certain wind shear conditions or may serve to explain the generation of a certain class of waves, such as long vertical wavelength wave generation associated with deep convective heating.

3.1.3. Shear Generation

[45] The excitation of gravity waves by unstable shears has been studied for many years but remains one of the least quantified sources of gravity wave activity. A major challenge in these efforts was to account for the emergence of gravity waves that are propagating away from the shear layer on a timescale competitive with the most rapidly growing Kelvin-Helmholtz (KH) instability. This proved difficult for linear modes of instability for which the growth rate depends on the horizontal wave number. The subharmonic interaction, or pairing, of KH modes was proposed by *Davis and Peltier* [1979] to provide such excitation, but *Fritts* [1984b] showed pairing not to be an efficient mechanism when the exterior flow is stably stratified. By invoking a nonlinear interaction between KH and propagating modes, however, *Fritts* [1984b] and *Chimonas and Grant* [1984] were able to account for rapid excitation of propagating gravity waves. This "envelope" radiation is essentially excitation of a gravity wave by the packet-scale motions accompanying a packet of coherent KH billows evolving together in an unstable shear layer of finite horizontal extent. Two aspects of this mechanism have been assessed more recently in greater detail. *Bühler et al.* [1999] and *Bühler and McIntyre* [1999] examined wave radiation from the collapse of a mixed region due to KH billows of finite extent and concluded that this source could not be neglected in the momentum budget at greater altitudes. The mechanism envisioned by *Bühler et al.* [1999] is represented schematically in Figure 7. *Scinocca and Ford* [2000] reexamined the nonlinear radiation from spatially localized KH billows and concluded, like *Fritts* [1984b], that envelope radiation is a viable mechanism for gravity wave generation and likely an important contributor to the mesospheric momentum budget.

[46] Assuming envelope radiation to be the predominant shear excitation mechanism, we can infer characteristic horizontal scales of tens to ~100 KH wavelengths or a few to tens of kilometers, with horizontal phase speeds comparable to the mean wind at the unstable shear layer. There is, nevertheless, some observational evidence suggesting that certain linear modes of shear instability can be excited [*Mastrantonio et al.*, 1976; *Lalas and Einaudi*, 1976]. Under such circumstances the gravity wave scales are determined by the character of the shear flow and tend to be considerably larger than KH wavelengths.

3.1.4. Geostrophic Adjustment

[47] Most evidence for gravity wave excitation accompanying the restoration of balanced flow, commonly termed geostrophic adjustment, even though the balance need not be geostrophic, comes from theoretical or numerical treatments of adjustment processes. In such a process, an initial or evolving unbalanced flow relaxes to a new balanced state via both a redistribution of mean momentum, energy, and potential vorticity and a radiation of excess energy away as inertia-gravity waves. Such

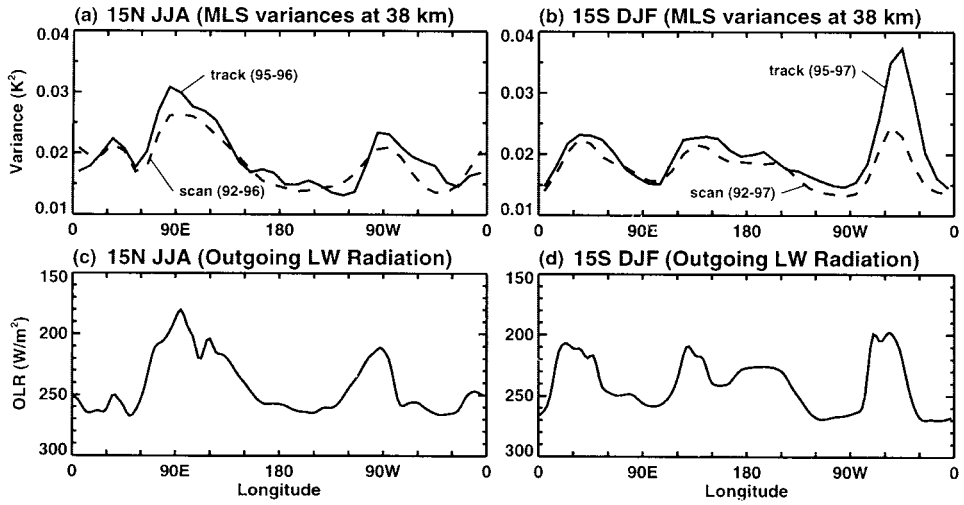

Figure 6. (a) Observations of gravity wave temperature variance as a function of longitude at 15°N from the Microwave Limb Sounder (MLS) instrument on the UARS satellite, averaged over the June-July-August season. (b) Observations of Outgoing Longwave Radiation for the same season and locations plotted on an inverse scale. The two plots show a close correspondence between gravity wave variance and infrared emission from deep, cold convective clouds. The gravity waves were also noted to have large horizontal phase speeds and very long vertical wavelengths. The close correspondence between Figures 6a and 6b provided observational evidence that long vertical wavelength gravity waves are preferentially excited by deep latent heating. After *McLandress et al.* [2000, Figure 8].

unbalanced initial flows can arise, for example, where cross-stream pressure gradients are varying along the fluid motion (requiring an acceleration or deceleration of the motion), accompanying frontal evolution and baroclinic instability, or in response to local body forces due to gravity wave dissipation and momentum flux divergence. The first of these was modeled in 2-D and 3-D by *Fritts and Luo* [1992] and *Luo and Fritts* [1993] as adjustments to unbalanced initial conditions and was found to lead to both new balanced 2-D or 3-D flows and a spectrum of inertia-gravity waves that owe their character to the geometry of the source perturbation. Observations of inertia-gravity wave activity by *Hirota and Niki* [1985] and *Thomas et al.* [1992] exhibiting downward phase progression above the jet stream and upward phase progression below the jet stream appear to provide some support for this conceptual model. Further support comes from the more recent study by *Guest et al.* [2000] who found both a high correlation of inertia-gravity wave observations with a synoptic pattern having a jet stream nearby and a tendency for reverse ray tracing to suggest the jet stream as the wave source. Our understanding of such adjustment processes is nevertheless poor at this time and will benefit from further research efforts.

[48] Frontogenesis and baroclinic instability were found by *O'Sullivan and Dunkerton* [1995], *Griffiths and Reeder* [1996], and *Reeder and Griffiths* [1996] to yield similar results, with both adjusted mean and waves scales largely defined by the character of the unbalanced flow. An example of the inertia-gravity waves emitted accompanying adjustment of an evolving baroclinic flow is shown in Figure 8 [*O'Sullivan and Dunkerton*, 1995]. As discussed above, gravity waves are seen to arise preferentially in regions of strong flow deceleration.

[49] Gravity waves arising from local body forces due to dissipating gravity waves were considered theoretically by *Zhu and Holton* [1987] and more recently by

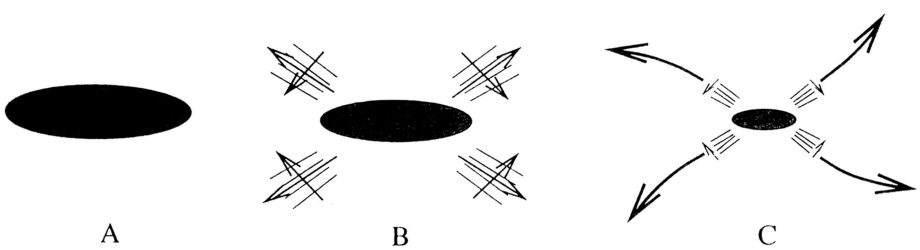

Figure 7. Schematic of the consequences of collapse of a train of KH billows which trigger radiation of gravity waves at larger scales. After *Bühler et al.* [1999] (reprinted with permission of the American Meteorological Society).

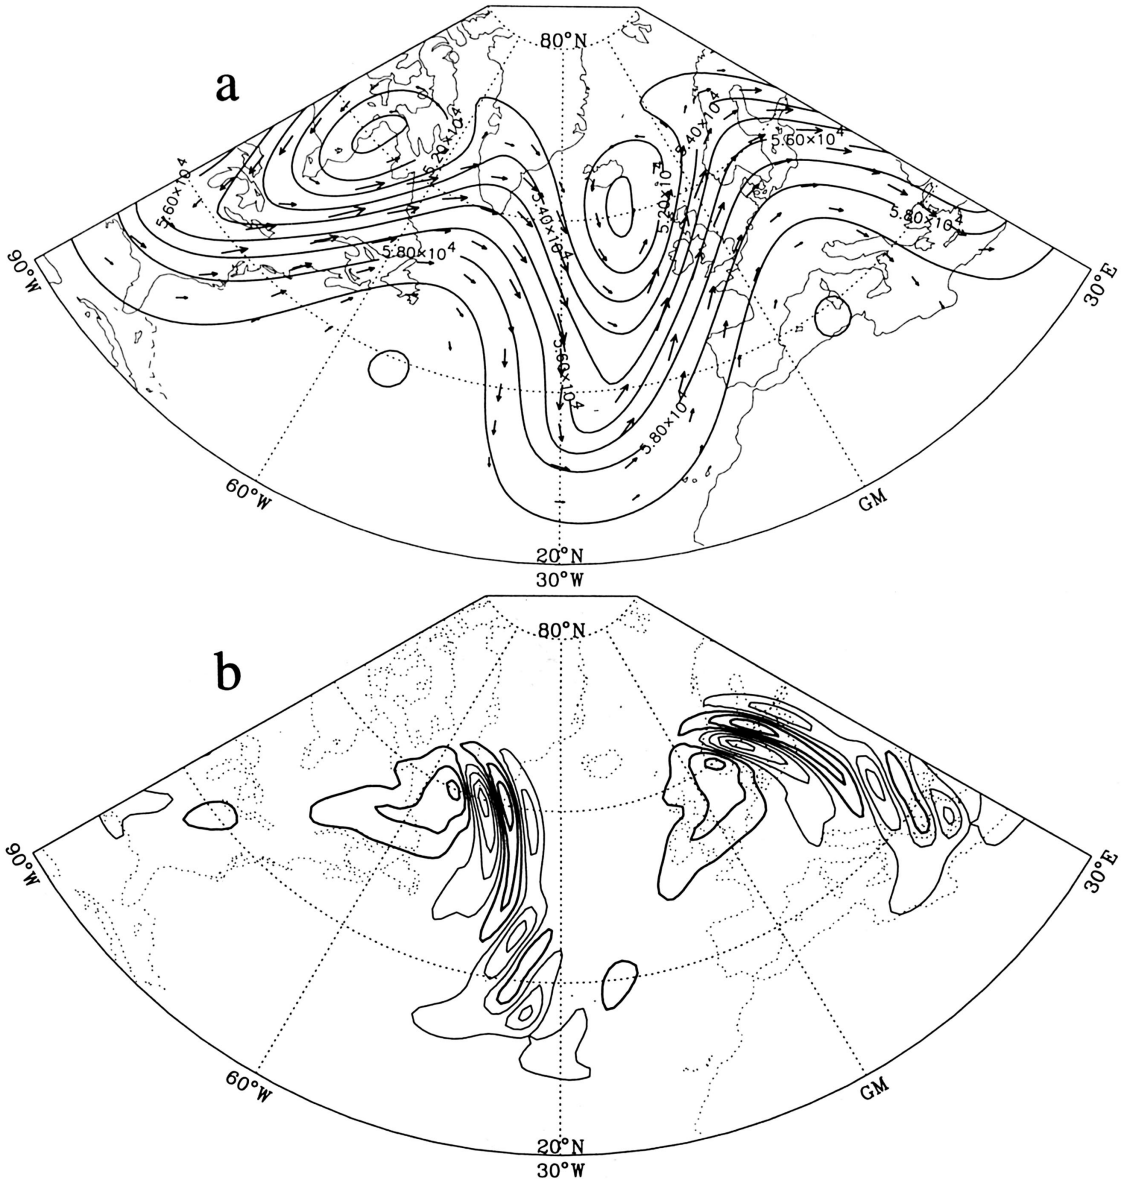

Figure 8. The (a) 500 hPA geopotential height and winds and (b) 130 hPA horizontal divergence (bottom) displaying the excitation of inertia-gravity waves by geostrophic adjustment processes. After *O'Sullivan and Dunkerton* [1995] (reprinted with permission the American Meteorological Society).

Vadas and Fritts [2001]. In all cases, the response is a combination of an adjusted mean (with redistributed momentum or potential vorticity), an altered mean thermal structure, and radiated inertia-gravity waves ensuring energy conservation in the absence of dissipation. The study by *Vadas and Fritts* [2001] considered a temporally evolving body force and showed (1) that the adjusted mean state depends on the momentum impulse and forcing geometry but not on the forcing duration and (2) that the radiated inertia-gravity waves are constrained by both the geometry and the temporal structure of the body forcing. Thus, while both long- and short-duration forcing (having the same geometry and momentum impulse) induce the same balanced mean flow, their gravity wave responses are quite different, with long-duration forcing strongly suppressing gravity waves having periods shorter than the forcing duration. The adjustment processes discussed here are also closely analogous to the radiation of gravity waves by a collapsing mixed layer due to shear instability examined by *Bühler et al.* [1999] and discussed above, though the source here is due to an addition, rather than a redistribution, of momentum.

[50] Scales of inertia-gravity waves arising from adjustment or body forcing processes are imposed by the source spatial scales and further constrained by the source timescales. Typical vertical scales are a few kilometers or more, with horizontal scales along the direction of propagation of ~10–100 times larger. Wave periods likely vary from an hour or so out to the inertial period. In cases where the source is elongated in one direction horizontally, the predominant direction of

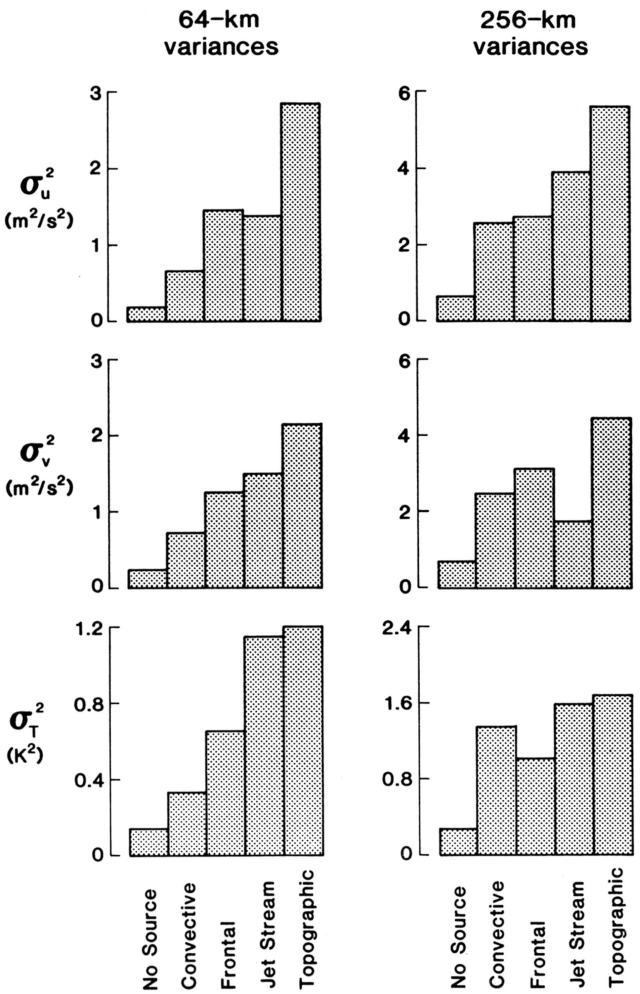

Figure 9. (top) Zonal velocity, (middle) meridional velocity, and (bottom) temperature variances in (left) 64-km and (right) 256-km data segments associated with various gravity wave sources. After *Fritts and Nastrom* [1992] (reprinted with permission of the American Meteorological Society).

propagation of the excited inertia-gravity waves is normal to the source axis.

[51] A comparison of gravity wave velocity and temperature variances associated with various sources computed using GASP data near the tropopause is shown in Figure 9 [*Fritts and Nastrom*, 1992]. These variances, for 64- and 256-km flight segments, suggest that topography, jet stream shears, and convective and frontal activity all contribute substantially to gravity wave excitation where these sources are prevalent.

3.1.5. Wave–Wave Interactions

[52] Nonlinear wave–wave interactions are arguably one of the more important mechanisms in energy exchanges, amplitude constraints, and spectral evolution for gravity waves in the middle atmosphere. Their roles and importance are not universally acknowledged, however, and there remains much to be done in quantifying their dynamics and effects.

[53] As a source of gravity waves the atmospheric community has taken guidance from oceanographers and attributed energy transfers to resonant and nonresonant interactions of various forms. There has been a long debate over the efficiency of such interactions and the validity of the various approaches in the oceanographic and atmospheric communities. Yet laboratory experiments and direct numerical simulations demonstrate that specific interactions, e.g., the parametric subharmonic instability (or PSI, see section 6.1), can be efficient and robust under a variety of circumstances [*McEwan*, 1971; *McEwan and Robinson*, 1975; *Mied*, 1976; *Dunkerton*, 1987; *Thorpe*, 1994; *Vanneste*, 1995; *Staquet and Sommeria*, 1996]. Indeed, *Klostermeyer* [1984, 1990] has argued for evidence of PSI in radar measurements of the middle atmosphere. Thus wave–wave interactions are likely an important source of waves at a range of scales not directly linked to source scales at lower altitudes. Because of their roles in spectral energy transfers and amplitude constraints, a more complete discussion of wave-wave interactions is deferred until section 6.1.

3.2. Propagation Issues

[54] Gravity wave propagation and inferences of gravity wave effects are complicated by a number of factors in the middle atmosphere. Spatially variable wind and stability profiles cause wave refraction, reflection, focusing, and ducting, while temporally variable winds alter wave phase speeds. Instability processes contribute to the generation of turbulence which may interact with or act as a source for additional wave activity. Gravity wave–vortical mode interactions may also exchange energy among these components of the motion spectrum. Our purpose in this section is to identify areas where these dynamics may confuse or obscure the inference of gravity waves and their effects in observational analyses.

3.2.1. Upward and Downward Propagation

[55] It is useful for many purposes to distinguish what fractions of the gravity wave spectrum are propagating upward and downward. Two approaches have usually been used to do this. One employs 2-D frequency–vertical wave number spectra or direct measurements of phase progression for individual waves to make the distinction, while a second employs a rotary spectral analysis of individual profiles. Each method is hampered by certain assumptions but yields insightful, if not precise, results.

[56] The 2-D spectral approach employed by *Fukao et al.* [1985], *Fritts and Cho* [1987], and *Wilson et al.* [1991a] assumes that observed and intrinsic frequencies are the same, thus confusing vertical directionality for motions having intrinsic phase speeds comparable to and opposed to mean winds and erring in the assignment of wave frequency. These are not generally serious errors when mean winds are not extreme because the total wave variance at small intrinsic phase speeds (hence small vertical scales and amplitudes) is not large. The

forms of the observed frequency spectra of horizontal velocity and temperature (slopes typically near $-5/3$) do not change dramatically for mean winds smaller than the intrinsic phase speeds of the most energetic waves [*Fritts and VanZandt*, 1987], however, while there is relatively less variance for $m \sim N/\bar{u}_h$ for which Doppler-shifting effects are larger. These and other observations suggest that the fraction of upward propagating gravity wave energy is much greater than 1/2 and that the upward propagating fraction is likely an underestimate because of uncertainties over wave frequencies [*Vincent*, 1984b; *Fukao et al.*, 1985; *Fritts and Chou*, 1987; *Wilson et al.*, 1991a; *Lintelman and Gardner*, 1994; *Gavrilov et al.*, 1996; *de la Torre et al.*, 1999].

[57] The second method, rotary spectral analysis, was first employed by *Vincent* [1984b] and is related to Stokes analysis used to assess the degree of polarization of the motion field [*Vincent and Fritts*, 1987; *Eckermann and Vincent*, 1989; *Eckermann and Hocking*, 1989; *Barat and Cot*, 1992; *Nakamura et al.*, 1993a; *de la Torre et al.*, 1999; *Zink and Vincent*, 2001a]. Rotary spectral analysis decomposes all oscillatory motions in the vertical into a superposition of upward and downward propagating motions assumed to be circularly polarized. This assumption causes a single upward propagating inertia-gravity wave with amplitude A and intrinsic frequency $\hat{\omega} > f$ (having elliptical polarization) to be misidentified as a sum of an upward propagating wave of amplitude $A_u = (1 + f/\hat{\omega})A/2$ and a downward propagating wave of amplitude $A_d = (1 - f/\hat{\omega})A/2$. As $\hat{\omega} \rightarrow f$, this yields $A_u \rightarrow 1$ and $A_d \rightarrow 0$ because the dynamics are then consistent with the assumptions. However, for $\hat{\omega} > f$ the inferred (and errant) downward propagating fraction of the total variance of $1/2 - f\hat{\omega}/(\hat{\omega}^2 + f^2)$ approaches 1/2 as $f/\hat{\omega} \rightarrow 0$ (or as $\hat{\omega} \rightarrow N$) and is entirely errant [*Eckermann and Vincent*, 1989]. Thus the rotary spectral analysis likewise leads to a conservative estimate of the upward propagating fraction of gravity wave energy. Effects of wave superposition, while not always significant, may also influence the results of a Stokes analysis and contribute to a lack of precision in partitioning of wave energy between upward and downward propagating components [*Eckermann and Hocking*, 1989]. Studies that use the technique of ellipse fitting to hodographs [*Tsuda et al.*, 1994a; *Hamilton and Vincent*, 1995; *Shimizu and Tsuda*, 1997] yield unambiguous estimates of the upward and downward propagating fractions, at least when a single dominant inertia-gravity wave is present in the profiles.

3.2.2. Vertical Propagation Versus Ducting

[58] Another issue that has arisen recently because of its implications both for estimates of gravity wave fluxes of heat and momentum and for the parameterization of gravity wave effects in large-scale models is the occurrence of gravity wave ducting. Waves that propagate vertically (with $m^2 > 0$) but having reflection (or turning) levels above and below are trapped or ducted. From the dispersion relation, equation (24) or equation (33), we see that variations in the thermal structure, as measured by the buoyancy frequency N, influence waves having any direction of propagation in the same manner, whereas the wind profile affects waves having different propagation directions very differently. In general, wind maxima in a particular direction favor ducting at that level (and in that direction) because of the relative maxima they imply in m^2, while maxima of N^2 favor ducting at this level for all propagation directions [*Chimonas and Hines*, 1986; *Fritts and Yuan*, 1989a]. Observational evidence of wind and thermal (N^2) ducts was obtained by *Isler et al.* [1997] and *Walterscheid et al.* [1999], while *Taylor et al.* [1995] and *Mitchell and Howells* [1998] inferred ducting from limited vertical wave extent. In all these cases, gravity waves having horizontal wavelengths of ~20 km or less were judged to have a high probability of being ducted by the wind and/or thermal structures of the atmosphere. The probability of ducting remains finite but decreases as horizontal wavelengths increase [*Swenson et al.*, 2000].

[59] Gravity wave structure within a duct typically exhibits very little vertical phase variation across the duct and is evanescent on either side, though more complex wave structures are also possible. Thus typical motions are largely in phase and vertical, have intrinsic frequencies near N, may have only a gradual decay of wave amplitude away from the duct, and have little or no associated momentum flux. Yet because of their structure such motions may make large contributions to vertical velocity, temperature, and airglow intensity variances.

[60] Despite our appreciation of the implications of gravity wave ducting, there have been several efforts to associate airglow intensity and/or temperature variances with gravity wave momentum fluxes (to which ducted waves contribute nothing, according to linear theory). These efforts by *Swenson et al.* [1999] and *Gardner et al.* [1999a] have been critiqued by *Fritts* [2000] and are flawed because of their neglect of ducting. *Swenson et al.* [2000] likewise recognized the lack of sensitivity to ducting behavior in earlier formulations and discussed the implications of the more complete dispersion relation, reaching similar conclusions to those of *Isler et al.* [1997] and *Walterscheid et al.* [1999] regarding susceptible horizontal wavelengths. The implications of these studies are that turning levels and ducting are important processes that impact gravity wave structure and inferred effects where wind and thermal variations are significant, particularly for shorter horizontal wavelengths.

3.2.3. Gravity Waves Versus Two-Dimensional Turbulence

[61] While quasi-2-D turbulence (hereafter 2DT, also called geostrophic or stratified turbulence under related assumptions) clearly makes contributions to atmospheric dynamics and velocity variances at some altitudes, the role it plays in the middle atmosphere appears

to be small, at least for scales well below synoptic and planetary scales (~500 km) [*Nastrom and Gage*, 1985]. *Gage* [1979] and *Lilly* [1983] have advocated 2DT as an explanation for the −5/3 power law in lower stratospheric horizontal wave number spectra, and *Lilly* [1983] has suggested that deep convection may be a viable source for 2DT. However, subsequent assessments using radar and balloon data by *Smith et al.* [1985], *Vincent and Eckermann* [1990], and *Eckermann and Vincent* [1993] suggested that only a small fraction of horizontal velocity variance could not be attributed to gravity waves. Increasing energy and momentum fluxes (per unit mass) and energy dissipation rates with altitude appear, at first sight, to imply a reduced role at greater altitudes. Without a more complete understanding of middle-atmosphere turbulence dynamics and energetics, however, it would be a mistake to assume that no strong middle-atmosphere sources of 2DT are present. This is particularly true given the potential role of gravity wave–vortical mode interactions as wave amplitudes increase [*Dong and Yeh*, 1988; *Yeh and Dong*, 1989], the departures of ratios of kinetic to potential energy from those predicted by gravity wave theories [*Tsuda et al.*, 1991; *Nastrom et al.*, 1997; *de la Torre et al.*, 1999], and the increasing scales and energies of turbulence with altitude (see section 4). We must be careful in attributing kinetic to potential energy ratios as evidence against a purely gravity wave interpretation, however, because such departures from theory can also arise from excess gravity wave energy near the inertial frequency [*Thompson*, 1978; *Sato et al.*, 1999].

4. SPECTRAL CHARACTER AND EVOLUTION

[62] Models of the gravity wave spectrum have evolved with time as we have identified spectral characteristics and constraints more precisely. As described in section 6, various theories constrain the gravity wave spectrum to behave in a particular manner over some range of wave numbers and/or frequencies. These observational and theoretical constraints have led to a canonical gravity wave spectrum that offers insights into mean properties of the gravity wave field and its variations with altitude. We emphasize, however, that this canonical spectrum cannot capture the true complexity of the gravity wave field or its evolution in altitude. There are, in addition, many reasons to expect that the spectrum will also exhibit considerable variability spatially and temporally because of various sources, filtering environments, quasi-discrete waves, and gravity wave interactions with larger scales of motion. We first review in this section the form and implications of the canonical mean spectrum. We then discuss some of the causes of departures from the canonical spectral forms.

4.1. Spectral Shape In *k, m,* and ω

[63] Frequency spectra of horizontal velocity and temperature typically vary as $E(\omega) \sim \omega^{-p}$ and exhibit slopes varying from $p \sim$ 1–2 for frequencies between f and N, with most slopes falling close to $p = 5/3$ [see, e.g., *VanZandt*, 1982; *Balsley and Carter*, 1982; *Nakamura et al.*, 1993b; *Collins et al.*, 1994]. Because horizontal wind and temperature variances tend to be concentrated near inertial frequencies, Doppler effects are small, and the intrinsic and Doppler-shifted (i.e., ground based) frequency spectra are expected to have nearly the same forms [*Scheffler and Liu*, 1986; *Fritts and VanZandt*, 1987]. This expectation is supported by the limited Lagrangian measurements that are available [*Quinn and Holzworth*, 1987; *Hertzog and Vial*, 2001]. Ground-based frequency spectra of vertical velocity, on the other hand, exhibit considerable variability with altitude, primarily because these spectra are highly sensitive to Doppler-shifting effects (see below).

[64] Vertical wave number spectra of velocities, temperatures, and various species concentrations have been measured with many instrument types. These spectra typically exhibit a distinct peak at the most energetic scales, with smaller power at lower and higher wave numbers. As noted above, a limited altitude range in observational data may result in a lack of sensitivity to motions with larger vertical scales. This causes those waves having larger vertical group velocities, thus potentially large energy and momentum fluxes, to be systematically underrepresented in such data sets. At the other extreme, resolution and measurement accuracy limits constrain the range of vertical scales that can be reliably measured. This suggests caution in assessments of characteristic scales, spectral slopes, and spectral amplitudes at large m. Nevertheless, multiple data sets suggest characteristic vertical wave numbers, m_* (i.e., the vertical wave number of the most energetic gravity waves), corresponding to vertical wavelengths of ~2–5 km in the lower stratosphere increasing to ~10–30 km near the mesopause.

[65] Spectral slope estimates at high m ($m > m_*$) also vary, but typical values range from −2.5 to −3 [*Dewan et al.*, 1984; *Tsuda et al.*, 1989, 1991]. Importantly, while there are departures from universal amplitudes and slopes (noted in section 4.2), particularly under strongly sheared conditions [*Eckermann*, 1995a], there is surprising conformity of spectral amplitudes and slopes at high m with the expectations of the various saturation theories over a broad range of altitudes [*Dewan and Good*, 1986; *Fritts and Chou*, 1987; *Smith et al.*, 1987; *Fritts et al.*, 1988a; *Sidi et al.*, 1988; *Tsuda et al.*, 1989, 1990a; *Wu and Widdel*, 1989, 1990, 1991; *Wilson et al*., 1991a; *Kuo et al.*, 1992; *Collins et al.*, 1994; *de la Torre et al.*, 1994; *Allen and Vincent*, 1995; *Mitchell et al.*, 1996]. An example of the vertical wave number spectra of radial velocities exhibiting both the decrease of m_* from the troposphere and stratosphere to the mesosphere and conformity to the spectral slopes expected for a satu-

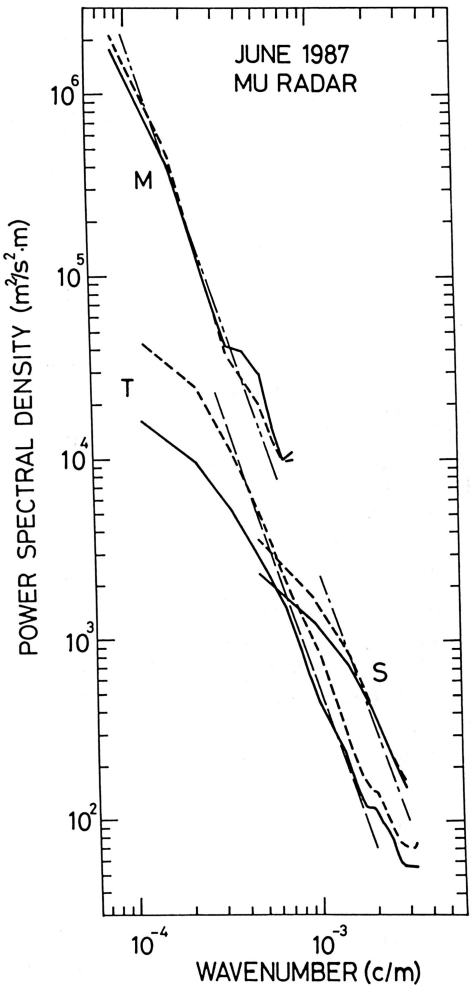

Figure 10. Radial velocity spectra assumed to represent largely horizontal velocities in the troposphere, stratosphere, and mesosphere (labeled T, S, and M) together with theoretical curves having amplitudes of $N^2/6m^3$. After *Tsuda et al.* [1989] (reprinted with permission of the American Meteorological Society).

rated gravity wave spectrum is shown in Figure 10 [*Tsuda et al.*, 1989].

[66] Saturated or nonlinear gravity waves are not the only explanation offered for the observed spectral character, however; a recurring alternative is buoyancy-range turbulence [*Weinstock*, 1985; *Sidi et al.*, 1988], which likely plays some role at the outer scales of turbulence accompanying initial instability processes. There is evidence, for example, that the ratio of kinetic to potential energy in the wave spectrum often exceeds that value predicted by the spectral model to be described later [*Tsuda et al.*, 1991; *Nastrom et al.*, 1997; *de la Torre et al.*, 1999], perhaps suggesting other 2DT turbulence or quasi-inertial components of the motion field not included in the gravity wave spectral formulation. Spectral amplitudes also exhibit, on occasion, departures from canonical values which cannot be attributed to the measurement technique. These departures and some of the reasons for them are discussed at greater length in sections 4.2 and 4.3.

[67] Horizontal wave number spectra are more challenging to measure unambiguously, as they mix spatial and temporal sampling. However, assuming that the speed of the measurement platform (typically, an aircraft) is large compared to wave horizontal phase speeds (this is not always true for the larger vertical scales), horizontal wave number spectra are obtained which are again in reasonable agreement with theory and other spectral measurements [*VanZandt*, 1982; *Fritts et al.*, 1989, 1993a; *Gardner et al.*, 1993; *Bacmeister et al.*, 1996; *Manson et al.*, 1998a]. Horizontal wavelengths range from ~10 km to thousands of kilometers; typical slopes are $\sim -5/3$, and different dynamics appear to account for the spectral slope at larger horizontal scales [*Nastrom and Gage*, 1985; *Nastrom et al.*, 1987; *Jasperson et al.*, 1990].

[68] A spectral description that captures much of the observed character of the gravity wave field is assumed (largely for convenience) to be separable in intrinsic frequency and vertical wave number and is given by

$$E(\mu, \omega, \phi) = E_0 A(\mu) B(\omega) \Phi(\phi) , \qquad (44)$$

where E is the total gravity wave energy,

$$A(\mu) = A_0 \frac{\mu^s}{1 + \mu^{s+t}}, \qquad (45)$$

$$B(\omega) = B_0 \omega^{-p} , \qquad (46)$$

$\Phi(\phi)$ expresses the azimuthal distribution of wave propagation directions, $\mu = m/m_*$, and the coefficients are chosen such that $\int_0^\infty A(\mu)d\mu = 1$, $\int_f^N B(\omega)d\omega = 1$, and $\int_0^{2\pi} \Phi(\phi)d\phi = 1$ [*Fritts and VanZandt*, 1993]. Typical values of the spectral slopes are $(s, t, p) = (1, 3, 5/3)$. The above form of the vertical wave number spectrum is more strongly peaked than was believed to be the case initially, while the requirement for a positive slope at small vertical wave numbers is imposed by the requirement for finite vertical energy fluxes (alternatively, one could impose a small-m cutoff to achieve a finite energy flux). Of these parameters, the slope at small m is perhaps the least well defined observationally or theoretically. The corresponding horizontal wave number spectrum can be derived from equations (45) and (46) and the gravity wave dispersion relation, equation (23); however, the overall spectrum in (k, ω) is then not separable. We also note that the spectrum given by equation (44) is specifically not separable in the presence of large-scale shears where vertical propagation implies differing evolutions for the m spectrum at different azimuths [*Fritts and Lu*, 1993].

[69] The gravity wave spectrum is assumed to be constrained in amplitude at $m > m_*$ by saturation processes, with all of the various saturation theories (see section 6) yielding limits for kinetic and potential energy within a factor of 2 or so of

$$E_k(m \gg m_*) \simeq \frac{pN^2}{10m^3} = \frac{N^2}{6m^3} \quad (47)$$

and

$$E_p(m \gg m_*) \simeq \frac{N^2}{10m^3}. \quad (48)$$

Variations of total wave energy density, $E(m)$, with variations in altitude and N are described approximately as [*VanZandt and Fritts*, 1989]

$$E(m) = E(\mu)d\mu/dm$$
$$= E_0 A(\mu)/m_* \sim (N/N_0)^{1/2} e^{z/H_E} A(\mu)/m_*, \quad (49)$$

where

$$m_* \sim (N/N_0)^{3/4} e^{-z/H_*} \quad (50)$$

for N increasing with height. Here $H_E \sim 2.3H$ is a value consistent with observations and linear, full-spectral propagation simulations by *Warner and McIntyre* [1996]. Corresponding values of H_* and E_0 are $H_* \simeq 2H_E$ and $E_0 = N^2/10m_*^2$. Equations (49) and (50) are also appropriate for N decreasing with height and for variable $\bar{u}(z)$, provided that the amplitude decreases implied by these effects are compensated by amplitude increases resulting from density decreasing with altitude.

[70] The corresponding energy flux by the wave field, assuming that all motions propagate upward, is

$$F_E \simeq \frac{NE_0}{18m_*}. \quad (51)$$

The factor $N/18m_* \simeq \overline{(1/m)}\bar{\omega}$ is appropriate at midlatitudes (with $f/N \simeq 1/200$) and may be interpreted as an effective vertical group velocity $\bar{c}_{gz}$ [*Fritts and VanZandt*, 1993]. Then $m_* \sim 3$ rad km^{-1} near the tropopause and $\sim 1/3$ rad km^{-1} near the mesopause, with corresponding $\bar{c}_{gz} \sim$ 0.5 and 5 m s^{-1}, respectively, and model variances are consistent with numerous radar measurements [*Vincent*, 1984a; *Fritts*, 1984a, 1989; *Balsley and Garello*, 1985; *Meek et al.*, 1985]. With $E_0 \sim 10$ and 10^3 m^2 s^{-2}, this implies $F_E \sim 5$ and 5×10^3 m^3 s^{-3}, respectively, near the tropopause and mesopause.

[71] With the above variations in E(m) and m_* and assuming, for simplicity, a constant N and that all energy flux divergence leads to turbulence, the corresponding turbulent energy dissipation rate may be written [*VanZandt and Fritts*, 1989] as

$$\epsilon \simeq \frac{NE_0}{18m_*}\left(\frac{1}{H} - \frac{3}{2H_E}\right), \quad (52)$$

with a corresponding dissipation timescale [*Fritts and Werne*, 2000] of

$$T_d \sim E_0/\epsilon \sim \frac{18m_*}{N}\left(\frac{1}{H} - \frac{3}{2H_E}\right)^{-1}. \quad (53)$$

There are, of course, uncertainties in E_0, m_*, and the fraction of wave energy that is directly dissipated as a result of wave interaction and instability processes. There are also variations that accompany changes of N, H_E, etc. with altitude. Nevertheless, these expressions provide useful guidance and/or limits for gravity influences throughout the middle atmosphere. The decreasing timescale for wave energy dissipation with increasing altitude, $T_d \sim E_0^{-1/2} \sim e^{-z/2H_E}$, is of relevance to the discussion of instability processes in section 6. The decrease with altitude implies a transition from a tendency for local dynamical (KH) instabilities in the lower stratosphere to a tendency for local convective instabilities in the mesosphere and lower thermosphere [*Fritts and Werne*, 2000] (also see section 6).

4.2. Spectral Universality, Separability, and Departures

[72] Despite the apparent role of various saturation processes in constraining wave amplitudes at large m, departures from the slopes and amplitudes predicted by the various saturation theories are common. In the troposphere, amplitudes are often larger by factors of ~ 2 to 3 [*Smith et al.*, 1987; *Tsuda et al.*, 1989, 1991; *Allen and Vincent*, 1995]. In the stratosphere, amplitudes vary from those expected from saturation theory due to wave filtering in mean shears [*Eckermann*, 1995a], enhanced saturation due to increasing N with altitude [*VanZandt and Fritts*, 1989], or other effects not yet quantified [*Cot and Barat*, 1990; *Senft and Gardner*, 1991; *Marsh et al.*, 1991; *Tsuda et al.*, 1991]. Spectral amplitudes may also exceed saturation values at any altitude (but especially in the mesosphere and lower thermosphere) where large vertical group velocities impose wave amplitude growth that is more rapid than the finite time required for instability dynamics to impose wave amplitude constraints (see section 6).

[73] Though departures from canonical frequency spectra of horizontal velocities or temperature occur in many, if not most, observations, the degree of uniformity in frequency spectra of horizontal velocity and temperature is initially surprising. The relative lack of variability of these spectra is due in part to the occurrence of the majority of the variance at (intrinsic and observed) frequencies near f and vertical wave numbers near or less than m_*. Large variances near f imply vertical scales near m_* (to enable large wave amplitudes) and corresponding large intrinsic phase speeds. This is especially the case in the mesosphere and lower thermosphere where m_* is small, vertical scales are large, and intrinsic phase speeds are often comparable to or exceed mean winds. In this case, observed frequencies cannot be Doppler shifted more than a factor of 2 or so away from their intrinsic frequency, and intrinsic and observed spectra bear a close resemblance [*Scheffler and Liu*, 1986; *Fritts and VanZandt*, 1987]. Even in the stratosphere, where vertical scales and intrinsic phase speeds are smaller, the variance is still largely dominated by

waves with large intrinsic phase speeds and low frequencies, and therefore Doppler shifting is not severe. In contrast, variances occurring at intrinsic frequencies near N are much smaller and may be Doppler spread more widely without significantly changing the shape of observed frequency spectra.

[74] The situation is quite different for frequency spectra of vertical velocity. For a frequency spectrum of horizontal gravity wave motions as described in section 4.1, we expect from equation (23) an intrinsic frequency spectrum of vertical velocities to have a slope of approximately $2 - p$ and a sharp peak (in variance content, $\hat{\omega}E_w(\hat{\omega})$) at frequencies just below N. Here large variances at high frequencies are associated primarily with (nonhydrostatic) wave motions having large k/m (see equation (30)) and vertical velocities comparable to or larger than horizontal velocities. Hence mean winds are often much larger than intrinsic phase speeds, Doppler-shifting effects may be large, and frequency spectra of vertical velocity exhibit significant variability and dependence on mean winds [*Fritts et al.*, 1990a; *Fritts and Wang*, 1991; *VanZandt et al.*, 1991]. Indeed, several studies using vertical velocity frequency spectra have shown a tendency for waves to be propagating preferentially against the local mean flow [*Fritts and Wang*, 1991; *VanZandt et al.*, 1991], in agreement with inferences from momentum flux measurements.

[75] Apart from theories which couple wave number and frequency spectra increasingly at higher altitudes [*Dewan*, 1994, 1997], there are no known reasons why frequency spectra of horizontal gravity wave motions should be universal. Indeed, specific sources impart to the wave field their own spectral attributes (see section 3). The tendency toward a canonical frequency spectrum as altitude increases more likely reflects a combination of (1) averaging over many wave sources and wave field realizations, (2) the variations of intrinsic frequency accompanying wave propagation in wind shear, and (3) systematic nonlinear interactions among spectral components which increase in importance with altitude.

[76] There is no reason to suppose that the gravity wave spectrum is separable among any two variables on theoretical grounds. Nor is separability fundamental to any saturation theory, despite claims to the contrary [*Gardner et al.*, 1999b]. Separability simply provides a convenient means of describing the dependence of gravity wave spectra on observed frequency, vertical wave number, and/or azimuth of propagation having some experimental justification [*Smith et al.*, 1987; *Fritts and Chou*, 1987; *Fritts and VanZandt*, 1987; *VanZandt and Fritts*, 1989; *Sidi et al.*, 1988].

[77] Finally, we note that estimates of gravity wave spectral parameters depend to some extent on the technique employed, as each technique has its own measurement biases and limitations. Thus care must be taken in interpreting and, in particular, intercomparing these estimates. Limited altitude coverage, limited temporal extent, spatial and temporal averaging, and windowing and linear trend removal additionally cause underestimates of spectral variance at lower wave numbers and frequencies [*Lefrere and Sidi*, 1990]. Geophysical variations of the mean wind and stability profiles with altitude likewise introduce biases in spectral amplitudes and slopes [*VanZandt and Fritts*, 1989; *Eckermann*, 1990, 1995a].

4.3. Broad Spectrum or Discrete Waves?

[78] Spectral characterization of the gravity wave field almost always gives the impression that the wave field is composed of many components at various scales. This is true even for spectra formed from a single time series or vertical profile [*Dewan*, 1979; *Reid et al.*, 1988; *Fritts et al.*, 1988a; *Wu and Widdel*, 1989, 1991; *Allen and Vincent*, 1995; *Sato and Yamada*, 1994]. There is ample evidence, however, that spectra are often composed of only a few waves of significant amplitude, lending support to the arguments advanced by *Hines* [2002a] (see section 6.1). Most vertical profiles of velocity or temperature exhibit in any altitude range a single dominant wave structure; the corresponding vertical wave number spectrum typically has ~70% of the variance within a factor of 2 of the characteristic vertical wave number, m_* (see equation (49)).

[79] Additional evidence for a discrete or "narrow spectral," rather than a "broad spectral" description of the local wave field comes from many studies. Airglow observations more often than not exhibit a single or very few wave structures extending over a few to many wavelengths [*Taylor et al.*, 1991, 1995, 1998; *Hecht et al.*, 1997; *Nakamura et al.*, 1998; *Swenson et al.*, 1999; *Yamada et al.*, 2001].

[80] Airglow and noctilucent cloud (NLC) observations have also yielded evidence of gravity wave instability processes accompanying single or a few large-amplitude wave motions at specific spatial scales [*Fritts et al.*, 1993b; *Swenson and Mende*, 1994; *Hecht et al.*, 1997; *Yamada et al.*, 2001]. Balloon, lidar, and rocket data provide evidence of large-scale overturning of apparently individual waves, or superpositions of a few large-amplitude waves [*Shutts et al.*, 1988; *Hecht et al.*, 1997; *Goldberg et al.*, 1997; *Williams et al.*, 2002]. Radar and optical estimates of gravity wave momentum fluxes provide enticing evidence of discrete, large-amplitude events [*Riggin et al.*, 1997; *Fritts et al.*, 2002] and suggest that such events may comprise a significant part of the mean forcing. Finally, *Sato and Yamada* [1994] found that a single wave approaching a critical level can yield a vertical wave number spectrum having a -3 slope, while *Eckermann* [1999] showed that such a spectrum can arise from as few as four discrete sets of wave scales. Thus we must be cautious of claims that the spectral character of the gravity wave field implies a broad mix of waves occupying a common volume, as this often appears not to be the case.

5. CLIMATOLOGIES OF GRAVITY WAVE ACTIVITY

[81] Because global model studies are increasingly recognizing the need to describe gravity wave effects via parameterization, efforts to observe and understand the climatology of gravity waves is an area of active research. Climatology in this context refers to the geographical and temporal variations in gravity wave activity (specifically momentum fluxes) and variations in gravity wave characteristics (wavelengths, phase speeds, etc.). If the mechanisms for gravity wave generation were completely understood and if their sources were fully characterized, we could in theory perfectly describe the temporal and geographical variations in gravity wave occurrence along with the specific wave characteristics for a given set of meteorological conditions. The largest obstacle to accurate parameterization of gravity wave effects in the middle atmosphere would then be overcome. Unfortunately, we instead have a disjointed set of observations that sometimes agree with one another and other times do not. We also have idealized model studies of gravity wave sources which are often poorly constrained by observations. Where such constraints do exist, models and observations do not always agree. Progress is being made, but the global characterization of the climatology of gravity wave occurrence remains a daunting observational challenge.

[82] In the last 15 years there have been a number of compilations of observations of small-scale temperature and horizontal wind structure in the middle atmosphere, with these structures interpreted as gravity wave perturbations. These compilations include long-term observations at single sites from which seasonal and interannual variations can be observed, global observations over some more limited period of time, and regional observations showing both temporal and geographical variations. The reasonably constant appearance of vertical wavelength and ground-based frequency spectra described in section 4 can be deceptive because of the logarithmic axes plotted. In fact, the gravity wave climatology information that has appeared in the literature shows substantial variations with time, with height, as well as with geography.

[83] Part of the difficulty in inferring a climatology of gravity waves from the existing set of observations is related to the fact that gravity waves are phenomena that occur with a broad and multidimensional spectrum of characteristics. Each observation technique tends to be sensitive only to some portion of that spectrum while being almost totally insensitive to other portions. These observational limitations can themselves be responsible for the climatological patterns observed in the data because the vertical wavelengths, intrinsic frequencies, and phase speeds of gravity waves can be dramatically altered by variations in the background atmosphere [*Alexander*, 1998]. These variations in gravity waves due to background atmosphere effects must then be separated from variations associated with gravity wave sources before we can achieve accurate interpretations of gravity wave climatological observations.

[84] Our understanding of the nature of gravity wave sources was summarized in section 3.1. In this section we summarize global patterns and seasonal variations of gravity wave variances and fluxes that have been reported using different observational techniques. We then review the theoretical studies that have helped to explain some of these observed variations and separate background atmosphere effects from source variations. Inferences thus gained about global variations in gravity wave sources are then summarized.

5.1. Observations

5.1.1. Remote Sensing Measurements From Space

[85] Observations from satellite platforms hold great promise for providing the kind of global coverage at frequent time intervals that is needed to understand gravity wave variability. However, gravity waves can have quite small vertical and horizontal scales and short periods. They can therefore be challenging to observe remotely from space. New techniques have emerged, yet each has been capable of observing only some fraction of the gravity wave spectrum that may be present in the atmosphere, while missing other portions of the spectrum.

[86] Infrared limb-viewing profiles like the Limb Infrared Monitor of the Stratosphere (LIMS) instrument [*Gille and Russell*, 1984] retrieve temperature profiles from 15 to 60 km at high vertical resolution (~1.5 km). However, line-of-sight (LOS) integration effects and the spacing between profiles limit these data to observation of only longer horizontal wavelengths. *Fetzer and Gille* [1994] retrieved global fields of gravity wave temperature perturbations by subtracting Kalman-filtered temperature fields from unfiltered temperature profiles. The Kalman-filtered data included planetary waves with zonal wave number ≤ 6. The difference field, assumed to be gravity wave perturbations, included information on waves with vertical wavelengths of ~6–50 km and horizontal wavelengths longer than ~200 km. (Note that aliasing from shorter unresolved horizontal wavelengths was evident, but these represented a small fraction of the total gravity wave variance observed [*Fetzer and Gille*, 1994].) *Fetzer and Gille* [1994] noted that the temperature variances derived from these data are likely dominated by low-frequency inertia-gravity waves. Maps of the LIMS gravity wave temperature variance (Figure 11a) as a function of latitude and height showed a peak near the equator in the lower stratosphere below 20 km and a peak in the winter stratospheric jet above 20 km. Seasonal variation above 40 km at the equator related to the semiannual oscillation (SAO) was also evident in the gravity wave variance.

[87] Maps of gravity wave temperature variance have been similarly derived from Cryogenic Infrared Spectrometers and Telescopes for the Atmosphere

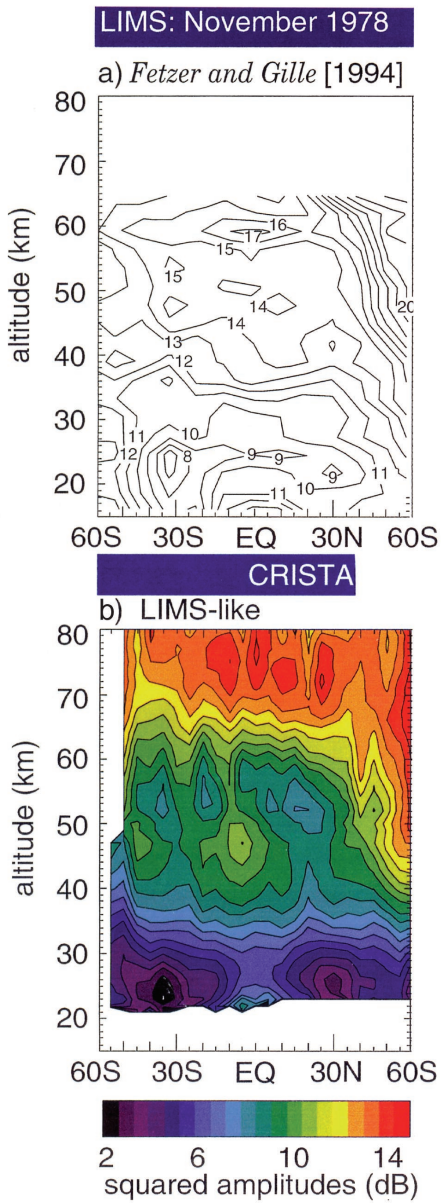

Figure 11. Comparison of zonal mean gravity wave temperature variance in November from (a) LIMS (after *Fetzer and Gille* [1994], reprinted with permission of the American Meteorological Society) and (b) CRISTA filtered to reflect the same vertical resolution as LIMS (after *Preusse et al.* [2000]).

(CRISTA) data [*Preusse et al.*, 1999]. These data give temperature profiles at finer horizontal resolution and slightly better vertical resolution than LIMS. CRISTA's altitude range varies with observational mode but can extend from ~20 to 80 km. The CRISTA data were used to infer that topography was the source for waves observed in the stratosphere from space [*Eckermann and Preusse*, 1999; *Preusse et al.*, 2002]. Global maps of the gravity wave temperature variance show similar features as those from LIMS (Figure 11b).

[88] *Tsuda et al.* [2000] derived global maps of gravity wave potential energy derived from GPS occultation data temperature profiles [*Rocken et al.*, 1997]. These observations include gravity waves with vertical wavelengths of ~2–10 km in the 15- to 40-km altitude range. The LOS integration path length is also ~200 km, so the observed wave characteristics are similar to LIMS and CRISTA. The gravity wave energy shows a similar equatorial maximum below ~25 km and midlatitude winter maxima at higher altitudes. At lower latitudes (≤30°), the gravity wave energy was particularly enhanced over regions of active convection. At midlatitudes, gravity wave energy was observed to be larger over continents than over oceans.

[89] Observations from the Microwave Limb Sounder (MLS) have been used to derive global maps of gravity wave temperature variance in the stratosphere and mesosphere [*Wu and Waters*, 1996a, 1996b]. These data include only gravity waves with long vertical wavelengths $\lambda_z > 12$ km because of the deeper weighting functions associated with microwave profilers compared to infrared profilers. One observation mode (the scanning mode) reportedly included gravity waves with horizontal wavelengths of ~60–150 km [*Wu and Waters*, 1996a], while another (the tracking mode) included gravity waves with horizontal wavelengths up to 1000 km. *McLandress et al.* [2000] noted that the integrated variance observed by the two modes is similar, suggesting that aliasing effects may be extending the range of wavelengths contributing to the variance in data from the scanning mode. *Wu and Waters* [1997] note that most of the observed waves propagate opposite to the direction of the wind. This, together with the long vertical wavelength restrictions, suggests these waves have much higher intrinsic frequencies than those observed via the other space-based observations described above. The global maps show peaks in variance at middle to high latitudes in winter, with a minor peak at subtropical latitudes in summer. Variances at the equator were indistinguishable from noise [*McLandress et al.*, 2000]. Longitudinal variations suggest deep convection as a source of the waves observed in the summertime and topography as the source for waves at southern midlatitudes in winter [*McLandress et al.*, 2000] (see also Figure 6).

5.1.2. Radiosonde Profiles

[90] Observations of temperature and horizontal wind profiles from radiosondes have provided information on short vertical wavelength gravity waves in the lower stratosphere below ~25 km. Several studies have inferred latitudinal, seasonal, and interannual variations in gravity wave activity in these data. The frequency of radiosonde launches rarely exceeds twice per day, so gravity wave perturbations are generally obtained by subtracting a low-order polynomial fit to the profiles and assuming the perturbations as a function of height are caused by gravity waves. In studies near the equator, however, where the inertial period is very long, radiosonde data have also been analyzed in the time domain

for information on 1- to 3-day period oscillations as inertia-gravity waves [*Sato et al.*, 1994; *Sato and Dunkerton*, 1997].

[91] Radiosonde profiles of horizontal wind plotted as hodographs generally show rotation indicative of upward propagating inertia-gravity waves [*Ogino et al.*, 1995; *Vincent and Alexander*, 2000]. In fact, there is abundant evidence from analyses of radiosonde horizontal wind and temperature profiles that the perturbations in these vertical profiles are dominated by very low intrinsic frequency inertia-gravity waves, specifically those with frequencies between ~1 and 3*f* [*Vincent et al.*, 1997; *Vincent and Alexander*, 2000; *Zink and Vincent*, 2001a].

[92] Seasonal variations at northern midlatitudes and high latitudes show a maximum in gravity wave activity in winter and minimum in summer [*Yoshiki and Sato*, 2000; *Kitamura and Hirota*, 1989]. At very high northern latitudes, significant gravity wave variances were observed only in the absence of mountain wave critical levels [*Bacmeister et al.*, 1990b; *Worthington and Thomas*, 1996; *Whiteway and Duck*, 1996; *Whiteway et al.*, 1997]. At midlatitudes in the Southern Hemisphere, observations also show peak wave activity in winter [*Allen and Vincent*, 1995; *Zink and Vincent*, 2001a]. At Antarctic latitudes a maximum in spring has instead been observed [*Allen and Vincent*, 1995; *Yoshiki and Sato*, 2000].

[93] At the tropical latitudes of northern Australia, Indonesia, and the Indian Ocean a seasonal cycle in wave activity has been observed with a maximum in December to February [*Allen and Vincent*, 1995; *Vincent and Alexander*, 2000]. This is a period of intense deep convection in that part of the world. Waves observed in radiosonde data from that area also often tend to have long horizontal wavelengths, ~1000 km [*Tsuda et al.*, 1994a; *Shimizu and Tsuda*, 1997; *Vincent and Alexander*, 2000]. Propagation directions of gravity waves observed in radiosonde data at low latitudes are influenced by the winds of the quasibiennial oscillation (QBO). An excess of eastward propagating waves has been observed most prominently during periods with strong westward winds in the lower stratosphere and eastward shear aloft [*Murayama et al.*, 1994; *Tsuda et al.*, 1994a; *Shimizu and Tsuda*, 1997; *Sato and Dunkerton*, 1997; *Vincent and Alexander*, 2000]. Cadet and Teitelbaum [1979] observed the analogous situation in the opposite phase of the QBO: westward propagating gravity waves in westward QBO wind shear.

[94] Latitudinal variations are also apparent in gravity waves observed in radiosonde profiles. The data show a trend toward increasing wave energy equatorward of ~30° [*Kitamura and Hirota*, 1989; *Allen and Vincent*, 1995; *Ogino et al.*, 1995]. Note that a similar equatorial maximum was observed in the GPS and IR limb sounding satellite observations in the lower stratosphere described above.

5.1.3. Rocket Soundings

[95] Rocket soundings of temperature and horizontal wind have been used to infer seasonal and latitudinal variations in gravity wave activity in the stratosphere below ~60 km at ~1-km resolution. Rocket profiles from launches in the 1970s and 1980s at sites in the Northern Hemisphere and in the tropics have provided information on the seasonal and latitudinal variations in gravity wave activity in the stratosphere [*Hirota*, 1984; *Hirota and Niki*, 1985; *Hamilton*, 1991; *Eckermann et al.*, 1995].

[96] The analysis method has varied between different studies, but the most common procedure is to subtract a background profile from the data and to assume that smaller-scale perturbations are gravity waves. In general, the rocket sounding analyses have shown a seasonal cycle in wave activity at high latitudes (~40°–80°N) with a maximum in winter, similar to results of radiosonde analyses. Hodograph or rotary spectral analyses of rocket profiles have also shown a dominance of upward propagation, again similar to the radiosondes. At low latitudes, different analyses gave different seasonal cycles in wave activity, suggesting a sensitivity of this result to the vertical scales of waves considered. Mean kinetic and potential energies in the 20- to 40-km altitude range both showed increases at latitudes <30° [*Eckermann et al.*, 1995]. A preference for eastward propagation at sites within 10° of the equator has been noted as a possible indication that the wave activity at these sites is dominated by equatorial Kelvin waves [*Hamilton*, 1991; *Eckermann*, 1995b; *Holton et al.*, 2001].

5.1.4. Lidar

[97] Lidar observations of middle atmosphere gravity waves have been restricted to a few specific sites. Among these, only a few have operated for long enough periods to provide information on seasonal variations in gravity wave activity [*Wilson et al.*, 1991b; *Marsh et al.*, 1991; *Mitchell et al.*, 1991; *Whiteway and Carswell*, 1995]. These are all Rayleigh lidar studies of gravity wave temperature or density perturbations at midlatitude sites. The data include gravity waves with vertical wavelengths as short as 1 km at altitudes in the upper stratosphere and lower mesosphere. The data have been analyzed both for vertical variations as well as in the time domain, though these observations are limited to nighttime only. The dominant pattern that has appeared in monthly mean averages of these data is a seasonal cycle with maximum in winter and minimum in summer: the same annual cycle that is observed in radiosonde and rocket sounding data at midlatitudes.

5.1.5. Radar

[98] Radar observations of gravity wave wind perturbations can be made in the lower stratosphere and in the mesosphere and lower thermosphere. Many of these observations have been made at a limited number of sites and on a short-term campaign basis. We focus here

on studies that have compiled observations over long enough time periods to study seasonal variations. These long-term studies have, to date, all been at midlatitude sites.

[99] Analyses of gravity wave observations in the mesosphere in the ~65- to 90-km region are generally reported for different ground-relative frequency bands for waves with periods ranging from 5 min to 24 hours. Gravity wave kinetic energy as well as variances ($\overline{u'^2}$, $\overline{v'^2}$, $\overline{w'^2}$) in each of the three component wind directions have shown a semiannual variation at these altitudes with maxima in summer and winter and minima in spring and fall [*Meek et al.*, 1985; *Vincent and Fritts*, 1987; *Tsuda et al.*, 1990a; *Manson and Meek*, 1993; *Nakamura et al.*, 1996]. These analyses included observations at both Northern and Southern Hemisphere sites, and the results show similar gravity wave activity in the two hemispheres. A seasonal asymmetry in the occurrence of polar mesosphere summer echos (PMSE) and the ice particles that cause them has been observed. Specifically, there is an absence of PMSE in the Southern Hemisphere that may be a result of warmer temperatures in the south due to a weaker mean meridional circulation and corresponding weaker gravity wave forcing [*Balsley et al.*, 1995; *Woodman et al.*, 1999]. Some mesopause temperature measurements support this idea [*Huaman and Balsley*, 1999] while others suggest similar thermal structures at high latitudes in each hemisphere [*Lübken et al.*, 1999]. A recent chemical-dynamical model study [*Siskind et al.*, 2003] supports the idea of hemispheric asymmetries in gravity wave forcing and an asymmetric narrow warm layer at the mesopause that may be difficult to resolve with some measurement techniques.

[100] Observations of horizontal and vertical wind covariance $\overline{u'w'}$ (momentum flux per unit density) in the mesosphere have shown an annual cycle, positive (i.e., eastward) in summer and negative (i.e., westward) in winter, so the flux tends to have the opposite sign as the winds at these altitudes [*Tsuda et al.*, 1990b; *Manson and Meek*, 1993; *Nakamura et al.*, 1993c, 1996]. The anticorrelation between flux direction and the background wind direction is a condition observed even more generally in shorter-term data records [*Vincent and Reid*, 1983; *Reid and Vincent*, 1987; *Fritts and Vincent*, 1987; *Reid et al.*, 1988; *Fritts and Yuan*, 1989b; *Meyer et al.*, 1989; *Wang and Fritts*, 1990; *Nakamura et al.*, 1993c]. The peak magnitudes of monthly mean fluxes (per unit mass) at mesospheric heights have been reported at ~1–4 $m^2 s^{-2}$. Reports of meridional fluxes $\overline{v'w'}$ have been variable, so no repeatable seasonal cycle is known, but reported magnitudes are often comparable to or slightly larger than the zonal fluxes.

[101] Reports of seasonal changes in the anisotropy of wave propagation directions have varied among different studies [*Manson and Meek*, 1988; *Nakamura et al.*, 1993d]. *Maekawa et al.* [1987] and *Fan et al.* [1991] inferred critical-level wind filtering as the mechanism responsible for anisotropies observed in the summer mesosphere wind field using the SOUSY and Arecibo VHF radars, respectively. Inferred propagation directions also depend greatly on the characteristics of gravity waves being observed. *Vincent and Fritts* [1987] and *Nakamura et al.* [1993b] observed a preference for meridional propagation of the dominant wave motions under winter conditions. *Nakamura et al.* [1993b] noted a tendency for propagation of the dominant motions toward either the NE or SW under summer conditions. *Taylor et al.* [1998] and *Nakamura et al.* [1998] observed propagation preferentially toward the NE for waves of shorter horizontal scales under summer conditions. Finally, *Nakamura et al.* [1993a] observed similar character in propagation directions at Adelaide and the MU radar at Kyoto in summer but with more isotropic propagation at Adelaide and more zonal propagation at Kyoto in winter.

[102] Observations in the stratosphere of the seasonal cycle of gravity wave activity measured by radar have been reported only for the MU radar near Kyoto in Japan for altitudes below 24 km [*Tsuda et al.*, 1994b; *Murayama et al.*, 1994; *Sato*, 1994]. These have shown an annual cycle in gravity wave variances ($\overline{u'^2}$, $\overline{v'^2}$, $\overline{w'^2}$) in all three wind components with minima in summer and maxima in winter to early spring. *Sato* [1994] and *Murayama et al.* [1994] also reported zonal and meridional momentum fluxes. The zonal component showed a clear annual cycle with large negative values ~ -0.1 $m^2 s^{-2}$ in winter and near zero in summer. The meridional component also tended to be negative but with smaller magnitudes and no clear annual cycle. The observed wave characteristics at this site have been generally consistent with topographic gravity wave generation. Specific campaigns have, however, also observed waves associated with convection (see section 3.1).

5.1.6. Aircraft

[103] Measurements of wind and temperature fluctuations by aircraft flying in the stratosphere have yielded information on the horizontal wavelength spectrum of gravity waves [*Nastrom et al.*, 1987; *Bacmeister et al.*, 1996] (see section 4.1). Some aircraft studies have related gravity wave characteristics in the stratosphere to the wave sources below, including mountains [*Gary*, 1989; *Bacmeister et al.*, 1990a, 1990b; *Nastrom and Fritts*, 1992; *Leutbecher and Volkert*, 2000] and convection and frontal systems [*Fritts and Nastrom*, 1992; *Pfister et al.*, 1993a, 1993b; *Alexander and Pfister*, 1995; *Alexander et al.*, 2000]. Several of these studies have provided in situ determination of gravity wave momentum fluxes. However, aircraft observations have been too limited in their duration to provide much information about the gravity wave climatology directly. Instead, they have contributed to our understanding of gravity wave variability by providing important quantitative constraints for theoretical and model studies of gravity wave sources (see section 3.1 and Figure 9).

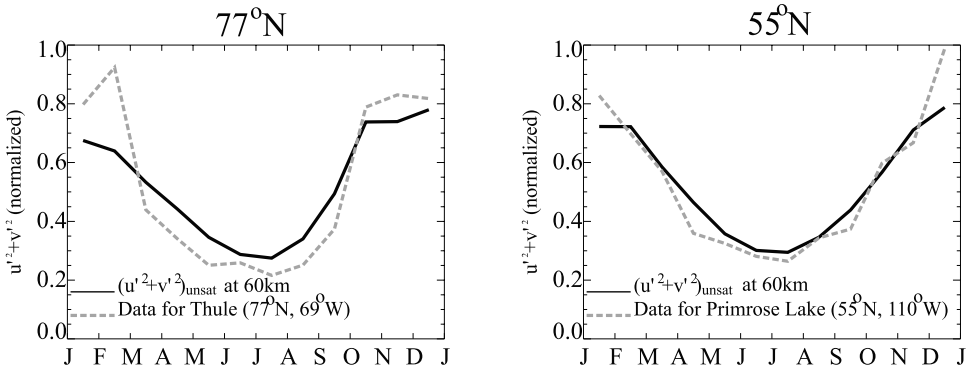

Figure 12. Seasonal variations observed in gravity wave horizontal wind variance in rocket soundings (dashed lines) and theoretical variations given by (54). The dotted line represents the seasonal variation that would be predicted if the wave amplitudes were saturated. After *Eckermann* [1995b] (reprinted with permission of Elsevier Science).

5.2. Theoretical Studies of the Global Patterns Observed in Gravity Waves

[104] At middle to high latitudes throughout the stratosphere the long-term measurements of gravity wave variances cited have shown an annual cycle with maximum in winter and minimum in summer. *Eckermann* [1995b] described a simple linear theoretical model that explained the annual cycle in both lidar and rocket sounding observations without any seasonal variation in gravity wave sources. This linear theory describes the change in amplitude of a gravity wave propagating vertically without dissipation from a source level z_0 where amplitudes are presumed constant to the observation level z. The theory predicts a simple proportionality for horizontal wind variance,

$$\overline{u'^2} \propto (N/N_0)(\rho_0/\rho)\,, \tag{54}$$

and for temperature variance,

$$\overline{(T'/\bar{T})^2} \propto (N^3/N_0)(\rho_0/\rho)\,, \tag{55}$$

that fit the observed annual cycles in variance quite well (Figure 12) despite the fact that shear effects are neglected. The theory yields larger variances in winter because the colder winter stratosphere (with correspondingly smaller-scale height and faster decrease in density) leads to faster amplitude growth with height. Note that the factor depending on stability N is more important for explaining temperature variance ($\propto N^3$) than wind variance ($\propto N$). Equations (54) and (55) may also be important for explaining the seasonal variations seen in radar and GPS observations. Note that in equations (54) and (55), z is the geometric altitude. For observations reported on pressure altitude levels $z_p = H\ln(p_0/p)$, such as radiosonde data, the density factor will be unimportant, and the effect greatly reduced.

[105] Seasonal and latitudinal variations observed in MLS gravity wave temperature variance were largely explained without variations in gravity wave sources by *Alexander* [1998]. Background wind effects were shown to have a controlling influence on the patterns in MLS gravity wave activity. *Alexander* [1998] showed how the MLS observation method essentially applies a low-pass filter to the vertical wave number spectrum of waves in the atmosphere that tends to allow the MLS to observe waves only at those places in the atmosphere where the background winds are very strong. In the stratosphere, these places are in the winter polar jet and in the summer subtropical jet. *McLandress et al.* [2000] further found that the waves seen by MLS in the winter hemisphere jet have, on average, smaller intrinsic phase speeds ($\sim$20 m s^{-1} or less), while those in the summer hemisphere subtropics tend to have larger intrinsic phase speeds ($\sim$50 m s^{-1} or less). This result is consistent with topographic sources being more important at high latitudes and deep convective sources being more important at low latitudes. *Alexander* [1998] also showed that seasonal changes in background winds can give rise to the late summer peak in variance that was observed in rocket sounding observations at low latitudes [*Eckermann et al.*, 1995] without any seasonal changes in sources.

[106] The December to February peak in wave activity observed in low-latitude radiosonde observations [*Vincent and Alexander*, 2000] was explained without any pronounced seasonal variation in wave sources in a companion model study [*Alexander and Vincent*, 2000]. However, the spectrum of waves input into their model required certain characteristics. The waves input needed to have slow phase speeds, < 5 m s^{-1} relative to the ground, and the source level had to be in the upper troposphere or at the tropopause. This is consistent with the spectrum of waves that would be generated if the source were slow-moving deep convective complexes that generated waves via the obstacle effect near the tropopause analogous to topographic wave forcing [*Clark et al.*, 1986; *Pfister et al.*, 1993b]. There is also a weak annual cycle in cloud top height near Cocos Island [*Vincent and Alexander*, 2000] that may imply some contribution to the gravity wave annual cycle due to source variations.

[107] GPS, CRISTA, radiosonde, and rocket sounding data have all shown a latitudinal variation in gravity wave energy in the lower stratosphere with increasing variance equatorward of ~30°. *Alexander et al.* [2002] proposed this peak is associated with the latitudinal variation in the Coriolis parameter f which defines the lowest gravity wave intrinsic frequency as a function of latitude. Each of these four observational techniques is sensitive to these low-frequency waves. The linear theory they applied to explain the peak accounts for the dependence of gravity wave vertical group velocity on intrinsic frequency (see equation (39)). If there is intermittency in the forcing of waves in the equatorial region (such as would be expected of waves generated by convection), then the slow vertical group velocities of the low-frequency waves make them the most probable waves to be observed. The theory then accounts for the nearly ubiquitous presence of low intrinsic frequency waves at low latitudes and also accounts for the low-latitude peak seen in long-term averages of gravity wave energy cited above. The results of *Alexander et al.* [2002] further imply that although higher-frequency waves appear relatively unimportant in the monthly mean zonally averaged gravity wave energy, they may dominate the gravity wave momentum flux spectrum.

[108] Seasonal variations in zonal momentum flux $\overline{u'w'}$ observed by radar in the midlatitude mesosphere, showing the mean flux opposes the background wind (positive in summer and negative in winter), are qualitatively consistent with our understanding of how the background winds would filter the gravity wave spectrum [e.g., *Maekawa et al.*, 1987; *Fan et al.*, 1991]: Summer westward winds would prevent most of the westward propagating waves from reaching the mesosphere, leaving primarily eastward propagating waves with positive momentum flux, and the reverse would be true in winter. Fluxes were observed to be small at equinoxes, but this is probably not due to averaging of large negative and positive fluxes together. Rather, the small equinoctal fluxes and kinetic energies, taken together, suggest that wave amplitudes are simply smaller at equinoxes. The equinoctal minima may be directly associated with the weak mesospheric winds at these times rather than any seasonal variation in sources. In weak wind conditions, waves are not Doppler shifted to high intrinsic phase speeds, and this results in smaller-amplitude limits inferred from linear instability theory (see section 6).

5.3. Summary: Global Characteristics of Gravity Waves and Their Sources and Variability

5.3.1. Sources

[109] There is convincing evidence for mountain waves in the stratosphere with fair quantitative agreement between high-resolution model studies and observations. Parameterized mountain waves, however, have a large effect in global models, and improved constraints on their properties and intermittency in occurrence are still needed. There is convincing evidence for convectively generated gravity waves in the stratosphere with qualitatively good agreement between observations and models. Observations that include both detailed information about the storm characteristics and about the waves that are generated are hard to find but are needed to make our understanding of convectively generated gravity waves more quantitative. There is evidence for low-frequency waves emanating from frontal zones in the jet stream and high-resolution model studies describing inertia-gravity wave generation under these conditions. Observational evidence detailed enough for a quantitative understanding of this wave source is lacking. A detailed understanding of the generation mechanisms and the resulting wave characteristics is needed for accurate description of gravity wave effects in global models.

5.3.2. Variability

[110] Observations of short vertical wavelength gravity waves in the lower stratosphere show increases in variance at latitudes $<30°$. This has been interpreted as evidence for very low intrinsic frequency waves at low latitudes that are excluded from higher latitudes by the variation in f and that have intermittent sources in time, such as would be expected from convection. Very close to the equator, at latitudes $<10°$, these measurements could also include contributions from short vertical wavelength Kelvin waves. Also in the tropics, there is evidence for geographical variations in long vertical wavelength gravity waves with high intrinsic phase speeds that are closely tied to deep convection. These observations support model studies that show how deep heat sources generate long vertical wavelength waves.

[111] The evidence for global variations in gravity wave sources from climatologies of gravity wave activity is currently weak because many of the most prominent variations observed can be explained by background atmosphere effects without any seasonal or geographical variations in sources. Yet we have clear evidence for the importance of topography, convection, and frontal generation of gravity waves, and these sources must clearly vary seasonally and geographically. The existing gravity wave climatologies that describe monthly mean gravity wave kinetic and potential energy have largely served their purpose. They have allowed us to test the linear theory of gravity waves and their interaction with the background atmosphere.

[112] Observational gravity wave studies in the future must begin to define the deviations in gravity wave activity from these climatological patterns. Observations and modeling tools must be used together to separate these variations due to the background atmosphere and observational biases from variations due to sources. Quantitative measures of the intermittency in wave activity are needed along with any monthly mean quantity since it is important to define whether a monthly mean

value represents intermittent large bursts of wave activity or more constant, smaller-amplitude wave activity.

[113] Satellite observations hold the most promise for providing the kind of geographical and temporal coverage needed to understand gravity wave variability. However, inherent observational limitations mean that continued in situ measurements from aircraft and high-resolution ground-based profiling instruments will still be needed to understand the full spectrum of gravity waves present in the atmosphere.

6. INTERACTIONS, INSTABILITY, AND SATURATION

[114] Nonlinearity is a ubiquitous aspect of gravity wave dynamics. At smaller wave amplitudes, nonlinearity leads to slow energy transfers via three-wave interactions satisfying resonance conditions for wave frequencies and wave number vectors. At larger amplitudes, multiple-wave, nonresonant, and wave–vortical mode interactions become possible, culminating in the local instability of the wave via generalized wave breaking or shear instability processes as amplitudes increase further. Wave–mean flow interactions may also play important roles at larger wave amplitudes, altering wave propagation, inducing instability, and/or leading to excitation of additional waves. Thus nonlinearity has pervasive influences and is always poised to intercede more vigorously when linear dynamics imply excessive wave amplitudes. A number of reviews of the earlier developments in these areas are available; several relevant to gravity wave instability processes include *Fritts and Rastogi* [1985], *Müller et al.* [1986], *Thorpe* [1987], and *Dunkerton* [1989].

[115] More recent theoretical, numerical, and laboratory studies have expanded our understanding of gravity wave instability processes considerably. Several studies have begun to clarify the diversity of instability character with wave amplitude and propagation angle, including identifying links between the resonant interactions arising at small wave amplitudes and the local instabilities accompanying wave breaking and turbulence generation at large amplitudes [*Klostermeyer*, 1991; *Lombard and Riley*, 1996; *Sonmor and Klaassen*, 1997; *Dunkerton*, 1997a]. Other efforts have demonstrated the role of wave–wave interactions at small and large wave amplitudes [*Dunkerton*, 1987; *Klostermeyer*, 1991; *Thorpe*, 1994; *Vanneste*, 1995] and defined the dynamics of the transition to turbulence for gravity waves that are locally convectively or dynamically unstable [*Winters and D'Asaro*, 1994; *Andreassen et al.*, 1994, 1998; *Fritts et al.*, 1994, 1996a, 1998; *Fritts and Werne*, 2000]. Further studies have addressed the processes accounting for more general spectral energy transfers, effects of finite amplitude and wave–mean flow interactions on wave propagation, dispersion, and instability, and the competition among and finite-amplitude responses to initial instabilities of varying amplitudes. Our purpose in this section is to review the more recent work in these areas.

6.1. Wave–Wave Interactions

[116] Wave–wave interactions as a source of middle atmosphere gravity waves were discussed briefly in section 3. The purpose here is to review their expected influences on the shape and evolution of the gravity wave spectrum more broadly. A number of authors have addressed wave–wave interactions and spectral evolution from a statistical perspective; others have approached the problem deterministically. There remain, however, substantial uncertainties and disagreements over the roles these interactions play in spectral evolution and wave amplitude constraints.

[117] Early studies of wave–wave interactions in the atmosphere identified the dominant interactions previously recognized in oceanic applications [*McComas and Bretherton*, 1977; *Yeh and Liu*, 1981; *Müller et al.*, 1986]. Three-wave (second order) resonant interactions require a match of wave numbers and frequencies among the participating waves satisfying

$$\mathbf{k} = \mathbf{k_1} + \mathbf{k_2} \tag{56}$$

and

$$\hat{\omega} = \hat{\omega}_1 + \hat{\omega}_2 , \tag{57}$$

where subscripts denote the secondary wave quantities, and include (1) elastic scattering, (2) induced diffusion, and (3) parametric subharmonic instability (PSI). Elastic scattering refers to the backscattering of an upward propagating wave into a downward propagating wave (or vice versa) of comparable vertical wave number by a low-frequency motion (or mean flow) having twice the vertical wave number (Bragg scattering). Induced diffusion refers to the transfer of energy from one wave to another having a nearly identical wave number through interaction with a low-frequency (or mean) structure at a much smaller vertical wave number. Alternatively, induced diffusion may be regarded as the evolution of a wave packet in a large-scale shear flow. The third interaction, and arguably the most important in terms of spectral broadening or wave amplitude constraints, is PSI. In its most studied form, PSI represents an exchange of energy from a dominant motion of intermediate frequency to two motions having approximately half the parent frequency and large and nearly opposite wave number vectors, though other wave number combinations exhibit preferred growth in certain circumstances, such as the presence of a mean shear.

[118] More recent efforts have identified other possibilities for energy exchange and further modes of interaction likely to occur among atmospheric waves and other motions. *Broutman and Young* [1986] and *Broutman et al.* [1997], for example, noted that an energetic resonant-triad member can result in an irreversible transfer of energy to small wave numbers not anticipated

by *McComas and Bretherton* [1977]. *Dong and Yeh* [1988] relaxed the assumptions of *Yeh and Liu* [1981] and considered wave–wave interactions not confined to a vertical plane or a resonance surface (nonresonant interactions were also discussed by *Müller et al.* [1986]). Further efforts revealed a potential for nonresonant gravity wave–vortical mode interactions for which the threshold amplitude is reduced or removed in the presence of rotation [*Yeh and Dong*, 1989]. As wave amplitudes increase, additional interactions become energetically viable. *Dunkerton* [1987] performed numerical studies to assess the impact of wave–wave interactions on wave momentum transport, with and without mean shear. He found a rapid energy transfer on the timescale of the forced waves following attainment of large amplitudes, followed by a nonlinear cascade toward increasing complexity as additional interactions became possible. When critical levels were present for the forced waves, *Dunkerton* [1987] found weaker resonant wave–wave interactions, the occurrence of additional nonresonant interactions, and the excitation of a wave having higher intrinsic frequency than the forced waves corresponding to a different branch of the PSI.

[119] *Klostermeyer* [1991] likewise found that larger primary wave amplitudes enable a cascade of interactions that quickly populate the spectrum, while waves that approach or exceed a convectively unstable amplitude support various modes of instability [*Hines*, 1971, 1988b; *Lombard and Riley*, 1996; *Sonmor and Klaassen*, 1997; *Dunkerton*, 1997a]. *Vanneste* [1995] performed both analytic and numerical studies of wave–wave interactions localized in space and noted good agreement between the two methods. In particular, *Vanneste* [1995] found that spatially localized interactions transferred significant energy on a timescale of ~10 primary wave periods for a primary wave amplitude of $a = u'/c \sim 0.25$. *Vanneste* [1995] also noted that mean shear suppresses the dominant unsheared wave–wave interaction but enables a "difference instability" which occurs near the primary wave critical level and has a secondary wave frequency larger than that of the primary wave (like *Dunkerton* [1987]), downward secondary wave propagation, and a growth rate that increases with shear strength. Such interactions are necessarily only resonant at specific locations but, nevertheless, enable rapid energy transfers under certain conditions [*Grimshaw*, 1988].

[120] An example of resonant excitation via PSI in the laboratory study by *Thorpe* [1994] is shown in Figure 13. Here a primary wave with phase aligned along the mean tilt of the tank transfers energy to a lower-frequency wave that becomes the predominant wave at later times. The wave–wave interaction proceeds quickly because of the large forcing wave amplitude, and the secondary wave achieves local convective instability. A numerical wave–wave interaction study performed by *Vanneste* [1995] is displayed in Figure 14 and exhibits the decay of a primary wave at higher frequency (Figure 14b) into two motions having lower frequencies (Figures 14c and 14d). The mean flow also experiences significant modifications in the presence of strong wave–wave interactions and can result in critical-level interactions and convective instability of the wave field [*Sutherland*, 2001]. Hence wave–wave and wave–mean flow interactions should be expected to play increasing roles in spectral evolution and energy and momentum fluxes as wave amplitudes increase with altitude.

[121] Theories of middle atmosphere spectral evolution employing statistical wave–wave interactions have also borrowed from the oceanic literature. The Lagrangian arguments by *Allen and Joseph* [1989] were employed in the Doppler spread theory by *Hines* [1991, 1993] to account for the form of the saturated "tail" spectrum. *Hines* [1996] extended these arguments and used the apparent success of this model to argue against the relevance of other existing saturation theories, most specifically "linear" saturation theory [*Dewan and Good*, 1986; *Smith et al.*, 1987] and the "nonlinear diffusion" theory by *Weinstock* [1976, 1982, 1984, 1990]. The Hines theory attributes the large majority of spectral energy transfers to Doppler spreading by a "broad" spectrum of waves, with wave amplitudes and interactions increasing with altitude. The theory presumes that dissipation generally does not occur except at small scales having vertical wave numbers $m > m_M$, where m_M is the maximum vertical wave number for which spectral character is determined largely by Doppler spreading, and infers a spectral shape approaching the m^{-3} value most often cited by other saturation theories and various observations cited above. Advantages of the Hines theory include a recognition of the increasing statistical importance of nonlinear wave–wave interactions with increasing wave amplitudes and a natural transition from "linear" source spectra at lower altitudes to a nonlinear "saturated" spectrum at higher altitudes.

[122] There has been considerable confusion over the *Allen and Joseph* [1989] results and their implications for Doppler-spread theory over time. *Hines* [1999] noted an error in the Allen and Joseph analysis overlooked in his earlier papers and suggested a corrected high-m spectral form of m^{-1} rather than m^{-3}. More recently, *Hines* [2001] and *Chunchuzov* [2002] argued for the removal of the m^{-1} term arising from the error correction to again infer a high-m spectrum of the form m^{-3} but with an amplitude ~2–3 times smaller than typically observed.

[123] The Hines Doppler spread theory has its detractors, however. Several authors have performed numerical studies that appear to seriously undermine the assumptions of Doppler spread theory [*Zhong et al.*, 1995; *Bruhwiler and Kaper*, 1995; *Broutman et al.*, 1997; *Eckermann*, 1997; *Buckley et al.*, 1999; *Walterscheid*, 2000]. Essentially, these studies show that when time dependence and vertical motions of the underlying wave field are accounted for, the tendency for transfer of spectral energy to ever smaller vertical scales is substantially reduced (or reversed). *Zhong et al.* [1995] employed

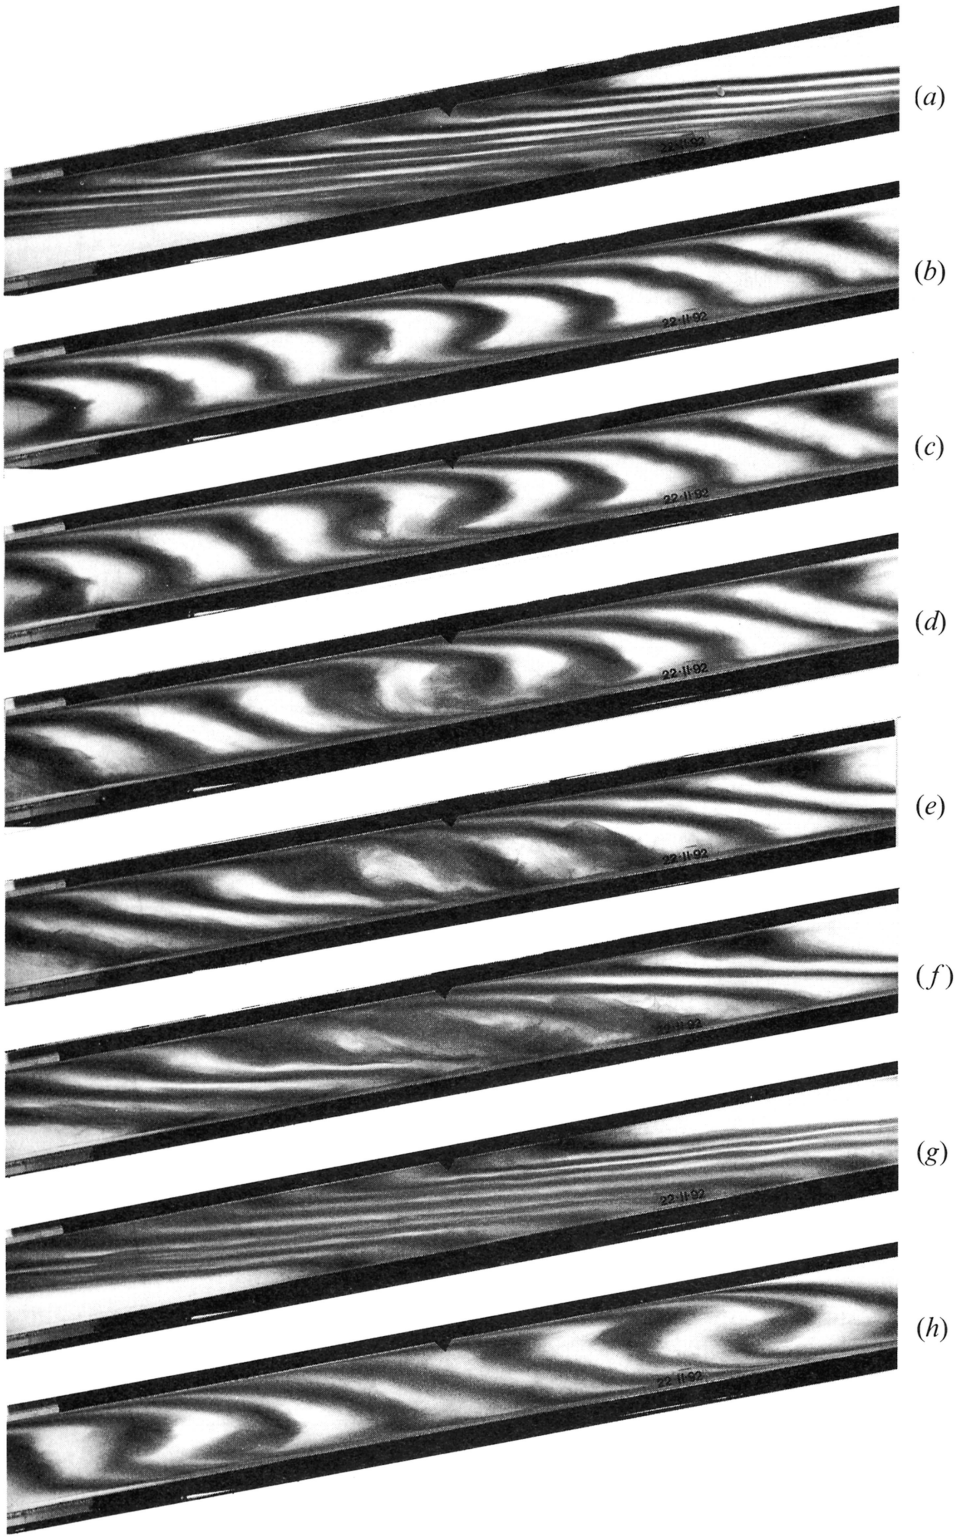

Figure 13. Dyed isopycnal surfaces in a rocked inclined tube showing the development and instability of a wave excited by the PSI. Note that the primary wave (with uniform structure along the tube) contributes largely at early times, whereas the subharmonic wave dominates the instability at later stages. After *Thorpe* [1994] (reprinted with permission of Cambridge University Press).

ray-tracing techniques to examine tidal modulation of wave propagation and noted that time dependence caused critical levels to become transient. *Bruhwiler and Kaper* [1995] formulated the problem from a Hamiltonian perspective and showed that the theory was in good agreement with ray-tracing results for a spectrum of waves with various background wave amplitudes. They found, in particular, a tendency for low-*m* waves to

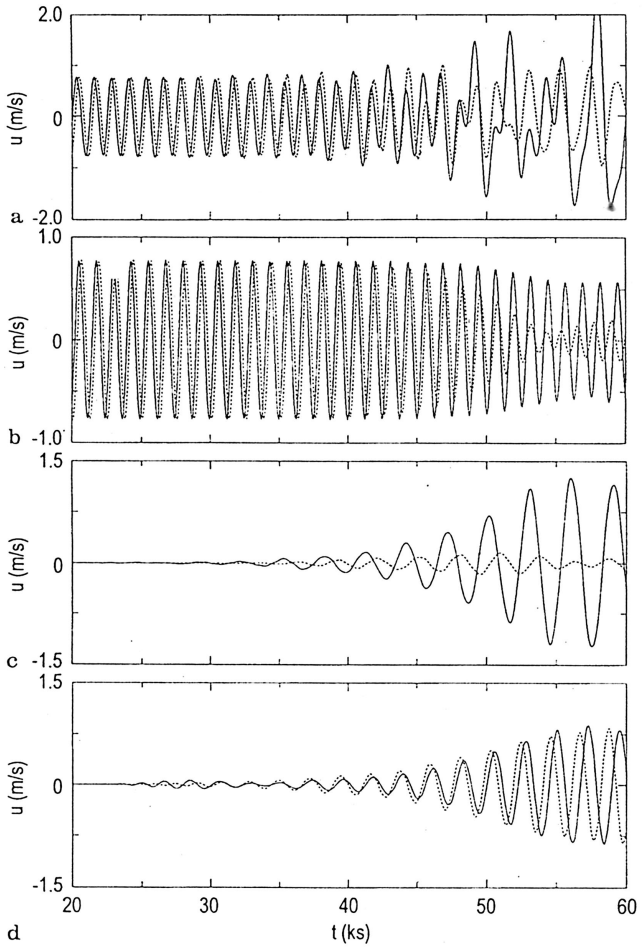

Figure 14. Numerical simulation of PSI in an unsheared atmosphere with a scale height of 7 km. Shown are the (first panel) total, (second panel) primary wave, and (third and fourth panels) two secondary wave vertical velocities at altitudes of 10.7 (solid lines) and 17.75 km (dashed lines). Note that both secondary waves grow to amplitudes exceeding that of the primary wave as the interaction proceeds. After *Vanneste* [1995] (reprinted with permission of Springer-Verlag).

remain at low m and for high-m waves to move preferentially to lower m, representing a sharp departure from expectations based on Doppler spread arguments.

[124] *Broutman et al.* [1997] performed both ray-tracing and full numerical simulations, demonstrating the equivalence of the two approaches and the various influences of spatial and temporal variability on short-wave propagation. These results are illustrated in Figure 15. In particular, they exhibit a scattering of short-wave (large m) energy to both smaller and larger wave numbers, consistent with previous assessments based only on ray tracing [*Broutman*, 1986; *Broutman and Young*, 1986; *Bruhwiler and Kaper*, 1995], and a spectral form close to m^{-3} that is consistent with the results of *Eckermann* [1999]. *Eckermann* [1997] and *Walterscheid* [2000] also considered single waves in backgrounds having various character. *Eckermann* [1997] addressed specifically the various assumptions underlying the Doppler spread theory by *Hines* [1991, 1993, 1996], concluding that wave field transience significantly reduces the tendency to transfer wave energy to smaller vertical scales and eliminates a cutoff in unspread vertical wave numbers near m_c, itself a key element of Doppler spread theory. *Walterscheid* [2000] obtained similar results, emphasizing both the mitigating effects of time dependence on Doppler spreading and the role of vertical velocities in allowing wave packets to penetrate anticipated critical levels. *Hines* [1999] raised strong objections to the analysis by *Eckermann* [1997], arguing that the multiple-wave background offset the results of a single-wave background to a significant degree.

[125] *Buckley et al.* [1999] and *Sonmor and Klaassen* [2000] extended the analyses by Eckermann, Broutman et al., and Walterscheid by considering the effects of a spectrum of background waves, isolated wave packets, and a mean shear. Both studies suggest a weaker tendency for refraction toward large m than with the steady assumptions underlying Doppler spread theory. *Sonmor and Klaassen* [2000] also found that multiple waves induce caustics under more general conditions than supported for single-wave environments, while both studies found that mean shears have significant cumulative refraction effects over timescales of a few inertial periods.

[126] Doppler spread theory, as it is presently developed, precludes competitive instability processes (i.e., linear saturation theory) from contributing to the shape of the vertical wave number spectrum except, to quote from *Hines* [1996], at wave numbers "a little less than m_M; but, arising as they almost certainly do in small-scale 'white-cap' regions, their effect is unlikely to extend very far". However, an increasing number of numerical and observational studies are providing evidence that local wave instability, via convective or shear instability, at large vertical scales is more the rule than the exception (see section 6.2.1), despite the clear potential for wave–wave interactions to contribute importantly to energy transfers as wave amplitudes increase. Additional observations suggesting that the atmospheric wave spectrum is often not broad but is composed of a single or a few dominant motions further undermine the ability of Doppler spreading among multiple waves to provide large enough spectral transfers and to reproduce the observed amplitude limits.

[127] Clearly, the jury is still out on these issues. There is clear evidence, as noted, of discrete, large-amplitude events or superpositions of a few waves which yield canonical spectral shapes in an Eulerian frame but which suggest a simpler Lagrangian viewpoint. Indeed, *Hines* [2001] stated "that the occurrence of the large-wave number Eulerian tail has nothing whatever to do with any physical process. . . . If one insists on defining 'waves' according to their Eulerian linear description, then one is forced to admit to the existence of 'nonlinear wave–wave interactions'. . .but these are mere mathematical artifacts and have no physical import." However, while transformation to a Lagrangian coordinate does remove

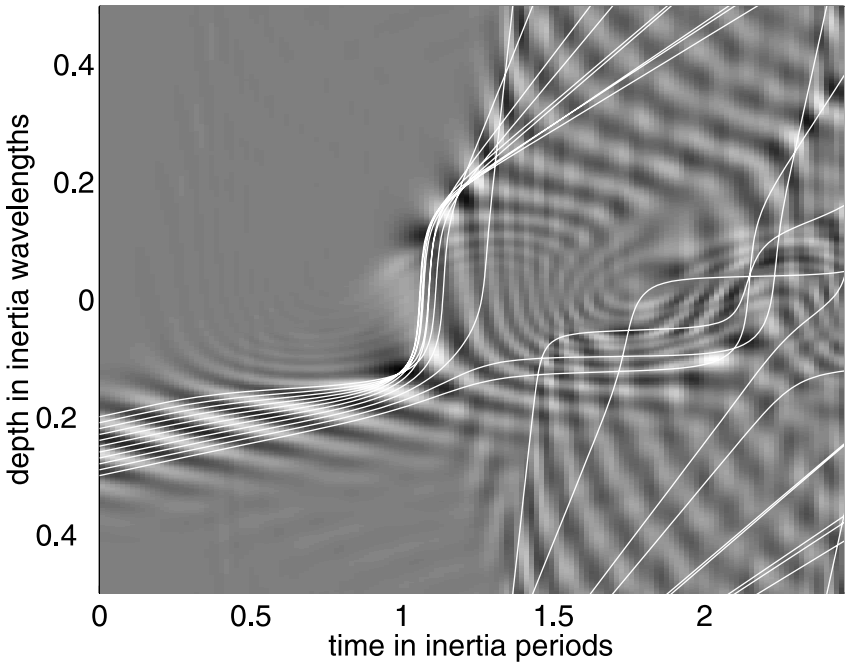

Figure 15. Perturbation density illustrating the encounter of a small-scale wave packet with an inertia-gravity wave of much larger scale. In this case, the small-scale wave has a horizontal phase speed 0.2 of the maximum of the inertia-gravity wave motion, no critical level trapping occurs, and both the vertical wavelength and horizontal phase speed of the small-scale wave increase dramatically. After *Broutman et al.* [1997].

the advective nonlinearity in the Navier-Stokes equations, it does not remove the coupling of wave scales that nonlinearity implies. For example, claims of Lagrangian linearity cannot explain the nonlinear coupling of scales observed in nonlinear simulations or laboratory studies revealing significant wave–wave interactions [*McEwan*, 1971; *Klostermeyer*, 1991; *Thorpe*, 1994; *Vanneste*, 1995]. Likewise, shears due to mean winds and large-scale waves imply critical levels, small vertical scales, and instability processes that are demonstrably not mathematical artifacts. Indeed, Broutman et al. (personal communication, 2002) have pointed out that the dispersion relation employed by *Hines* [2001, 2002a] does not include the influences of mean wind shear on vertical wave structure and thus does not describe the full effects of Doppler shifting. The important issue is not whether nonlinear wave–wave (and wave–mean flow) interactions are important, as they surely are, but whether they are the dominant mechanism in constraining wave amplitudes and shaping the spectrum for $m < m_M$, as argued by *Hines* [2001] and *Chunchuzov* [2002], or whether they are one of several key processes acting in this fashion, which seems a more defensible perspective, given the various evidence available to date. The identified links between wave instabilities at small and large amplitudes [*Sonmor and Klaassen*, 1997], however, may render such distinctions obsolete.

[128] The *Weinstock* [1976, 1982, 1985] theory was discussed in previous reviews and has itself served as the basis for additional saturation theories by *Zhu* [1994] and *Medvedev and Klaassen* [1995] having various attributes. All of these theories view nonlinearity as spectral diffusion of one form or another. There is no clearly defined link, however, with the predictions of wave–wave interaction theory or direct numerical studies [e.g., *Dunkerton*, 1987; *Klostermeyer*, 1991; *Vanneste*, 1995], so testing of the physical basis for the theory has proved challenging. Recently, *Hines* [2002b] has raised serious objections to assumptions in the original work by Weinstock and its successors by association. However, while Weinstock's theory is clearly an approximation to a class of nonlinear effects, like Doppler spread theory, it calls attention to the importance of nonlinear interactions in shaping the wave spectrum with increasing altitude. Indeed, Hines's criticism has itself been recently challenged (Klaassen and Medvedev, personal communication, 2000). In summary, nonlinear wave–wave interactions must be regarded, at present, as a viable means of exchanging energy among gravity waves at various scales and frequencies throughout the middle atmosphere. Evidence suggests, however, that they cannot account, by themselves, for the general shape or amplitude of the gravity wave spectrum. Rather, they represent one of several nonlinear processes that act jointly to define gravity wave spectral character and evolution with altitude. Wave–wave interactions likewise do not contribute directly to energy dissipation, except through their links to specific instabilities at larger wave amplitudes [*McEwan*, 1971].

6.2. Instability and Turbulence Dynamics

[129] Theoretical, numerical, and observational studies have made substantial contributions to our understanding of instability and turbulence dynamics accompanying gravity waves in recent years. Perhaps the greatest advances were made possible by the continuing evolution of high-performance computers, which are now capable of direct numerical simulations (DNS) of stratified and sheared flows having resolutions of $\sim 1000^3$ and above. Such simulations are capable of describing both the transition to turbulence in a geophysical flow and the vorticity dynamics driving the turbulence cascade. Observational capabilities have also progressed significantly over the last decade or so and have yielded high-resolution in situ and ground-based measurements of wave and turbulence structures. Other numerical and laboratory studies have contributed to our understanding of general turbulence dynamics in applications not specific to atmospheric gravity waves.

[130] Turbulence is generally believed to arise locally within a gravity wave (or a field of superposed waves) when the flow is either convectively or dynamically unstable and the timescale for instability growth is sufficiently shorter than that describing the evolution of the wave field. More recent analyses have shown, however, that a wide spectrum of instabilities is possible, with specific instability character depending on wave amplitude and intrinsic frequency, mean shear and stability profiles, and the form and amplitude of perturbations triggering flow instability. In particular, local instability can occur at wave amplitudes below that often considered necessary for convective instability in many instances [*McEwan*, 1971; *Hines*, 1988b; *Lombard and Riley*, 1996; *Sonmor and Klaassen*, 1997]. It is also believed, based on simple stability arguments, that dynamical instability should predominate for intrinsic frequencies $\hat{\omega} \sim f$ and that convective instabilities should predominate for intrinsic frequencies $\hat{\omega} \gg f$ [*Dunkerton*, 1984; *Fritts and Rastogi*, 1985] because of the very different relative amplitude thresholds in each case. These expectations are supported by the numerical simulations performed to date [*Andreassen et al.*, 1994, 1998; *Fritts et al.*, 1994, 1998, 2003; *LeLong and Dunkerton*, 1998a, 1998b].

[131] Because local instabilities at wave amplitudes below that normally identified as the "convective" instability limit,

$$a = u'/(c - \bar{u}) = 1.0\,, \tag{58}$$

generally exhibit slow growth, however [*Lombard and Riley*, 1996; C. Bizon, personal communication, 2001], we assume for our discussion that the nominal threshold amplitudes for dynamical and convective instability are those which yield $Ri < 1/4$ and $Ri < 0$, respectively, with the Richardson number (Ri) defined to be

$$Ri = \frac{N^2}{\bar{u}_z^2 + \bar{v}_z^2}\,, \tag{59}$$

where $\bar{u}_z$ and $\bar{v}_z$ are the local mean zonal and meridional wind shears and N is the local buoyancy frequency. For most intrinsic frequencies the two threshold amplitudes are nearly identical [*Dunkerton*, 1984; *Fritts and Rastogi*, 1985], departing significantly only for $\hat{\omega} \sim f$.

[132] With the high-resolution simulations now possible on current supercomputers, DNS studies of gravity wave breaking at sufficiently high intrinsic frequencies (i.e., more nearly comparable, rather than disparate, horizontal and vertical wavelengths) can capture both gravity wave scales and a broad range of turbulence scales simultaneously. On the other hand, the large disparity between inertia-gravity wave and turbulence scales ($\sim 10^6$ or more) prevents simulations that span this range of scales. Instead, relevant simulations have addressed the KH instability of inertia-gravity waves and the turbulence arising from KH instability separately.

6.2.1. Gravity Wave Breaking

[133] A number of numerical studies addressed gravity wave breaking and the accompanying wave amplitude limits in 2-D for lack of adequate computational resources to perform full 3-D studies. Because the instability processes are inherently 3-D, however, 2-D studies are either limited in their utility (e.g., in quantifying wave amplitude limits and momentum flux divergence) or complete misrepresentations of the relevant dynamics (e.g., in modeling wave breaking and turbulence dynamics) [*Andreassen et al.*, 1994]. Thus, we will review here only those studies addressing the 3-D character of wave instability or the occurrence and scales of such events in the atmosphere.

[134] The first 3-D numerical studies of gravity wave instability dynamics in the atmosphere were performed by *Andreassen et al.* [1994], *Fritts et al.* [1994], and *Isler et al.* [1994]. A parallel study examining similar dynamics in an oceanic context was performed by *Winters and D'Asaro* [1994]. These studies addressed gravity wave breaking via convective instability, which appears to be the preferred instability for gravity waves at relatively high intrinsic frequencies [*Dunkerton*, 1984; *Fritts and Rastogi*, 1985]. These simulations succeeded in describing the character of the primary wave instability process; this comprises counterrotating streamwise (along the flow) convective rolls or vortices (with spanwise, or normal, wave number). These convective rolls occupy the full depth of the convectively unstable region within the gravity wave, derive their eddy energy (or vorticity) from baroclinic and shear sources within the 2-D flow, and trigger a turbulence cascade via mutual vortex interactions as they interact with adjacent shear layers (or vortex sheets). Indeed, the initial study of gravity wave breaking in 3-D provided a plausible explanation for apparent streamwise instability structures observed in NLC near the summer mesopause [*Fritts et al.*, 1993b] (see Figure 16). Additional observational evidence of such instabilities has come from recent analyses of air-

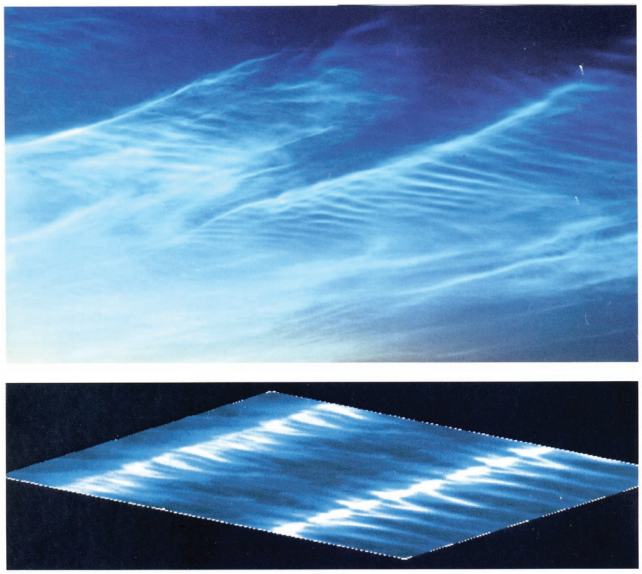

Figure 16. (top) Observed and (bottom) simulated gravity wave and instability structures in NLC. Photo was taken at Turku, Finland, on 21–22 July 1989, courtesy of Pekka Parvianien. Streamwise-aligned instability structures are believed to have accounted for the smaller-scale bright bands oriented approximately normal to the gravity wave phase fronts in the upper image. After *Fritts et al.* [1993b].

glow imaging data and correlative wind measurements [*Swenson and Mende*, 1994; *Hecht et al.*, 1997, 2000].

[135] Subsequent numerical studies at higher resolution addressed wave breaking in streamwise and transverse shear flows [*Fritts et al.*, 1996a], with superposed low- and high-frequency motions [*Fritts et al.*, 1997b], and the vorticity dynamics driving the turbulence cascade [*Andreassen et al.*, 1998; *Fritts et al.*, 1998]. The latter studies addressed in detail the vorticity dynamics of the initial shear-aligned instabilities as well as their subsequent interactions with adjacent vorticity sheets (the mean and 2-D gravity wave shears having spanwise vorticity).

[136] The vorticity field arising because of convective instability of the gravity wave, the subsequent transition to turbulence, and the dynamics within the turbulent flow are illustrated in Figure 17 at various times throughout the simulation described by *Andreassen et al.* [1998] and *Fritts et al.* [1998, 1999]. The simulation was performed for a gravity wave of horizontal wavelength ~30 km and intrinsic frequency at the level of wave breaking of $\sim N/6$. A mean shear was imposed to confine the breaking to the region below the initial critical level for the wave. The entire transition from a 2-D overturning gravity wave to quasi-isotropic turbulence occupies approximately a buoyancy period in this simulation. Vortex structures are displayed using a quantity representing the rotational or "tube-like" character of the motion field analogous to the minimum pressures within the flow (see *Jeong and Hussain* [1995] and *Andreassen et al.* [1998] for further details). The volumes are viewed from below, with the streamwise direction and wave propagation to the right.

[137] The transition from 2-D laminar flow to 3-D quasi-isotropic turbulence accompanying wave breaking involves several distinct phases: (1) the initial shear-aligned convective instability within the gravity wave (first two images in Figure 17), (2) a second phase in which divergent spanwise motions below adjacent streamwise vortices stretch and thin the adjacent spanwise vortex sheets, causing them to become locally dynamically unstable, (3) the formation of secondary, spanwise-localized KH billows on the intensified vortex sheets and their linkage to the overlying streamwise vortices to form series of intertwined vortex loops (second, third, and fourth images in Figure 17), and (4) the subsequent interactions of neighboring vortices, the excitation of twist waves on the various vortices, and the unraveling, fragmentation, and breakup of the vortices that comprises the cascade to smaller scales of motion (last four images in Figure 17). Indeed, the various stages in the transition to turbulence often occur nearly simultaneously in different (or the same) portions of the flow. Similar simulations having a spanwise mean shear component and more recent higher-resolution simulations having no mean shear confirm the general nature of the transition and turbulence dynamics described above [*Fritts et al.*, 1996a, 2003].

[138] Various stages in the turbulence evolution noted above also parallel in important respects vortex dynamics observed in other turbulent flows. Intertwined vortex loops, or similar "hairpin" or "horseshoe" vortices, are seen to arise in sheared boundary layers [*Gerz et al.*, 1994; *Adrian et al.*, 2000]; twist waves, so easily excited in the wave breaking simulations, were also observed, but not recognized as such, in laboratory studies of vortex dynamics [*Cadot et al.*, 1995]. Finally, the sequence of vortex dynamics seen in gravity wave breaking exhibits striking parallels to that observed in the transition to turbulence accompanying the KH instability to be discussed below [see also *Arendt et al.*, 1997, 1998; *Fritts et al.*, 1999]).

[139] The scales at which gravity wave breaking occurs are becoming better known based on both direct and indirect measurements. Such observations also address the current debate over the mechanisms constraining wave amplitudes and imposing saturation of the gravity wave spectrum (see sections 6.1 and 6.3). Direct measurements of density or temperature (via lidar and balloon- or rocket-borne instrumentation) reveal frequent occurrences of near-adiabatic or superadiabatic lapse rates, with occurrence frequency and vertical scale increasing with altitude. Recent examples include balloon and Rayleigh lidar measurements of large-amplitude wave motions at lower altitudes [*Hauchecorne et al.*, 1987; *Shutts et al.*, 1988; *Wilson et al.*, 1991a; *Whiteway and Carswell*, 1995; *Hoppe et al.*, 1999] and sodium resonance lidar measurements at greater altitudes

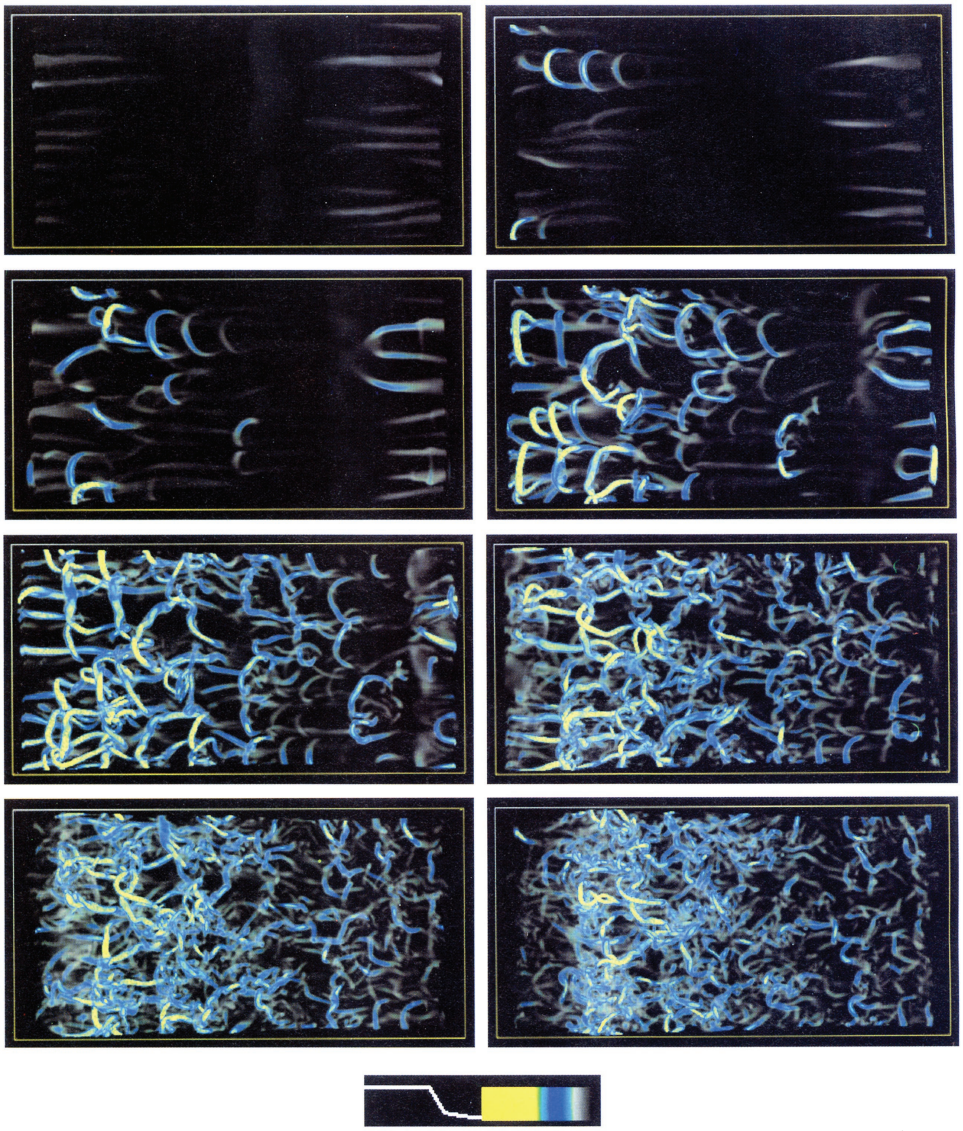

Figure 17. Vorticity structures in a breaking gravity wave viewed from below with the direction of wave propagation to the right. The images display vortex structures from left to right and top to bottom, spanning one buoyancy period following attainment of convective instability of the wave field. See text for details. After *Fritts et al.* [1999] (reprinted with permission of Terra Scientific Publishing Company).

[*Hecht et al.*, 1997; *Williams et al.*, 2002]. Rocket measurements employ various techniques, including falling spheres [*Fritts et al.*, 1988b], chaff [*Wu and Widdel*, 1991], ionization gauges [*Lübken*, 1997], and Rayleigh lidars [*Hoppe et al.*, 1999]. These observations reveal unstable or nearly unstable layers typically up to a few kilometers in depth, suggesting convectively unstable gravity waves having vertical wavelengths of ~3–10 km or more, with the larger scales more prevalent near the mesopause. The recent sodium lidar measurements by *Williams et al.* [2002] represent a particularly striking example, with multiple superadiabatic layers a few kilometers in depth within a near-adiabatic layer extending more than 10 km and persisting for more than 4 hours (see Figure 18). As noted above, these observations suggest, at least in this instance, wave saturation via local convective instability, though wave superposition or wave–wave interactions, specifically the PSI displayed in Figure 13, may play a role in the vertical fine structure within the overturning wave field. While this event is exceptional, the frequency of observation of such features suggests that they are far from the infrequent or pathological cases implied by *Hines* [1996]. Indirect inferences of convective overturning scales are provided by NLC and airglow measurements of horizontal instability scales [*Fritts et al.*, 1993b; *Swenson and Mende*, 1994; *Hecht et al.*, 1997, 2000], where the observed roll spacing is suggested to be comparable to the unstable layer depth in numerical simulations. Additional inferences of gravity wave amplitudes and instability depths are obtained from radar wind measurements via the gravity wave dispersion relation [*Muraoka et al.*, 1988].

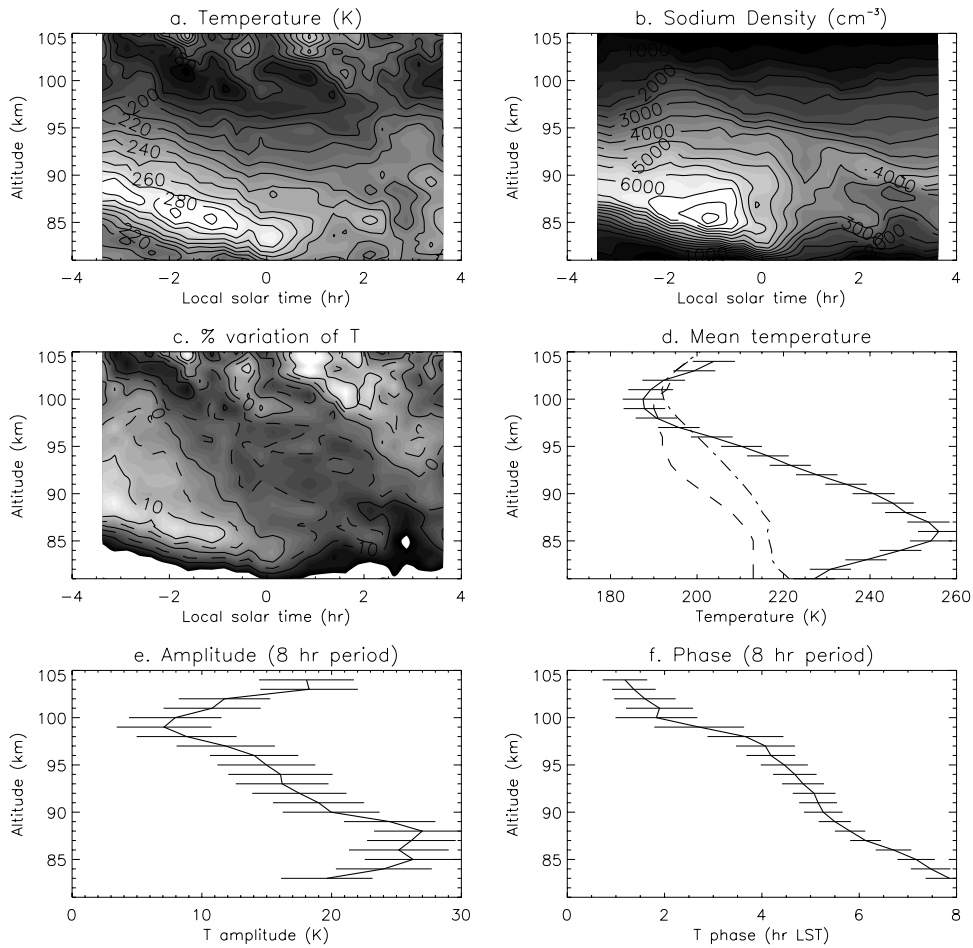

Figure 18. Contours of (a) temperature, (b) sodium density, (c) temperature perturbations as a percent of the mean value, and (d) profile of mean temperature for the 8-hour wave observation using the Fort Collins sodium lidar on day 307 of 1997. Also shown are the amplitude of the 8-hour wave in the temperature field (e) and the phase of the maximum temperature (f). The 1σ uncertainties are shown with horizontal bars and the dashed and dash-dotted lines in Figure 18d are the diurnal means for a 24-hour campaign in November 1998 and nightly mean for November averaged from 1990 to 1997. After *Williams et al.* [2002].

6.2.2. Kelvin-Helmholtz Instability

[140] KH instability is among the most common sources of turbulence in the atmosphere. In many instances it owes its existence, in part at least, to wind shears due to inertia-gravity waves because such motions contribute preferentially to wind shears throughout the atmosphere. Earlier evidence of KH instability due to inertia-gravity waves was reviewed by *Fritts and Rastogi* [1985]. More recent stability analyses have identified the preferred modes of instability of inertia-gravity waves with and without mean shears [*Fritts and Yuan*, 1989c; *Yuan and Fritts*, 1989; *Dunkerton*, 1997a]. Numerical simulations of unstable inertia-gravity waves revealed the character of the KH instability and its preferred orientation within the wave field [*LeLong and Dunkerton*, 1998a, 1998b]. The numerical studies showed a preferred direction consistent with the stability analysis by *Fritts and Yuan* [1989c] but with an increasing degree of isotropy as $\hat{\omega} \rightarrow f$. These simulations were also used to assess the theoretical prediction of the wave amplitude required for onset of shear instability by *Dunkerton* [1984] and *Fritts and Rastogi* [1985]. Results are displayed in Figure 19 and reveal that time dependence of the wave field increases the wave amplitude required to initiate instability, as anticipated by *Lombard and Riley* [1996] and *Sutherland* [2001] at higher intrinsic frequencies.

[141] Other evidence of the importance of KH instability and its relation to inertia-gravity waves comes from observations of wind and temperature profiles in the lower and middle stratosphere. Radar measurements at several sites have revealed persistent layers of enhanced radar reflectivity with spacings of a few kilometers, often exhibiting slow vertical motions and inferred unstable wave amplitudes [*Sato and Woodman*, 1982; *Yamamoto et al.*, 1987]. Likewise, high-resolution balloon measurements have revealed multiple layers yielding signatures of local turbulent mixing, with near-adiabatic layers sandwiched between sharp temperature inversions [*Cot and Barat*, 1986; *Coulman et al.*, 1995]. Examples of the

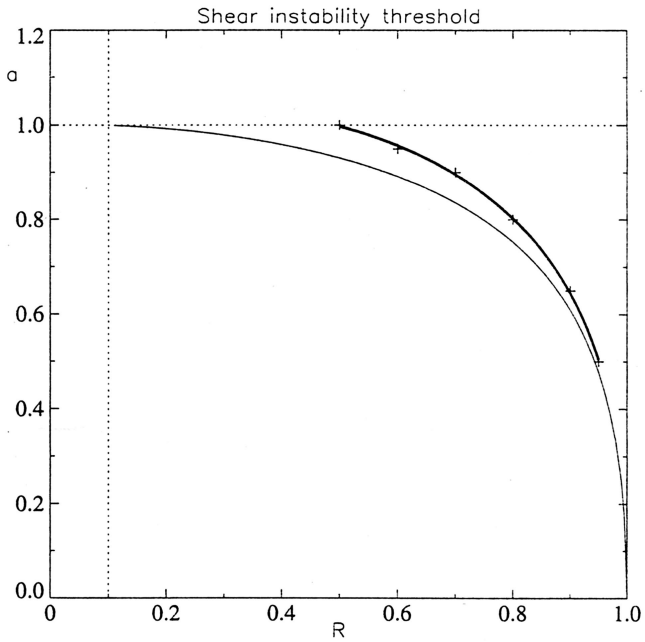

Figure 19. Threshold amplitude a for shear (KH) instability of inertia-gravity waves as a function of $R = f/\hat{\omega}$ in the absence of mean shear based on theory for a time-independent flow (solid line) and DNS simulations (thick solid line with data points). After *LeLong and Dunkerton* [1998a] (reprinted with permission of the American Meteorological Society).

latter, with profiles of the corresponding Richardson number, are displayed in the top and middle panels of Figure 20. Note, in particular, that the observations suggest a minimum Richardson number of ~1/4 following instability and mixing, well below what was often assumed to accompany restratification in the past. It will be seen below that these measurements are in good agreement with recent high-resolution DNS studies of KH instability.

[142] While observations help define the scales at which KH instability and mixing occur and the consequences of mixing for the temperature and wind fields, they cannot identify the dynamics of the turbulence transition or the evolution of the shear layer as KH breakdown and mixing occur. The only means of understanding these aspects of inertia-gravity wave instability is via DNS studies spanning KH growth, breakdown, and restratification.

[143] There have been many numerical studies of KH instability in the past. Only recently, however, have computational capabilities permitted 3-D studies of high enough resolution to confirm the predictions and laboratory observations of secondary instability [*Klaassen and Peltier*, 1985; *Thorpe*, 1987; *Palmer et al.*, 1994, 1996; *Caulfield and Peltier*, 1994; *Fritts et al.*, 1996b; *Smyth*, 1999]. Early 3-D KH simulations were not adequate to describe the transition to turbulence, the structure and anisotropy within the inertial-range of turbulence, and the implications for dissipation and mixing. However, recent simulations are now adequate to investigate these turbulence effects [*Werne and Fritts*, 1999, 2001; *Smyth and Moum*, 2001]. The vorticity dynamics accompanying this evolution and its relation to the vorticity dynamics of wave breaking were described by *Fritts and Werne* [2000].

[144] The KH simulations performed by *Werne and Fritts* [1999, 2001] have illustrated the dynamics of the transition to turbulence, the expansion of turbulence throughout the KH billow and the shear layer, and the turbulence statistics, dissipation, anisotropy, and decay. Most striking, perhaps, is the great degree of similarity of the turbulence dynamics to those observed in previous simulations of gravity wave breaking. Common features include (1) the initial streamwise, or shear-aligned, convective instability within the outer regions of the KH billow, (2) the stretching and wrapping of spanwise vortex sheets around the streamwise vortices, (3) the dynamical instability and rollup of the localized and intensified vortex sheets, and (4) the subsequent vortex interactions and twist wave excitation driving the cascade to smaller scales of motion [*Fritts and Werne*, 2000]. Major differences in the turbulence transitions accompanying wave breaking and shear instability are the timescale and the character of mixing. As noted above, the transition due to high-frequency wave breaking requires approximately one buoyancy period for the wave parameters simulated. The transition is somewhat longer due to KH instability, however, because turbulence requires time to expand from the initial site of instability throughout the KH billow and the full depth of the evolving shear layer. Implications for mixing are probably very different as well since KH instability mixes the shear layer vigorously prior to restratification, whereas turbulence due to wave breaking is quickly advected out of the unstable phase of the wave motion, allowing vigorous turbulence to act within the stably stratified portions of the wave field.

[145] The vorticity dynamics and impact on the thermal field of KH turbulence are illustrated in Figure 21 at four times throughout the simulation described by *Werne and Fritts* [1999]. In this simulation, a buoyancy period corresponds to 28 time units. Note here the gradual penetration of turbulence throughout the KH billow, the rapid obliteration of thermal gradients by turbulence shortly after it occurs, the homogenization of the expanded shear layer, the very sharp thermal gradients that evolve as a result of efficient mixing within the shear layer, and the continuing small-scale dynamics and mixing within the edge regions of the mixed layer at later times. Profiles obtained in the KH DNS at $t = 165$ are displayed in the fourth panel of Figure 20 and exhibit good agreement with those observed by *Coulman et al.* [1995] (first and second panels), despite the markedly different Reynolds numbers of the two flows. The implications for inertia-gravity waves include (1) instability, turbulence, and mixing on timescales short compared to wave periods, hence confined to the unstable phase of the wave, (2) reduced shears and wave amplitudes due to mixing, and (3) alternating layers of low and high static

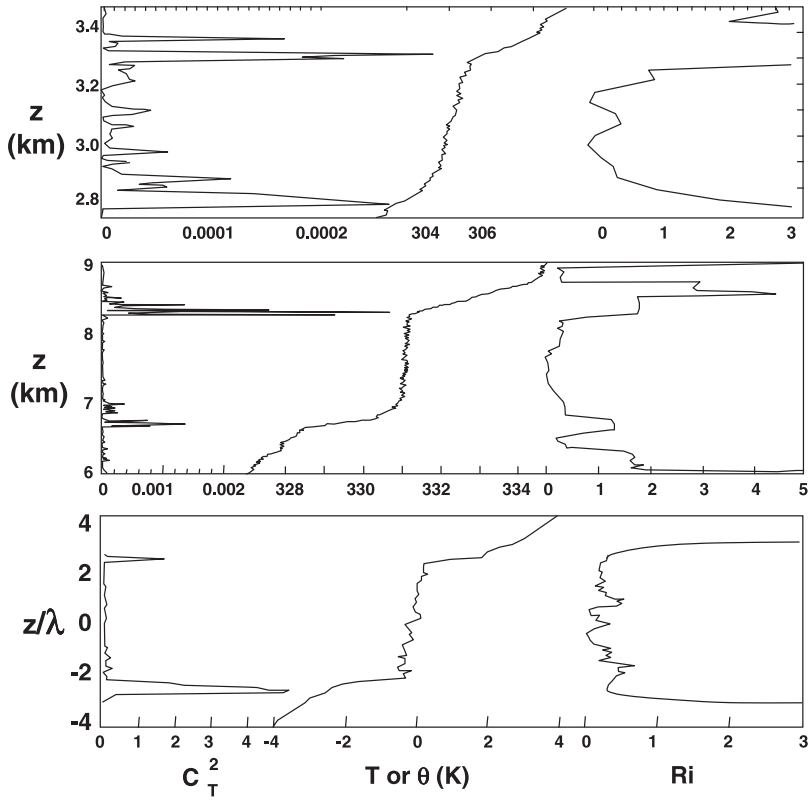

Figure 20. Profiles of C_T^2, θ, and *Ri* obtained by (top and middle) high-resolution balloon measurements and (bottom) DNS showing the aftermath of KH instability and mixing events. Note that the magnitude of C_T^2 and the gradient of θ maximize at the edges of the mixed region and that $Ri \approx 1/4$ throughout the mixed region. Modified after *Coulman et al.* [1995] and *Fritts et al.* [2003].

stability that may influence subsequent instability and mixing processes.

6.2.3. Synthesis and Other Instability and Large-Amplitude Processes

[146] Studies cited above have expanded greatly our understanding of gravity wave instability processes over the last decade. Importantly, these studies have also suggested links between specific modes of instability of small- and large-amplitude gravity waves. *Klostermeyer* [1991] found the PSI to be related to a 2-D parametric instability at finite amplitude and suggested, based on his analysis, that resonance may underlie all gravity wave instability processes. *Klostermeyer* [1991] and *Lombard and Riley* [1996] also identified transverse modes of instability at finite amplitudes below those required for local convective or dynamical instability.

[147] The links between instabilities at small and large wave amplitudes were further clarified and generalized by *Sonmor and Klaassen* [1997] to include all instability types and all wave amplitudes and intrinsic frequencies (or phase propagation angles) assuming no rotation. Specifically, they found a link between the PSI and the "slantwise static instability" (SSI) of *Hines* [1971, 1988b] at small wave amplitudes and with convective instability and high wave number parametric instability at amplitudes $a > 1$ (see equation (58)). *Sonmor and Klaassen* [1997] further linked the "branch-C" instability of *Yeh and Liu* [1981] to the resonant elastic scattering and induced diffusion interactions originally identified by *McComas and Bretherton* [1977] but noted quite different growth rates than inferred in the earlier study. The "shear-aligned instability" (SA, having spanwise wave number, as noted in the wave breaking simulations discussed in section 6.2.1) is itself linked to higher-order resonant instabilities at smaller wave amplitudes and exhibits an amplitude threshold near the convective limit for waves at high intrinsic frequencies [*Winters and Riley*, 1992; *Sonmor and Klaassen*, 1997]. A 2-D dual-mode instability represents a generalization of the KH instability within an inertia-gravity wave and competes favorably with SA or convective instability at large amplitudes [*Sonmor and Klaassen*, 1997] but is itself stabilized by weak environmental shear [*Thorpe*, 1994]. *Dunkerton* [1997a] examined the relative roles of these instabilities in the presence of rotation, employing a steady, plane-parallel approximation to the wave structure and obtained similar results concerning the dominant instabilities at large wave amplitudes.

[148] A further class of instability, "oblique instabilities" (having nonzero streamwise and spanwise wave numbers), was found by *Lombard and Riley* [1996] and *Sonmor and Klaassen* [1996, 1997] to represent the most rapidly growing instability for an important physical

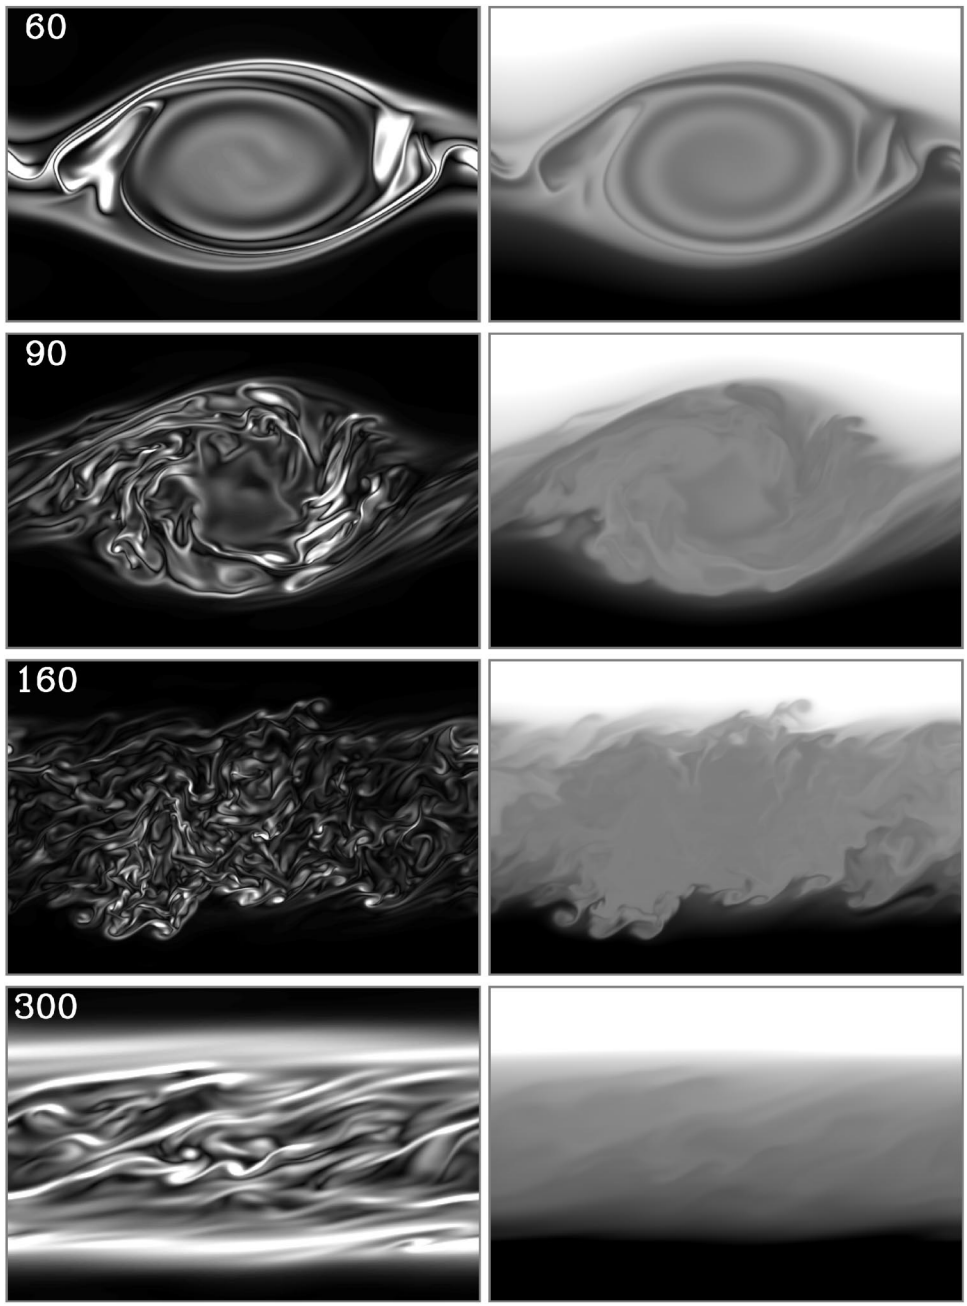

Figure 21. The 2-D streamwise-vertical cross sections of (left) 3-D vorticity magnitude and (right) temperature fields at four times throughout the turbulence transition and restratification of a KH billow. See text for details. After *Werne and Fritts* [2001] (reprinted with permission of Elsevier Science).

range of wave amplitudes at high intrinsic frequencies. *Sonmor and Klaassen* [1996, 1997] argue that oblique instabilities connect smoothly to SA instabilities at higher frequencies and larger wave amplitudes but are the preferred form when shear is the primary source of instability energy, whereas SA instabilities are preferred when buoyancy is the dominant source. The parameter ranges in which these various instabilities predominate are displayed in Figure 22. Here the dash-dotted line denotes an overturning amplitude, and high intrinsic frequencies have large phase elevation angles. We note, however, that recent DNS studies [*Fritts et al.*, 2003] reveal SA instabilities to predominate over 2-D dual-mode and oblique instabilities at finite amplitude for a wide range of the wave parameters displayed in Figure 22. This may be due either to the Sonmor and Klaassen analysis being inviscid (while the DNS studies are viscous) or to the selection of a finite-amplitude response in the DNS from among a variety of initial instabilities at infinitesimal amplitude.

[149] Other types of instabilities are enabled as a result of wave packet localization or by the induced mean flows accompanying waves of finite amplitude. *Sutherland* [2001] demonstrated numerically the modulational

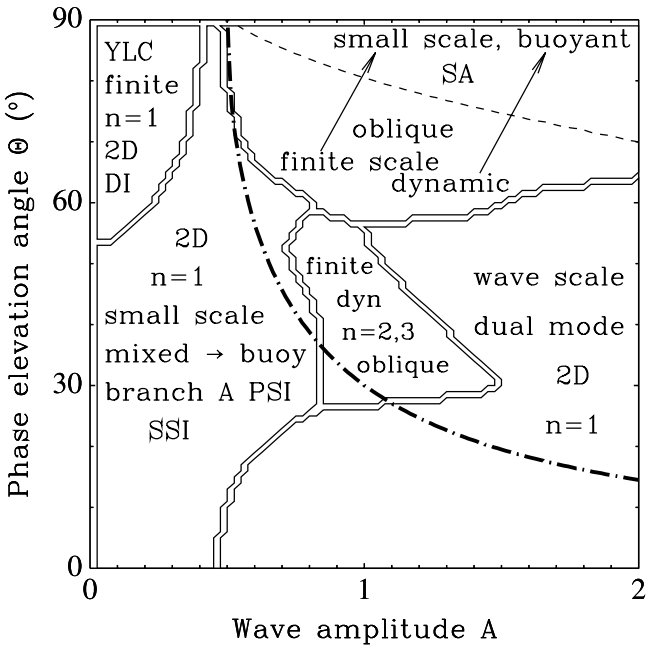

Figure 22. Fastest growing linear instabilities as a function of wave amplitude and phase elevation angle. The dash-dotted line corresponds to the amplitude of overturning ($a = 1$ in our terminology), and the dashed line represents the transition from oblique to shear-aligned instability and from shear to buoyancy as the dominant source of eddy energy. After *Sonmor and Klaassen* [1997] (reprinted with permission of the American Meteorological Society).

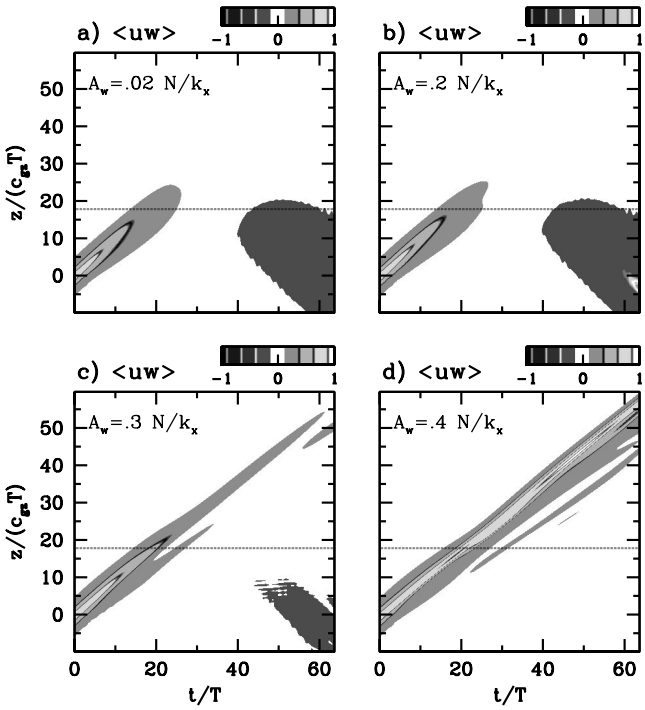

Figure 23. Time series of wave momentum flux for wave amplitudes of various vertical velocities incident on a turning level. The turning level anticipated by linear theory is shown by the horizontal line in each panel. After *Sutherland* [2000] (reprinted with permission of the Royal Meteorological Society).

instability (and stability) of a localized wave packet anticipated by *Whitham* [1965, 1974] but noted that this instability does not necessarily imply wave breaking. Sutherland also argued that self-acceleration of a vertically localized wave packet can lead to local convective instability at sufficiently large amplitudes and high intrinsic frequencies, providing a means by which wave localization can contribute to instability. The mechanism by which instability occurs is the differential tilting of surfaces of potential temperature by the wave-induced mean flow. Similar effects accompany localized wave packets incident on a turning level and may lead to wave instability via either self-acceleration (as above) or as a result of enhanced wave amplitude due to incident and reflected wave superposition [*Sutherland*, 2000]. Interesting additional consequences of wave packet localization and finite amplitude include tendencies (1) for wave packets that are vertically localized and of large amplitude to yield permanent momentum flux divergence near a turning level and (2) for wave packets that are both horizontally and vertically localized to penetrate substantial distances beyond a turning level based on linear theory [*Sutherland*, 1999, 2000]. Indeed, both of these mechanisms may have important but as yet unquantified implications for gravity wave momentum transport and redistribution in the middle atmosphere. The tendency for spatially localized, large-amplitude packets to penetrate turning levels may be particularly relevant for middle atmosphere momentum transport, where such packets may be more the rule than the exception. A demonstration of the tendency for penetration of a turning level as wave amplitude increases is shown in Figure 23. In these cases, total and partial reflection occur for small and intermediate wave amplitudes, while wave packet propagation appears to be increasingly unaffected by mean shear (and increasing intrinsic phase speed and frequency) as wave amplitude increases. Wave packet transmission and reflection for the largest wave amplitude are displayed at several stages throughout the event in Figure 24. Note, in particular, the phase distortions at the leading edge of the wave packet above the turning level which exhibit the self-acceleration effects discussed by *Fritts and Dunkerton* [1984] and *Sutherland* [1999, 2000].

[150] A final topic relevant to our understanding of instability dynamics in gravity waves is the optimal perturbation theory pioneered by *Farrell and Ioannou* [1996a, and references therein]. This theory has provided considerable insights into the occurrence of or competition among various instability modes in Couette, Poiseuille, and other time-independent shear flows known to be asymptotically stable below a threshold (or for any) Reynolds number. However, the theory also can be applied to time-dependent flows and to more general stratified problems including secondary KH and gravity wave instabilities for which the equations of motion are

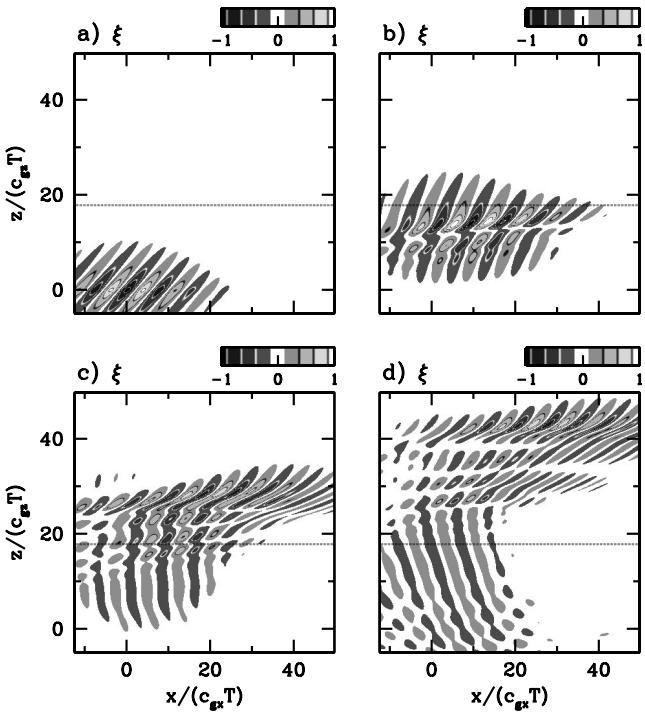

Figure 24. As in Figure 23 but showing vertical displacements at four times throughout the turning level encounter for the wave packet of largest amplitude. After *Sutherland* [2000] (reprinted with permission of the Royal Meteorological Society).

non-self-adjoint [*Farrell and Ioannou*, 1996b]. In such flows, particular superpositions of linear modes, termed "optimal perturbations", may exhibit rapid transient growth exceeding the growth rates of all eigenfunctions of the linear system. If this growth achieves a sufficient amplitude to have nonlinear consequences, either among the perturbations or for the mean flow, then it will be the optimal perturbation which dictates the finite-amplitude behavior of the nonlinear system. In applications to the KH instability problem, the optimal perturbation methodology has shown that the structures of both the initial 2-D instability and the secondary 3-D instabilities depend sensitively on the form and amplitude of the initial perturbations (J. Werne, personal communication, 2001). Optimal perturbation theory also reveals why the details of the turbulence transition and cascade discussed above depend so sensitively on the initial noise spectrum [*Werne and Fritts*, 1999; *Fritts and Werne*, 2000]. In the atmosphere, then, we anticipate that instability structures accompanying wave breaking or shear instability may often be dictated more by other finite amplitude perturbations than by the exact form of the most rapidly growing linear eigenmode of the unstable flow. While initial perturbations dictate the details of the transition to turbulence, they appear not to alter the statistical effects of turbulence on the larger-scale flow [*Fritts and Werne*, 2000].

6.3. Saturation Theories

[151] The dynamics underlying gravity wave saturation in the atmosphere, i.e., instability and wave–wave interaction processes, appear to impose a near-universal spectral form far from the dominant sources at lower altitudes (but subject to all of the caveats about departures from universality noted above). Our purpose in this section is to review the various theories for the shape and evolution of the wave spectrum and to identify how they are linked to the instability dynamics discussed above.

[152] The earliest wave amplitude limits attributed to instability dynamics were proposed by *Hodges* [1967] and involved the convective instability of a gravity wave due to its exponential growth with height. Subsequent studies by many authors considered the implications of such dissipation for momentum transports, turbulence, and mixing (see *Fritts* [1984a] for a review). Motivated by *VanZandt*'s [1982] suggestion of a universal gravity wave spectrum and their own observations of near universality in stratospheric wind spectra [*Dewan et al.*, 1984], *Dewan and Good* [1986] proposed the first theory of a saturated spectrum employing saturation (via local convective or shear instability) separately at each vertical wave number. Their dimensional analysis yielded a saturated range for gravity waves varying as CN^2/m^3 with C dependent on spectral bandwidth (and a bandwidth $dm \sim m$). The study by *Smith et al.* [1987] extended this theory to account for attainment of saturated wave amplitudes by the wave spectrum as a whole, yielding a saturation spectrum amplitude of $N^2/6m^3$ for velocities and a natural explanation for the evolution of the dominant vertical wave number, m_*, toward smaller m with increasing altitude. Further refinements of this theory yielded a corresponding saturated amplitude for gravity wave temperature spectra of $N^4/10g^2m^3$ and implications for enhanced saturation and dissipation where N increases with altitude [*Fritts et al.*, 1988a; *VanZandt and Fritts*, 1989]. Attributes of this "linear saturation theory" include a simple conceptual mechanism for amplitude limits for superposed waves of various scales and frequencies, general agreement of the predicted spectral form and amplitude and variations of wave energy density with altitude with observations throughout the atmosphere [*Allen and Vincent*, 1995], and a natural explanation for the increase in the dominant vertical wavelength with increasing altitude [*Tsuda et al.*, 1989]. Failings of the theory include an inability of the spectral description to account for specific wave sources having character quite different from the canonical spectral form, an inability to account for amplitudes in the stratosphere below the saturation limit because of wind shear effects on vertical wavelengths [*Eckermann*, 1995a; *Alexander*, 1996], relative amplitudes of velocity and temperature spectra that depart from predictions [*Tsuda et al.*, 1991; *Nastrom et al.*, 1997; *de la Torre et al.*, 1999], and the neglect of wave–wave interactions that are known to cause spectral energy transfers.

[153] An alternative explanation of the evolution of gravity wave spectral characteristics with increasing altitude was provided by *Weinstock* [1982, 1985, 1990] based on "nonlinear damping." Weinstock argued that this mechanism could both constrain wave amplitudes and account for spectral broadening with increasing altitude. Accounting for nonlinear influences within the wave spectrum, even without accounting explicitly for resonant interactions, was an appealing approach and spawned a number of extensions to the theory by *Zhu* [1994], *Gardner* [1994], and *Medvedev and Klaassen* [1995]. As with linear saturation theory, however, the various extensions to Weinstock's theory have their detractors (see section 6.1), and clarification of the mechanisms controlling spectral amplitude and shape remains a high priority. Appealing aspects of the nonlinear damping theories include a recognition of the central role of nonlinearity in shaping the wave spectrum and approximate agreement with observed spectral shape and evolution with altitude. Liabilities include an inability to account explicitly for local wave field instability and turbulence and concerns by *Hines* [2002b] over the legitimacy of the underlying assumptions.

[154] A further approach to gravity wave saturation and spectral evolution was taken by *Hines* [1991, 1993, 1996], who modeled wave-wave interactions by "Doppler spreading" of any one member of the spectrum by all of the remaining members. The Hines theory relies on the Lagrangian description of wave–wave interactions by *Allen and Joseph* [1989] and shares the attributes and liabilities of this formalism discussed at length in section 6.1. This approach accounts qualitatively for increasing interactions and effects with increasing altitude and yields predictions of a tail spectrum that is also in approximate agreement with observations, subject to correction of the earlier estimates of spectral slope [*Hines*, 2001; *Chunchuzov*, 2002]. The theory has also led to the development of a gravity wave parameterization that has experienced a number of successes (see section 7) but has been criticized (see section 6.1) for simplifications in the underlying assumptions that are inconsistent with the claimed cascade toward smaller vertical scales. Perhaps its major contribution has been a focusing of attention and renewed research activity on the role of wave-wave interactions in gravity wave spectral evolution in the atmosphere.

[155] A final approach to describing gravity wave spectral shape and evolution in the atmosphere is the "saturated-cascade similitude" theory by *Dewan* [1991, 1994, 1997]. The theory, as it has developed, embodies both the linear saturation ideas of *Dewan and Good* [1986] and *Smith et al.* [1987] as amplitude constraints and the notion that wave-wave interactions drive a cascade of wave energy from larger to smaller scales analogous to that observed in inertial-range turbulence. As in turbulence theory, spectral amplitudes are controlled by the energy dissipation rate ϵ, which represents both energy input at large scales via vertical wave propagation and energy dissipation at sufficiently small scales. The theory is appealing in its simplicity and its dependence on scaling arguments, and it makes a number of predictions of 1-D spectra that are either in reasonable agreement with observations or pose observational tests of the theory. The suggestion that saturation and cascade dynamics are jointly at work in shaping the gravity wave spectrum is more realistic than theories relying largely on one or the other. Dewan's theory is also more in line with recent results by *Sonmor and Klaassen* [1997] indicating that local wave field instability and spectral energy transfers via wave-wave interactions are manifestations of related dynamics at different wave amplitudes. As such, further advances merging or generalizing saturation and cascade processes and effects may help to unify the divergent views of wave saturation and spectral evolution prevailing at present. There are, however, a number of shortcomings or uncertainties in the present formulation, hence motivation for further improvements to the theory. It is unclear but likely not the case that wave energy is transferred from large to small scales without dissipation, while the direction and/or efficiency of the cascade are uncertain, based on the discussion in section 6.1. Finally, the current theory does not predict 2-D spectra, although these would be valuable in assessing the interaction and cascade dynamics, and the prediction of the vertical wave number spectrum of vertical velocities has a slope of $+1$ which differs significantly from the various observations to date of order -1 to -3 [*Kuo et al.*, 1985; *Larsen et al.*, 1986; *Wu and Widdel*, 1990; *Fritts and Hoppe*, 1995].

7. GRAVITY WAVE PARAMETERIZATIONS

[156] The effects of gravity waves on the larger-scale circulation must be parameterized in global models because the spatial resolution required to model them directly is prohibitively fine. The waves important to the circulation in the atmosphere have horizontal wavelengths ranging from approximately tens to thousands of kilometers. The largest of these can be resolved in some global models; however, the vertical wavelength of a gravity wave will vary substantially with height owing to the effects of wind shear. Vertical wavelengths as small as 1–2 km are important to resolve in the lower stratosphere. Gravity waves with periods as short as ~10 min can carry significant momentum flux vertically. Further, the sources of these waves include processes that are also parameterized and/or poorly resolved, namely, convective heating, fine-scale topography, localized shear zones, and frontal structures. The parameterizations for convection for example are designed for purposes other than generating a realistic wave spectrum [*Ricciardulli and Garcia*, 2000]. Direct modeling of a realistic gravity wave spectrum in global models is therefore still not feasible at the present time nor in the near future. Two effects of gravity wave dissipation that are currently

believed to be necessary in global models are a body force on the background flow (important at the tropopause and throughout the middle atmosphere) and mixing effects on temperature and trace constituent distributions (important in the upper stratosphere and above).

[157] The essential ingredients of gravity wave parameterizations include specification of input parameters describing the gravity wave sources and estimation of the wave dissipation as a function of height. Observational constraints on parameterization inputs are, however, still lacking in necessary detail. There is also no current consensus on how to compute the dissipation with height. Therefore middle atmosphere models currently have an uncomfortably large degree of freedom in the parameterization of gravity wave effects.

[158] There are currently at least eight parameterization schemes proposed or in various stages of implementation in global models [*Lindzen*, 1981; *Holton*, 1982; *Palmer et al.*, 1986; *McFarlane*, 1987; *Fritts and Lu*, 1993; *Medvedev and Klaasen*, 1995; *Hines*, 1997a, 1997b; *Lott and Miller*, 1997; *Alexander and Dunkerton*, 1999; *Scinocca and McFarlane*, 2000; *Warner and McIntyre*, 2001]. *McLandress* [1998] reviews the approach and basic mathematics for four of these. Here we will not embark on detailed descriptions of each parameterization. We will instead discuss the basic components of a gravity wave parameterization and describe some of the commonalities and differences among the various approaches in that context. The basic components are (1) specification of the characteristics of the waves at the source level, (2) wave propagation and/or spectral evolution as a function of height, and (3) wave dissipation and calculation of the effects on the background atmosphere.

7.1. Parameterization of Gravity Wave Sources

[159] Parameterizations of gravity wave effects all require input of the amplitudes and propagation properties of the waves at some altitude in the troposphere or at the model lower boundary. These would ideally be related to specific gravity wave sources as in the work of *Rind et al.* [1988], but this approach is insufficiently constrained by present observations. Stationary gravity waves ($c = 0$) generated by flow over topography are presently parameterized in many global models [e.g., *Palmer et al.*, 1986; *McFarlane*, 1987; *Miller et al.* 1989]; however, the properties of other nonstationary gravity waves ($c \neq 0$) and their sources are too poorly constrained to be included in this way. Instead, nonstationary waves, when they are included at all, are input with globally uniform properties or with properties that vary only as a function of latitude [*Garcia and Solomon*, 1985; *Holton and Schoeberl*, 1988; *Smith and Brasseur*, 1991; *McLandress and Ward*, 1994; *Roble and Ridley*, 1994; *Norton and Thuburn*, 1996; *Mayr et al.*, 1997a; *Manzini and McFarlane*, 1998; *Medvedev et al.*, 1998; *Scaife et al.*, 2000].

[160] Linear gravity wave theory tells us that the required information about gravity wave sources includes their phase speeds, horizontal wavelengths, propagation directions, and momentum fluxes. (Note that horizontal wavelength or phase speed could be replaced with vertical wavelength or frequency using the dispersion relation (23).) A factor describing gravity wave spatial and/or temporal intermittency must also be considered because the waves with the specified properties will not generally be occurring throughout the model area at all times.

[161] *Palmer et al.* [1986] and *McFarlane* [1987] defined parameterizations for topographic wave sources. Momentum fluxes are related to the subgrid-scale orographic variance, atmospheric stability, and surface wind. The waves are launched propagating opposite to the surface wind with phase speed relative to the ground $c = 0$. *Bacmeister* [1993] further considered the alignment of mountain ridges perpendicular to the surface wind. An efficiency factor is generally included because only a fraction of the surface stress will be carried by vertically propagating waves [*Schär and Durran*, 1997; *Lott*, 1998]. Horizontal wavelength is a free parameter, generally chosen to be ~100 km or considered to be a tunable parameter.

[162] *Kershaw* [1995] describes a parameterization for momentum flux due to convectively generated gravity waves by assuming a mechanism analogous to topographic waves, but the waves are assigned a phase speed equal to the wind speed at the center of the convective layer. *Chun and Baik* [1998] describe a convective heat source parameterization that models convective heating as a steady process that similarly generates only waves that are stationary relative to the heat source. The horizontal wavelength spectrum that results is also highly dependent on a set of assumed properties of the convective heating that are currently poorly constrained. By contrast, other model studies [e.g., *Piani et al.*, 2000] (also see Figure 5) instead suggest that in the absence of strong shear, convection may generate a very different spectrum of gravity waves with much larger phase speeds (see section 3.1).

[163] For nonstationary gravity waves ($c \neq 0$), there is no consensus on the value of momentum flux at the source level, so it is yet another free parameter. Many model studies have not reported the value that has been assumed, making comparisons difficult. The best constraints on the momentum flux are indirect and are derived from estimates of the zonal mean wave-driven force that must be present to explain global temperature, wind, and trace constituent patterns. These constrain the gravity wave momentum flux crossing the tropopause and are described in section 8.1. A wide variety of gravity wave parameterizations are currently in use in global models. Intercomparison of these studies will begin to be possible when distributions of the cross-tropopause gravity wave flux with latitude are reported, as *Manzini and McFarlane* [1998] have done.

[164] Other properties of the spectrum of nonstationary waves input to parameterizations currently vary widely, and these differences may be of fundamental importance in explaining the differences among the results obtained. Some input an isotropic energy spectrum that is separable in $\hat{\omega}$ and m with power law dependencies on these variables that resemble observations in the troposphere and stratosphere (see section 4) [*Fritts and VanZandt*, 1993; *Fritts and Lu*, 1993; *Hines*, 1997a, 1997b; *Medvedev et al.*, 1998; *Medvedev and Klaassen*, 2000; *Warner and McIntyre*, 2001]. *Hines* [1997a] argues that the fundamental difficulty with this approach is that the low-m portion of the spectrum is very poorly constrained by observations, yet it is this portion that has the largest effect in the mesosphere. The assumption of isotropy is also poorly constrained and probably wrong. *Alexander and Dunkerton* [1999] proposed a parameterization that can employ arbitrary source spectral shapes and anisotropies that are input as momentum flux versus phase speed. This approach suffers similar uncertainty in the input spectrum, particularly at high phase speeds (corresponding to low m), although model studies and observations of high phase speed waves generated by deep convection are beginning to constrain the phase speed spectrum of this source (see section 3.1.2).

[165] For nonstationary wave sources like convection the intermittency may be a small number, $\varepsilon \ll 1$, yet there are few observational constraints for this parameter. *Alexander* [1996] derived estimates of intermittency as a function of frequency and horizontal wavelength for high-frequency waves above deep convection in a cloud-resolving model, and *Zink and Vincent* [2001b] estimated intermittency for low-frequency waves in midlatitude radiosonde observations. The values will depend on the bandwidths of the wave properties considered (e.g., c, $\hat{\omega}$, etc.) [*Alexander and Dunkerton*, 1999].

7.2. Treatment of Wave Propagation and Dissipation

7.2.1. Commonalities and Differences

[166] All parameterizations assume a set of gravity wave properties, specified either as a continuous wave spectrum or as a collection of discrete waves at some source altitude. The spectral properties of the sources may vary considerably among the different parameterizations, and except for topographic waves (input at the ground), the source altitude for nonstationary waves will additionally vary even among different applications of the same parameterization. Differences in the specification of gravity wave sources among parameterizations may be responsible for some large part of the differences in their effects seen in models. However, no controlled comparisons have yet been made that address this issue.

[167] All parameterizations are one-dimensional in that they assume the waves considered propagate only vertically and that only vertical variations in the background atmosphere influence wave propagation. All parameterizations use linear theory in the absence of dissipation and use the midrange frequency approximation to the linear dispersion relation (32) for at least some portion of the calculation. Total internal reflection is included via equation (30) in one [*Alexander and Dunkerton*, 1999], but this is generally only important for gravity waves with horizontal wavelengths shorter than ~50 km.

[168] Aside from gravity wave source specification, the main differences among parameterizations reside in their treatment of nonlinearity and mechanisms of wave dissipation. These differences result in different vertical variations in gravity wave effects.

7.2.2. Treatment of Nonlinearity and Wave Dissipation

[169] Most global model studies that have included gravity wave effects parameterized nonlinear effects using a scheme related to that proposed by *Lindzen* [1981] and formalized by *Holton* [1982]. These "Lindzen-type" parameterizations specify some discrete set of wave properties at a source level, use the midrange frequency approximation to calculate wave propagation with height, and then use the linear convective instability threshold to determine where wave dissipation will occur. Wave dissipation continues above the unstable level via a saturation condition (see *Fritts* [1984a] for a review). This basic formula is the basis of the widely used mountain wave parameterizations by *Palmer et al.* [1986] and *McFarlane* [1987], who added a Froude number condition for finding the altitude regions where wave saturation would occur. There are also nonstationary wave analogs to these mountain wave parameterizations [e.g., *Kiehl et al.*, 1996; *Norton and Thuburn*, 1999].

[170] *Alexander and Dunkerton* [1999] used Lindzen's convective instability criterion but assumed total wave breakdown at that level rather than employing the wave saturation assumption. This simplification reduced computation time, allowing a treatment of a detailed spectrum of waves rather than the typical small set of 5–10 waves employed in Lindzen-type schemes. They also made explicit the separation of the parameters describing local wave momentum flux magnitude (which determines breaking levels) and net wave momentum flux (which is generally smaller if there is intermittency in the wave occurrence). The parameterization by *Norton and Thuburn* [1999] instead locked these two parameters together so that smaller fluxes gave higher breaking levels and vice versa. This is appropriate for mountain waves where amplitude and net flux are naturally linked because the intermittency in the source is modeled directly via topography and surface wind variations but is inappropriate for nonstationary wave sources with globally averaged input properties.

[171] *Warner and McIntyre* [2001] used the midrange frequency approximation to the linear dispersion relation and a saturation condition to limit wave amplitudes to a "quasi-saturation" spectrum. They developed a spectral analogue to the *Lindzen* [1981] saturation crite-

rion and simplified the computation with a three-part spectrum approximation. Short horizontal wavelength waves in their source spectrum [*Warner and McIntyre*, 1996] carry significant momentum flux, so their neglect of wave reflection is a potentially serious problem. *Fritts and VanZandt* [1993] and *Fritts and Lu* [1993] used saturation theory and empirical constraints on the gravity wave spectrum to describe the spectrally integrated energy density and momentum flux as functions of height.

[172] *Hines* [1991, 1997a, 1997b] used linear theory and the midrange frequency approximation to describe wave propagation with height but treated dissipation as resulting from wave-wave interactions which cause Doppler-shifting and refraction of portions of the wave spectrum to vertical wavelengths shorter than a prescribed cutoff wave number where dissipation is assumed to occur. *Medvedev and Klaassen* [1995, 2000] instead treated dissipation via the nonlinear diffusion ideas of *Weinstock* [1982, 1990]. Both of these mechanisms have, however, been questioned in the recent literature (see section 6.1).

[173] Note that although many of the spectral gravity wave parameterization schemes [*Fritts and Lu*, 1993; *Medvedev and Klaasen*, 1995, 2000; *Hines*, 1997a, 1997b; *Warner and McIntyre*, 1996, 2001] have been constrained to reproduce the "universal" m^{-3} gravity wave energy spectrum observed at high m (section 4), these parameterizations can produce very different results (see section 8.4). This leads to the natural conclusion that the shape and magnitude of the spectrum at high m alone do not sufficiently constrain parameterizations of gravity wave effects in the middle atmosphere.

[174] For a parameterization to be effective at both forcing the stratospheric QBO winds and driving the mesopause wind reversals, dissipation of nonstationary waves must occur for increasingly large intrinsic phase speeds and increasingly long vertical wavelengths at increasing altitudes. In other words, waves may dissipate fairly close to their critical levels in shear zones in the lower stratosphere but must dissipate far from their critical levels in the upper mesosphere. Intrinsic phase speed and vertical wavelength are related via equation (33). The result is that for nonstationary waves the force will tend to accelerate the mean wind (the force will have the same sign as the wind) in the lower stratosphere but decelerate the mean wind (the force will have opposite sign as the wind) in the upper mesosphere. (Note that this trend should not hold for the large amplitude mountain waves with phase speeds $c \sim 0$ that have been observed. Such waves can break and cause decelerations at all levels.) The potential for gravity waves to accelerate the mean wind is one reason to avoid the term "gravity wave drag" since this is an example of "gravity wave push."

[175] The vertical variation in wave dissipation described above is a natural consequence of linear instability theory for small amplitude waves propagating through exponentially decaying atmospheric density and the observed zonal mean middle atmosphere winds [*Alexander and Rosenlof*, 1996] (see also section 4). It can thus occur using any of the parameterizations above based on convective instability for some range of source spectrum properties. That includes the Lindzen-type, *Warner and McIntyre* [1996, 2001], and *Alexander and Dunkerton* [1999] parameterizations. It can also arise naturally in the *Hines* [1997a, 1997b] parameterization for wave dissipation because the amplitudes of the waves that drive the dissipation in this mechanism grow with altitude. They can thus shift waves with larger and larger intrinsic phase speeds (and vertical scales) to the prescribed dissipation scale as a function of height. The Hines dissipation scale is further allowed to vary with height adding another means of tuning this effect.

[176] Vertical gradients of gravity wave energy and momentum fluxes give rise to important terms in the energy and momentum conservation equations in global models (see section 8). All of the parameterizations will drive the deceleration of the winds in the mesosphere, but only a few have been shown to be effective at driving QBO circulations in global models. In addition to mean flow forcing effects of parameterized gravity waves, vertical mixing effects in the thermal energy and constituent transport equations are also important in the mesosphere of global models. Global model studies of both these effects are described in section 8.

8. INFLUENCES ON ATMOSPHERIC CIRCULATION AND STRUCTURE

8.1. Mean Flow Forcing Effects

[177] Around 20 years ago, gravity wave effects on the zonal mean winds in the mesosphere and lower thermosphere were becoming widely appreciated. The gravity wave zonal mean forces cause reversals of the zonal mean jets and drive a mean meridional transport circulation that leads to a warm winter mesopause, a cold summer mesopause, and a reversal of the latitudinal temperature gradient expected in the absence of wave driving [*Lindzen*, 1981; *Holton*, 1982, 1983; *Garcia and Solomon*, 1985]. Gravity wave effects at slightly lower altitudes such as those driving the mesopause SAO [*Dunkerton*, 1982b] and QBO [*Lindzen and Holton*, 1968] had been proposed but were not generally accepted. Since that time, gravity wave effects at even lower altitudes, such as mountain wave drag effects on the circulation in the troposphere, have become widely accepted and are now included via parameterization in most global models to provide a drag force on the jet stream [*Palmer et al.*, 1986; *McFarlane*, 1987; *Miller et al.*, 1989]. Most recently, direct gravity wave effects in the stratosphere have been inferred. These effects include contributions to driving the tropical QBO [*Gray and Pyle*, 1989; *Takahashi and Holton*, 1991; *Takahashi and Boville*, 1992; *Alexander and Holton*, 1997; *Dunkerton*,

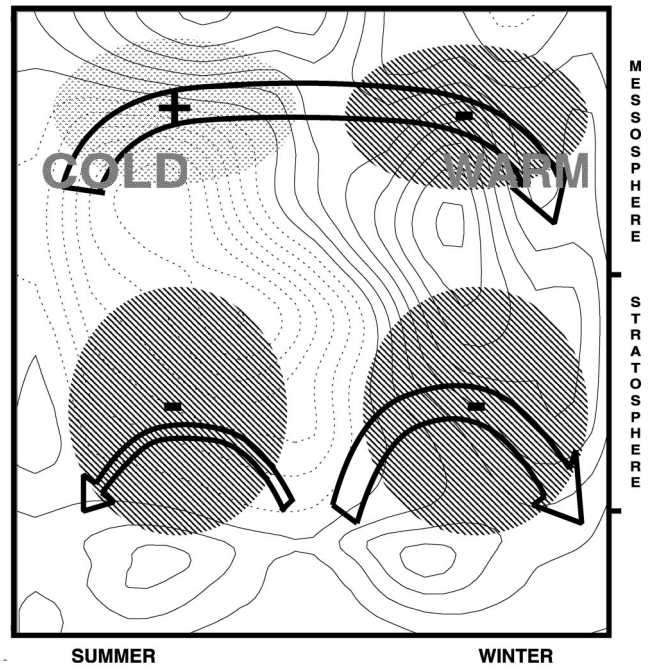

Figure 25. Schematic diagram illustrating gravity wave driving of the middle atmosphere transport circulation and effects on the zonal-mean extratropical winds and temperatures. The thin contours denote zonal mean wind at intervals of 10 m s^{-1} (dotted contours are for westward winds). The transport circulation is illustrated with thick arrows, and the gravity wave driving is illustrated with hatched areas with minus signs denote westward forcing and a plus sign denotes eastward forcing.

1997b; *Scaife et al.*, 2000; *Baldwin et al.*, 2001] and SAO (both in the stratosphere and mesosphere) [*Hitchman and Leovy*, 1988; *Hitchman et al.*, 1992; *Sassi and Garcia*, 1994, 1997; *Ray et al.*, 1998; *Garcia and Sassi*, 1999], contributions to driving the summer hemisphere equator to pole meridional transport circulation [*Rosenlof*, 1996; *Alexander and Rosenlof*, 1996], and effects on the winter polar vortex [*Hitchman et al.*, 1989; *O'Sullivan and Dunkerton*, 1994; *Kinnersley*, 1996; *Garcia and Boville*, 1994]. Figure 25 illustrates these mean-flow forcing effects. The role of waves in the middle atmosphere transport circulation was reviewed by *Holton and Alexander* [2000]. The theory underlying wave driving of the transport circulation is embodied in the downward control principle [*Haynes et al.*, 1991].

[178] In general, in the lower stratosphere the gravity wave mean body force will have the same sign as the local shear (and may or may not have the same sign as the local wind). Examples include the westward drag exerted by mountain waves at levels above the tropospheric jet peak winds and the QBO forcing that is eastward in eastward shear and westward in westward shear. In the mesosphere the force, in general, opposes the background winds. Wave amplitudes can grow large enough in the mesosphere that waves with large intrinsic phase speeds can break, while in the stratosphere, where wave amplitudes are smaller, breaking or dissipation will tend to occur only as waves approach their critical levels (see, e.g., equation (58)) unless the amplitudes are rather large.

[179] Several studies have estimated forces due to gravity waves in the stratosphere and mesosphere. Three basic techniques have been used: (1) Estimates of the zonal mean wave driving in the middle atmosphere, not explained by the observed planetary-scale wave driving, are presumed due to gravity waves. (2) Radar observations of zonal and meridional gravity wave momentum flux gradients employed in equation (42) give an estimate of gravity wave driving. (3) Atmospheric model studies with parameterized wave driving are constrained by observations to infer the contribution due to gravity waves.

8.1.1. Zonal Mean Momentum Balance Studies

[180] The first method estimates the gravity wave contribution to the wave driving through examination of the zonal mean momentum balance. The difference between the total momentum forcing and the resolved EP flux divergence contribution is presumed to be due to gravity wave driving. The total force is calculated using global satellite observations of temperature and the important radiatively active gases (O_3, H_2O, etc.) input to a radiative transfer model to estimate the zonal mean radiative heating rate. This total force is what drives the zonal mean residual circulation (or transport circulation) in the middle atmosphere. Satellite temperature observations are then also used to compute global winds with a balance model, and the temperature and wind fields together are then used to define the planetary-scale wave fluxes and EP flux divergence. Examples of this method are described by *Hamilton* [1983], *Smith and Lyjak* [1985], *Hitchman et al.* [1989], *Shine* [1989], *Marks* [1989], *Rosenlof* [1995; 1996], and *Fetzer and Gille* [1996]. These studies have improved in accuracy over the years, partly because of improvements in the temperature and constituent measurements and partly through improvements in the models used to calculate the wind fields.

[181] Calculations of EP flux divergence give inherently noisy fields, so it is not surprising that most studies looking for the residual gravity wave term have focused on high altitudes near the stratopause and above where the gravity wave forcing becomes large [*Hamilton*, 1983; *Smith and Lyjak*, 1985; *Shine*, 1989; *Marks*, 1989; *Fetzer and Gille*, 1996]. At lower altitudes in the winter stratosphere the calculations of the residual gravity wave forcing have been highly variable, which could result both from errors in the calculations and true variability.

[182] *Rosenlof* [1996] and *Alexander and Rosenlof* [1996] focused on the summer stratosphere where resolved EP flux divergence is small and gravity wave driving is believed to dominate. A simple model of gravity wave propagation and dissipation was found to generate gravity wave driving in the summer strato-

sphere that was consistent with the observational constraints. The model used a constant spectrum of nonstationary gravity waves input in the troposphere. *Ray et al.* [1998] applied the same methods in the equatorial stratophere and inferred that gravity wave driving is important to the eastward phase of the stratopause SAO. The gravity wave driving in the summer stratosphere is westward and below ~1 hPa has an estimated magnitude of order ~1 m s^{-1} d^{-1}. Similar westward forcing magnitudes have also been estimated near the tropopause in both summer and winter. The gravity wave driving at the onset of the stratopause SAO eastward phases (at equinoxes) has been estimated at ~1–3 m s^{-1} d^{-1}.

[183] Calculations of this type in the mesosphere extending up to ~80 km altitude show the annual cycle in extratropical gravity wave driving of the summer-to-winter pole-to-pole zonal mean circulation. The wave driving is westward in winter and eastward in summer [*Shine*, 1989; *Marks* 1989; *Fetzer and Gille*, 1996]. Two of these studies suggested that the mesopheric gravity wave driving in the Southern Hemisphere winter is significantly larger than that in the Northern Hemisphere winter. These estimates of the mesosphere force peak at magnitudes ~30–60 m s^{-1} d^{-1} at solstice seasons. This hemispheric asymmetry seems opposite to that suggested by PMSE and temperature observations described in section 5. The differences could suggest a high degree of variability or could be due to errors in the estimates.

8.1.2. Radar Observations of Momentum Flux Convergence

[184] Radar observations of gravity wave momentum fluxes at a number of sites have been used to estimate the body force due to gravity waves in the lower stratosphere and in the mesosphere and lower thermosphere. Mean momentum fluxes in the lower stratosphere over the MU radar (at 35°N latitude) were ~0.1–0.3 m^2 s^{-2}, with peak values of ~1 m^2 s^{-2} and implied mean flow forcing of ~1 m s^{-1} d^{-1} [*Fritts et al.*, 1990b]. Momentum fluxes in the mesosphere and lower thermosphere have been measured more widely. At extratropical sites, mean values of ~1–10 m^2 s^{-2} have been measured with mean flow forcing in the range ~10–70 m s^{-1} d^{-1} that generally oppose the mean winds [*Reid and Vincent*, 1987; *Fritts and Yuan*, 1989b; *Tsuda et al.*, 1990b; *Nakamura et al.*, 1993c]. At the tropical Jicamarca radar (12°S) [*Hitchman et al.*, 1992] fluxes of 1–4 × 10^{-4} Pa (~2–8 m^2 s^{-2}) were observed with mean flow forcing ~10–60 m s^{-1} d^{-1}. Measurements at 35° northern and southern latitudes have been compared [*Nakamura et al.*, 1996], and like the residual force calculations, these suggest larger gravity wave driving in the Southern Hemisphere winter than in the Northern Hemisphere winter. Momentum fluxes observed in the mesosphere and lower thermosphere are highly variable, with peak values of ~30–60 m^2 s^{-2} greatly exceeding the mean values. These imply correspondingly larger and possibly localized mean flow forcing and have been correlated with larger-scale motions [*Fritts and Vincent*, 1987; *Fritts et al.*, 1992; *Murphy and Vincent*, 1998].

8.1.3. Model Studies of Zonal Mean Wave Driving

[185] A third method for estimating the gravity wave mean flow driving uses models of the middle atmosphere with parameterized radiative transfer and wave driving. The model results are then constrained by observations so that inferences about the gravity wave driving can be made. *Holton* [1982, 1983], *Garcia and Solomon* [1985], *Holton and Schoeberl* [1988], *Hitchman et al.* [1989], and *Huang and Smith* [1991, 1995] examined gravity wave driving at extratropical latitudes in the mesosphere. The gravity wave mean flow force in these models peaked at midlatitudes at solstice seasons with values ranging from ~30 to 120 m s^{-1} d^{-1}, with more recent work tending to report smaller values.

[186] Other global and mechanistic model studies have focused specifically on the magnitude of the zonal mean transport circulation required to account for the summer mesopause thermal structure [*Garcia*, 1989; *McIntyre*, 1989; *Fritts and Luo*, 1995, *Zhu et al.*, 1997]. These have suggested vertical velocities near the mesopause of ~5 cm s^{-1} and meridional motions of ~20–30 m s^{-1}; values that are comparable to radar and satellite measurements of mean meridional winds near the polar summer mesopause. The observed meridional winds differ somewhat in their latitudinal distribution with peak magnitudes observed at higher and lower latitudes [*Nastrom et al.*, 1982; *Lieberman et al.*, 1998] than the model studies' inferred meridional transport circulation winds. Variability in wave driving can also account for abrupt temperature transitions that have been observed at the summer mesopause [*Luo et al.*, 1995; *Lübken*, 1999].

[187] *Dunkerton* [1997b] modeled the QBO and SAO and inferred that gravity waves likely contribute at least half of the wave momentum flux needed to drive the QBO. His estimates of the cross-tropopause momentum flux carried by gravity waves with phase speeds in the range of QBO wind speeds were ~2–3 × 10^{-3} Pa.

8.2. Gravity Wave–Tidal–Planetary Wave Interactions

[188] As discussed in section 2 and further in section 8.4, gravity waves play a central role in controlling the mean circulation and thermal structure through wave momentum transport, wave filtering, and the body forces arising from wave dissipation and momentum flux divergence. Such filtering and effects arise in response to mean shears as well as lower-frequency gravity waves (see section 6.1) and larger-scale tidal and planetary wave motions. The first studies along these lines were theoretical and addressed feedbacks on tidal structures due to selective gravity wave filtering near critical levels [*Walterscheid*, 1981], excitation of planetary waves at altitudes of asymmetric gravity wave body forcing imposed by variable source strengths [*Holton*, 1984], and

damping of planetary waves in response to modulation of gravity wave filtering processes [*Miyahara*, 1985; *Miyahara et al.*, 1986]. More recent model assessments of such interactions have revealed a number of potential influences on tidal and planetary wave structures and variability. Various studies suggest either tidal amplitude reductions [*Forbes et al.*, 1991; *Miyahara and Forbes*, 1991; *Lu and Fritts*, 1993; *Meyer*, 1999a] or increases [*Mayr et al.*, 1998], depending on which gravity wave parameterization scheme is used. However, *Akmaev* [2001] has argued that the *Miyahara and Forbes* [1991] results are due to an incorrect implementation of the Lindzen parameterization, while *McLandress* [2002] argues that gravity wave driving and induced diffusion are much less important in controlling tidal amplitudes than other nonlinear interaction and advection processes.

[189] Several studies considered the implications of tidal modulation of gravity wave-induced diffusion and/or momentum deposition, arguing that these may be important in minor species chemistry and the creation of temperature inversions [*Forbes et al.*, 1991; *Liu et al.*, 2000], in altering mean momentum deposition [*Lu and Fritts*, 1993; *McLandress and Ward*, 1994], and in enhancing planetary wave excitation in the mesosphere in response to spatially localized orographic sources [*McLandress and Ward*, 1994]. Other studies suggested that seasonal variations in mean winds enable a gravity wave modulation of tidal amplitudes that accounts for the observed semiannual variations [*Mayr et al.*, 1998; *Meyer*, 1999a] and that filtering of gravity waves by planetary waves at lower altitudes imposes a periodic forcing near the mesopause which enables 2-day and 16-day wave influences to penetrate well into the thermosphere [*Meyer*, 1999b; *Norton and Thuburn*, 1997].

[190] All of the above studies exhibited complex coupling between the imposed spectrum of gravity waves and the larger-scale motions accounting for wave filtering. In particular, tidal amplitude changes accompanying gravity wave-tidal interactions were found to be sensitive not only to geophysical parameters but also to the specific gravity wave parameterization employed. This is because tidal amplitudes (as well as any other variable wind field accounting for gravity wave filtering, i.e., mean winds, planetary waves, or the semiannual and quasi-biennial oscillations) respond to gravity wave filtering and momentum flux divergence differently depending on the phase of the gravity wave forcing relative to the phase of the filtering wind field, which can differ between parameterizations. If parameterized gravity waves are dissipated near and below the wind maxima (in the direction of gravity wave propagation), then the result is a wind acceleration and an induced downward phase motion (as discussed in section 7.2.2). If, on the other hand, parameterized gravity waves dissipate by breaking (due to amplitude growth with height where the winds are a minimum or where intrinsic phase speeds are large), then gravity wave forcing reduces wind amplitudes and the induced phase motion depends on where forcing occurs relative to the wind maxima. For these reasons, comparisons with observations may pose important constraints on the gravity wave parameterizations underlying such interactions in numerical models.

[191] Observational studies were slower to yield insights into gravity wave interactions with tidal and planetary wave motions. Nevertheless, several studies have shed light on the degree of modulation of gravity wave amplitudes and fluxes and their potential influences on the structures responsible for wave filtering. Evidence of gravity wave-tidal and gravity wave-planetary wave interactions has come primarily from various radars spanning equatorial to high latitudes. Measurements of gravity wave momentum fluxes and tidal amplitudes at Adelaide, Australia, and Poker Flat, Alaska, revealed a tendency for an out-of-phase relationship between fluxes and tidal winds [*Fritts and Vincent*, 1987; *Wang and Fritts*, 1991], a potential for very large momentum flux modulations correlated with large tidal amplitudes and shears (as large as ~ 40 m^2 s^{-2}), and a reduction of tidal amplitudes accompanying strong gravity wave filtering [*Fritts and Vincent*, 1987]. An example of the modulation of gravity wave momentum fluxes by the diurnal tide for 3 days during which the tide was strong is shown in Figure 26. In this example, the flux estimates are 8-hour averages, the modulation increases with altitude, and the peak values are ~ 10 times as large as the mean momentum flux [*Fritts and Vincent*, 1987]. A similar modulation of momentum fluxes by the 2-day wave was suggested by the observations of *Murphy and Vincent* [1998], while *Thayaparan et al.* [1995], *Isler and Fritts* [1996], and *Manson et al.* [1998b] noted significant peaks in gravity wave variances at the dominant tidal and planetary wave periods, suggestive of strong mutual interactions. Finally, indirect evidence of gravity wave filtering by planetary waves and of gravity wave influences on tidal structures has also been obtained. *Smith* [1996] inferred gravity wave filtering by and forcing of planetary waves from out-of-phase zonal wind anomolies at stratospheric and mesospheric altitudes, respectively, while *Nakamura et al.* [1997] inferred gravity wave-tidal interactions from tidal structure and variability at multiple equatorial and subtropical radar sites. There is insufficient data at this stage, however, to be able to distinguish between or guide the development of more quantitative gravity wave parameterizations.

8.3. Turbulent Mixing and Transport

[192] The impact of turbulence arising from gravity wave instability processes is one of the least quantified aspects of gravity wave forcing of the middle atmosphere at present. In fact, there are two separate issues. One is the energy dissipation rate ϵ accompanying gravity wave instability and its spatial and temporal variability; a second is the efficiency of mixing that occurs for a fixed energy dissipation rate. The former is becoming better known as measurements and theoretical inferences are beginning to converge. In the stratosphere, both ϵ and

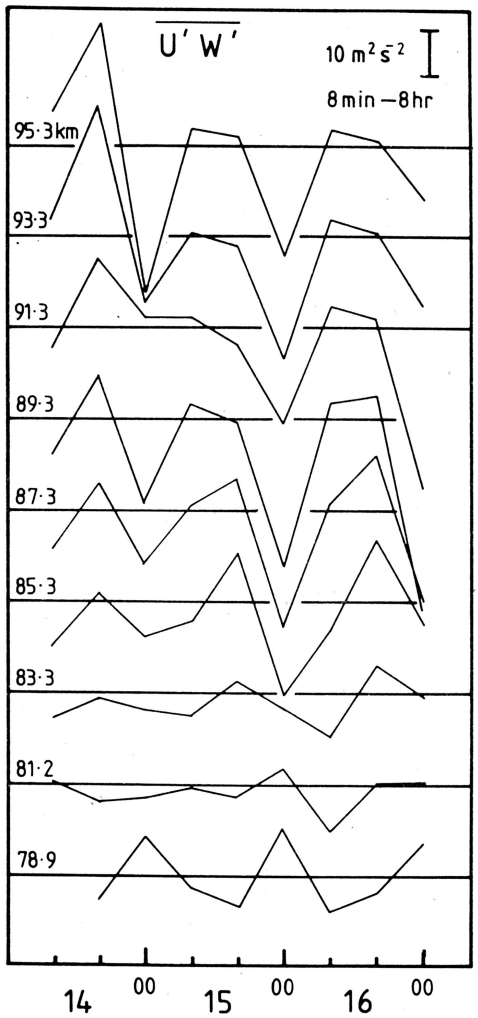

Figure 26. Zonal gravity wave momentum fluxes for 8-hour data segments during 3 days of large diurnal tidal winds over Adelaide, Australia. Note that peak momentum fluxes are ~10 times mean values. After *Fritts and Vincent* [1987] (reprinted with permission of the American Meteorological Society).

turbulent mixing and transport are relatively small and have minor impact on the large-scale thermal and constituent structures. Because, however, gravity wave energy flux and energy dissipation rate increase rapidly with altitude (see equations (51) and (52)), their influences are greater in the mesosphere and lower thermosphere. Early estimates of ϵ at higher altitudes based on radar spectral width and rocket trail diffusion measurements tended to be very high, but more recent estimates are typically ~10–300 mW kg^{-1} at altitudes from ~80 to 110 km [*CIRA*, 1986; *Hocking*, 1990]. More recent in situ measurements have refined these estimates even further, lowering mean ϵ estimates at high latitudes in winter below previous values and suggesting a sharp peak in ϵ at the high-latitude summer mesopause [*Blix et al.*, 1990; *Lübken et al.*, 1993; *Lübken*, 1997]. Peak values in these estimates are ~200 mW kg^{-1} and are in reasonable agreement with earlier CIRA 86 estimates. Peak values are also in reasonable agreement with recent theoretical estimates based on mean gravity wave energy densities [*Fritts and VanZandt*, 1993; *Hall and Hoppe*, 1998] and with estimates based on the gravity wave forcing required to account for the summer mesopause thermal structure [*Fritts and Luo*, 1995]. Comparable estimates have arisen from in situ measurements at equatorial latitudes [*Goldberg et al.*, 1997], while *Fuller-Rowell* [1994] attributed observed latitudinal variations in nitric oxide to a latitudinally varying turbulent transport with a maximum at midlatitudes.

[193] As noted in section 8.3, several studies have anticipated more efficient turbulent transport of momentum than of heat and constituents based on localization of turbulence within the wave field [*Fritts and Dunkerton*, 1985; *Coy and Fritts*, 1988; *McIntyre*, 1989; *Gavrilov and Yudin*, 1992] and assessments of the turbulent transport required to account for observed thermal and constituent profiles [*Strobel et al.*, 1985, 1987; *Holton and Schoeberl*, 1988; *Smith and Brasseur*, 1991]. More efficient turbulent transport of momentum than of heat implies a turbulent Prandtl number significantly larger than unity, with expected values in the range $Pr \sim 3$–10. The implication of a large Pr is a significantly reduced turbulent diffusivity, K_{zz}, relative to that anticipated from energy dissipation rates inferred from either discrete wave or spectral descriptions of gravity wave dissipation [*Lindzen*, 1981; *Fritts and VanZandt*, 1993]. These gravity wave dissipation studies together with more recent numerical modeling of wave breaking and turbulence dynamics [*Fritts et al.*, 2003] suggest that the turbulent Prandtl number will depend on wave amplitude and intrinsic frequency, with more efficient mixing accompanying larger wave amplitudes and more vigorous turbulence. We also anticipate that turbulent mixing accompanying KH instability of the wave field may imply smaller Pr since in this case strong mixing occurs in a sheared and stratified environment. Our understanding of the details of turbulence generation and mixing is insufficient, however, to be able to quantify middle atmosphere effects more completely at this time.

8.4. General Circulation Model Studies

[194] Several studies have used high-resolution GCMs to examine the properties of gravity waves resolved in these models and to examine their effects on the middle atmosphere circulation. Experiments with the SKYHI GCM [*Hamilton*, 1995, 1996; *Jones et al.*, 1997] have shown a tendency toward better simulation of the middle atmosphere circulation with increasing latitude and longitude resolution from 3° × 3.6° to 0.6° × 0.72°. The spectrum of wave momentum flux versus zonal wave number in these simulations is rather flat, suggesting that even wave numbers beyond 140 would need to be resolved to capture the wave fluxes important to the middle atmosphere circulation. The conclusion of these studies is that gravity wave effects in middle atmosphere GCMs must be included via parameterization at least for the foreseeable future.

[195] A number of studies have applied parameterizations of gravity wave effects in GCMs in order to study the role of gravity waves in various phenomena important to middle atmosphere dynamics. The results of such experiments are often difficult to interpret because they are complex in that they include many parameterized processes and modes of interaction. Insights gained from such experiments are described in this section.

8.4.1. Mesospheric Circulation

[196] Every gravity wave parameterization in use has been designed to yield the summer eastward and winter westward momentum forcing in the mesosphere that drives the pole-to-pole residual circulation (section 8.1). This role for gravity waves in the mesosphere was recognized decades ago [*Lindzen*, 1973, 1981; *Holton*, 1982] and has more recently been validated by full GCM studies [*Roble and Ridley*, 1994; *Norton and Thuburn*, 1996; *Hamilton*, 1997; *Manzini and McFarlane*, 1998].

[197] Two recent studies considered the effects of asymmetries in the eastward and westward gravity wave momentum fluxes input via parameterization but came to opposite conclusions. *Manzini and McFarlane* [1998] launched an isotropic spectrum of waves at two different source levels (at the ground and near the tropopause) in the MA/ECHAM4 model using the *Hines* [1997a, 1997b] parameterization. Launching the waves at the ground led to smaller eastward and larger westward momentum flux crossing the tropopause at midlatitudes because of filtering of eastward waves by the tropospheric jets (Figure 27). The larger westward fluxes in turn produced more realistic middle atmosphere zonal mean winds. *Medvedev et al.* [1998] applied their gravity wave parameterization [*Medvedev and Klaassen*, 1995] in the CMAM model. They compared results with an isotropic tropopause launch spectrum, with phase speeds in the range $0 < c < 60$ m s^{-1} in four azimuths, to results with only the eastward propagating waves with larger fluxes. The results with eastward waves alone showed weaker and more realistic zonal mean winds in both summer and winter (Figure 28). This is an apparently paradoxical result since the westward forcing needed to decrease the winter jet strength would be expected to decrease in the anisotropic case given the physics embodied in equation (42).

[198] *Norton and Thuburn* [1996, 1997] applied a Lindzen-type parameterization of gravity wave forcing in the UGAMP GCM. They found the model with gravity wave forcing developed a realistic 2-day wave while no 2-day wave developed in the model with only Rayleigh friction. They concluded that gravity wave forcing in their model was essential to maintaining the unstable zonal mean state that led to the 2-day wave generation.

[199] Several studies have employed mechanistic versions of GCMs to study the effects of various gravity wave parameterization schemes in the mesosphere. A comparison of the effects of the *Hines* [1997a, 1997b] and *Fritts and Lu* [1993] parameterizations on the diurnal tidal structure suggested that the Hines scheme tended to amplify tidal amplitudes, while the Fritts and Lu scheme caused excessive dissipation of the tides [*McLandress*, 1998]. Other mechanistic and simplified

GCMs have been used to test gravity wave parameterization effects in the mesosphere [*Hamilton*, 1997].

8.4.2. High-Latitude Stratosphere

[200] Through the concept of "downward control" of the mean meridional circulation by wave-induced mean zonal forces [*Haynes et al.*, 1991], *Garcia and Boville* [1994] stress that the winter mesospheric gravity wave forcing can have effects down to ~30 km in the high-latitude stratosphere that can help to alleviate the "cold pole" problem that plagues GCM studies of the winter stratosphere. *Hamilton* [1997], however, also suggests that gravity wave forcing at stratospheric altitudes, although smaller in magnitude, is also important to the winter circulation.

[201] The role of gravity wave forcing in sudden stratosphere warming (SSW) events has been examined in several global model studies. *Lawrence* [1997] compared effects of Hines and Fritts and Lu parameterization on the winter stratosphere. Both parameterizations generated reasonable zonal mean mesosphere winds, but the Fritts and Lu parameterization was found to inhibit the occurrence of SSW events while Hines did not. *Pawson* [1997] found that topographic gravity wave drag in the lower stratosphere influenced the onset of SSW events but found little or no sensitivity to mesospheric drag parameterized as Rayleigh friction. *Rind et al.* [1988] found that gravity wave forcing experiments, designed to describe waves generated by different sources, affected both the character and existence of SSW events in the GISS GCM.

8.4.3. Equatorial Oscillations

[202] At the equator, where the Coriolis force vanishes, the atmospheric response to a zonal force is simply zonal acceleration. Dissipation of zonally propagating waves at tropical latitudes provides the forcing that drives or helps to drive the three dominant equatorial oscillations: (1) the QBO in the lower stratosphere, (2) the stratopause SAO, and (3) the mesopause SAO. Both gravity waves and planetary-scale waves likely participate in driving all three of these oscillations to differing degrees. What remains to be quantified is the spectrum of wave momentum flux in the tropics. Global model studies are therefore free to include adjustable parameterized gravity waves without adequate constraints either on the gravity wave fluxes or on the resolved planetary-scale wave fluxes. *Mayr et al.* [1997b] demonstrated the potential of the gravity-wave-driving mechanism for all three of these equatorial oscillations in a simplified global model with parameterized gravity wave fluxes.

[203] The QBO in the lower stratosphere zonal winds is a wave-driven phenomenon believed to be predominantly driven by dissipation of planetary-scale waves [*Baldwin et al.*, 2001]. However, zonal forcing accompanying the dissipation of gravity waves is likely to contribute significantly, with recent estimates suggesting they may transport roughly half of the flux [*Dunkerton*, 1997;

Piani et al., 2000]. Until very recently, obtaining a QBO in GCM studies had proved difficult. Recent GCM studies with increased horizontal and vertical resolution and decreased numerical diffusion have since developed QBO-like oscillations [*Takahashi*, 1996; 1999; *Horinouchi and Yoden*, 1998; *Hamilton et al.*, 1999]. These successes are believed to be due to the increase in tropical wave fluxes allowed by the finer resolution and reduced numerical dissipation [*Boville and Randel*, 1992; *Nissen et al.*, 2000]. *Scaife et al.* [2000] instead modeled a QBO in a GCM by including parameterized small-scale gravity wave fluxes.

[204] The SAO at the stratopause is driven in part by the meridional advection of summer hemisphere westward (easterly) winds across the equator and in part due to zonal wave driving particularly important during the eastward (westerly) wind phases of the SAO [*Sassi et al.*, 1993; *Hamilton et al.*, 1995; *Müller et al.*, 1997; *Garcia et al.*, 1997]. *Rind et al.* [1988], *Jackson and Gray* [1994], and *Medvedev and Klaasen* [2001] modeled realistic SAOs by including parameterized gravity wave fluxes, the latter with a model deep enough to include an SAO at the mesopause.

9. SUMMARY, NEEDS, AND RECOMMENDATIONS

[205] Our intent in this review was to provide a broad overview of the current understanding of gravity wave dynamics and effects in the middle atmosphere. Considerable research activity in this area over the past two decades made this a daunting undertaking. In choosing to be comprehensive in scope we have necessarily provided less discussion and fewer references in many areas than we would have preferred, emphasizing the more significant contributions and directing readers, where appropriate, to related reviews having more limited foci.

[206] We began our review with a derivation of the dispersion and polarization relations using linear theory and with a discussion of the simplifications and dynamics appropriate for various ranges of intrinsic frequency. These offer, in most cases, significant insights into wave structure and effects at a small cost in accuracy. Also noted were departures from the expectations of linear theory accompanying wave transience, spatial localization, or finite amplitude effects that may have important implications for the middle atmosphere. Particularly relevant here are self-acceleration effects that enable wave packets to penetrate beyond the turning and critical levels anticipated by linear theory, with corresponding implications for wave dissipation and momentum transport. The impact of such effects in the middle atmosphere is not yet known, but studies addressing these effects are underway.

[207] We then summarized what is known of the more important sources of gravity waves, dominant wave scales, and factors influencing wave propagation in variable environments. Theoretical, modeling, and observational studies have yielded considerable advances in quantifying the mechanisms of and responses to wave forcing due to topography, convection, wind shear, geostrophic adjustment, body forcing, and wave–wave interaction sources. Mountain waves occur on scales dictated by the topography, may propagate to high altitudes, and have peak momentum fluxes at horizontal scales of ~10–100 km. Convection excites gravity waves having a wide range of spatial scales and phase speeds via several mechanisms that are dependent on the cloud environment and which exhibit significant temporal variability. Wind shear appears to support envelope radiation of gravity waves on the scale of patches of Kelvin–Helmholtz instability with attributes that favor their penetration to greater altitudes, while geostrophic adjustment favors inertia-gravity wave radiation due to the slow timescale and large spatial scale of the adjustment process. Body forcing due to local gravity wave dissipation and momentum flux divergence, in contrast, may occur on fast or slow timescales and on many spatial scales, resulting in a spectrum of radiated waves that mirror the source characteristics. Finally, wave–wave interactions are operative throughout the atmosphere, with interaction rates increasing with wave amplitude and energy transfers toward both larger and smaller scales. Dominant scales, amplitudes, and phase speeds are dictated largely by the various gravity wave sources at lower altitudes but are increasingly determined by propagation effects, filtering, and wave–wave interactions at greater altitudes. As altitude increases, so do the dominant vertical scales because wave amplitudes at smaller vertical scales are constrained by saturation processes whereas amplitudes at larger vertical scals are not. Despite significant advances, there remain many aspects of gravity wave sources and propagation that require further quantification. These are delineated below.

[208] Broad consistency in spectral shape and evolution with altitude led naturally to a spectral description of gravity wave motions. While far from the universal spectrum advocated initially, the frequency and vertical wave number spectra of horizontal velocity and temperature have near-universal forms throughout the middle atmosphere. Such descriptions constrain wave amplitudes, fluxes, and parameterizations and offer insights arising from spectral character and variability (or lack thereof). We also noted, however, that spectra often conceal, rather than reveal, the dynamics underlying spectral shape and pointed out where caution is warranted. Present unknowns include the degree to which adherence to or departures from specific spectral shapes are indicative of specific dynamics (e.g., saturation processes) or whether other spectral descriptions (e.g., wavelet spectra) might be more enlightening, given the localized nature of gravity waves in space and time that is often observed.

[209] Climatologies of gravity wave velocity and temperature perturbations have been compiled; however, these do not yet adequately constrain the inputs to

gravity wave parameterizations for global models. What is needed are descriptions of gravity wave sources and the detailed properties of the waves generated. The gravity wave climatologies instead have primarily served to partially validate the use of linear models for describing gravity wave propagation through the middle atmosphere and interaction with the background atmosphere with height. Departures from linear theory have been treated in these models with dissipation that is tied to linear instability or saturation of wave amplitudes. These treatments, of course, have serious limitations that are underscored by the more detailed studies of wave instability and mean flow interactions summarized below. The linear theory, however, remains a valuable research tool and is the starting point for most gravity wave parameterization approaches.

[210] Patterns observed in gravity wave climatologies are also influenced by the range of gravity wave properties each observation method is capable of detecting. The climatology of gravity waves that is ultimately needed will have to be constructed from a variety of measurement techniques, with modeling tools employed to aid in the interpretation of the observations.

[211] We next surveyed recent work addressing wave–wave interaction, wave instability, and wave saturation processes. These studies have yielded dramatic advances in our understanding of the myriad types of instabilities to which gravity waves are susceptible. Notable findings include the identification of wave–wave interactions that are facilitated by mean shear, the occurrence of wave–wave interactions (at large wave amplitudes) on a timescale competitive with local wave field instability, and characterization of the spectral energy transfers due to wave–wave interactions. Other studies identified links between instabilities occurring at small and large wave amplitudes, instability processes due to finite amplitude wave packets via wave–mean flow interactions, and definition of the instability dynamics leading to and occurring within a turbulence cascade. Despite these advances the competition between wave–wave interactions and local instability dynamics and their respective control over spectral shape and amplitude remain major unknowns.

[212] The last two decades also saw the development of several classes of saturation theories and a number of attempts to distinguish the most relevant dynamics. The major contenders are linear saturation theory (with amplitude constraints due to local instability), various nonlinear diffusion theories (relying on wave–wave interactions for spectral transfers and wave amplitude limits), Doppler spread theory (describing nonlinear interactions as advection by other spectral members, assuming they all occupy a common volume in physical space), and saturated cascade theory (employing elements of local instability and wave–wave interactions). Deciding which theories are most realistic has proven difficult, however, because all yield estimates of spectral amplitude and shape that are arguably consistent with the various measurements available. Perhaps more importantly, all of these theories are at present incomplete because they all fail to incorporate quantitatively the two nonlinear effects known to occur, i.e., wave–wave interactions and local wave field instability. As such, it is likely more valuable to recognize the insights we have gained from each rather than attempt to identify the "most correct" among deficient or incomplete alternatives. The result is a recognition of the dual role of nonlinearity, via both wave–wave interactions and local instability, in causing wave saturation and in determining the spectral shapes that arise from these dynamics. Thus a complete saturation theory will almost assuredly not be analytic but will rely instead on numerical studies of the competition among or merging effects of dynamics that are now believed to be linked theoretically.

[213] Parameterizations of middle atmosphere gravity wave effects presently suffer acutely from the lack of constraints on their inputs and tunable parameters. Global modelers can use these poorly constrained parameterizations, given the wide range of free parameters available, to get almost any answer they require. Until the needed constraints on parameterization inputs are forthcoming, the differences between different methods of parameterizing gravity wave dissipation and interaction effects will be difficult or impossible to quantify. The process of tuning gravity wave parameterizations in global models to attempt to infer the properties of the gravity wave input parameters is unwise at present because the range of parameters is too broad, and the solutions are not unique. As a result, GCMs tuned for one result (and at one resolution) using a gravity wave parameterization cannot confidently be used in any prognostic way.

[214] There has been significant progress in quantifying gravity wave–mean flow effects over the last two decades. The important mechanisms of wave dissipation are, however, still being debated and likely vary with altitude through the middle atmosphere. In the case of wave breaking, the mixing effects appear to be highly sensitive to the detailed properties of the wave at the point of breakdown. Tidal and planetary wave interactions likewise prove to be highly sensitive to details of the gravity wave field that are not known. To parameterize these effects therefore requires much more extensive knowledge of the properties of gravity waves in the middle atmosphere and of their sources than was imagined 20 years ago.

[215] Gravity waves almost certainly play a role in driving the prominent QBO and SAO equatorial wind oscillations. Quantifying that role remains illusive, however, until more complete knowledge is attained of the momentum flux spectrum of tropical wave motions ranging from planetary-scale to small-scale gravity waves. Similar lack of quantification of gravity wave fluxes and other gravity wave properties at high latitudes also hinders our ability to quantify their role in extratropical

processes such as sudden stratospheric warmings and the wave-driven transport circulation.

[216] Gravity wave interactions with larger-scale waves are strong and have been studied numerically and observationally. However, the details of the interactions appear to be highly sensitive to the relative phase of the gravity wave dissipation and the larger-scale wind variations with height. These remain poorly understood, as is evident from the fact that different gravity wave parameterizations yield very different results.

[217] Our field has experienced dramatic advances in understanding the dynamics and effects of middle atmosphere gravity waves over the last two decades. It is also clear that we require further advances in a number of areas before we can claim a comprehensive understanding of gravity wave dynamics and an ability to account for these dynamics statistically in large-scale operational or research models. We offer here our view of the further advances that are most needed to achieve these goals.

1. Observations and modeling studies that characterize and quantify the dominant gravity wave sources, especially scales, phase speeds, and momentum fluxes, as functions of meteorological conditions are a high priority, as this information underlies any attempt to quantify gravity wave influences at greater altitudes. More detailed observations and numerical studies are also required to quantify wave intermittency imposed by variable sources, propagation conditions, etc., as intermittency has major implications for wave effects at greater altitudes, including instability processes, wave–wave and wave–mean flow interactions, and radiation of secondary waves.

2. Further studies are also required to define the interplay of and competition among the nonlinear processes controlling spectral evolution with altitude in various environments, as these control gravity wave propagation, dissipation, and forcing at greater altitudes. These advances are likely to require numerical studies, as current and anticipated observational capabilities are unlikely to permit complete specification of the motion fields and their evolution in three dimensions. For the same reasons, numerical studies are required to characterize fully the mixing dynamics and transport accompanying the various wave instability processes leading to turbulence, including the statistical effects of multiple waves and events.

3. Finally, the accurate parameterization of gravity wave effects remains a critical need, as these may not ever be adequately described directly in large-scale models. New parameterizations will need to describe gravity wave sources, propagation and filtering, wave–wave (including tidal and planetary wave) interactions, spectral evolution, mean and variable climatologies, and instability and mixing far more quantitatively than present schemes. It seems unlikely, in fact, that any single scheme will satisfy all of these needs and that different schemes will be required to characterize different dynamics. Importantly, advanced parameterizations will rely to a large degree on the needed observational, numerical, and theoretical advances noted above and will advance together with successes in these areas.

[218] Recent theoretical and numerical activities have clarified key concepts, defined important dynamics and effects, and highlighted unresolved issues. Atmospheric and laboratory measurements have yielded similar advances in quantitative measurement techniques and definition of gravity wave sources, propagation characteristics, climatologies, instability processes and dissipation, mean and large-scale wave forcing, and variability. Ongoing and future research promises additional advances and further quantification of gravity wave dynamics and effects. Of the major needs identified above, there are none that seem insurmountable, given a continuation of our successes to date and the increasing awareness of the importance of the field, and we look forward to vigorous and stimulating interactions in achieving our collective objectives in the future.

[219] **ACKNOWLEDGMENTS.** D.C.F.'s review effort was supported by the National Science Foundation under grants ATM-9618004, ATM-9708633, ATM-9816160, the Air Force Office of Scientific Research under contracts F49620-98-C-0029 and F49620-00-C-0008, and the National Aeronautics and Space Administration under contracts S-46579-G and NAG5-02036. Support for M.J.A. came from the National Science Foundation grant ATM-9907501 and NASA contract NASW-01017. The authors would like to thank Jim Holton, Bob Vincent, and two anonymous reviewers for valuable comments on the first draft.

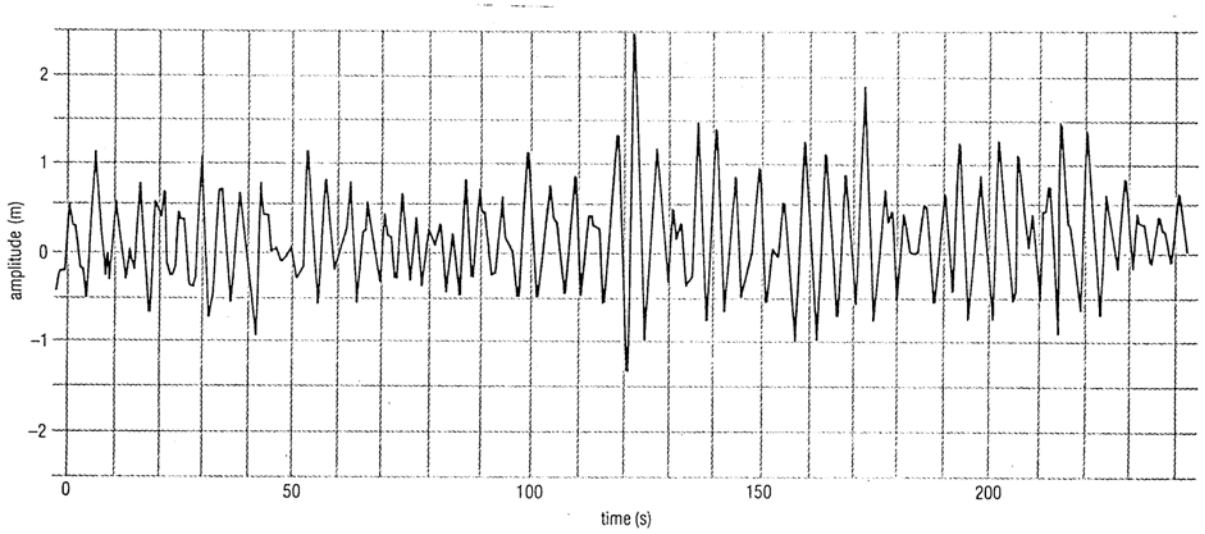
Surface Gravity Wave Generation

A typical wave record is shown below

Figure 1.5 A typical wave record, i.e. a record of variation in water level with time at one position.

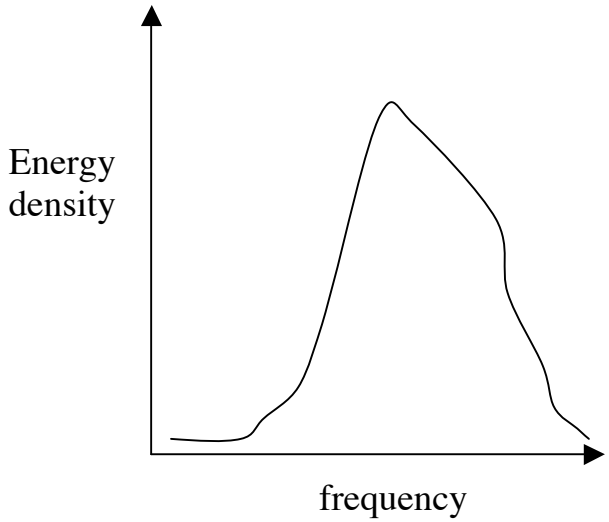


(from Waves, Tides and Shallow Water Processes).

From the record, we can see that the wave cannot be simply described as one sinusoid. Instead, it is characterized by many waves with different periods and phases. The spectrum of energy is usually plotted as energy density, (unit of energy/unit frequency interval, *Hz*). The energy density is given by the amount of energy in a particular frequency interval

$$\frac{1}{2}\rho g a^2 / Hz$$

To quantify the sea state, we make a plot of the energy density as a function of frequency.



Another way we can describe the waves, or the *sea state*, is with the *significant wave height*. The significant wave height $H_{1/3}$ is the average height of the highest 1/3 of all waves observed in a given period of time. This is the average height given by an experienced observer. The Beaufort scale gives a relationship between the wave height and the wind speed, so given the observed significant wave height, one can infer the wind speed.

Table 1.1 A selection of information from the Beaufort Wind Scale.

Beaufort No.	Name	Wind speed knots	Wind speed ms^{-1}	State of the sea-surface	Wave height* (m)
0	Calm	<1	0.0–0.2	Sea like a mirror.	0
1	Light air	1–3	0.3–1.5	Ripples with appearance of scales; no foam crests.	0.1–0.2
2	Light breeze	4–6	1.6–3.3	Small wavelets; crests have glassy appearance but do not break.	0.3–0.5
3	Gentle breeze	7–10	3.4–5.4	Large wavelets; crests begin to break; scattered white horses.	0.6–1.0
4	Moderate breeze	11–16	5.5–7.9	Small waves, becoming longer; fairly frequent white horses.	1.5
5	Fresh breeze	17–21	8.0–10.7	Moderate waves taking longer form; many white horses and chance of some spray.	2.0
6	Strong breeze	22–27	10.8–13.8	Large waves forming; white foam crests extensive everywhere and spray probable.	3.5
7	Moderate gale	28–33	13.9–17.1	Sea heaps up and white foam from breaking waves begins to be blown in streaks; spindrift begins to be seen.	5.0
8	Fresh gale	34–40	17.2–20.7	Moderately high waves of greater length; edges of crests break into sprindrift; foam is blown in well-marked streaks.	7.5
9	Strong gale	41–47	20.8–24.4	High waves; dense streaks of foam; sea begins to roll; spray may affect visibility.	9.5
10	Whole gale	48–55	24.5–28.4	Very high waves with overhanging crests; sea-surface takes on white appearance as foam in great patches is blown in very dense streaks; rolling of sea is heavy and visibility reduced.	12.0
11	Storm	56–64	28.5–32.7	Exceptionally high waves; sea covered with long white patches of foam; small and medium-sized ships might be lost to view behind waves for long times; visibility further reduced.	15.0
12	Hurricane	>64	>32.7	Air filled with foam and spray; sea completely white with driving spray; visibility greatly reduced.	>15

*$H_{1/3}$, i.e. the significant wave height.

11

While it is fairly intuitive how strong winds can generate larger waves, it is not as clear how the strength of the wind influences the dominant frequency of the waves, and thus the wave spectrum. To understand this, it is important to think about how waves grow. Initial disturbances are due to turbulent pressure fluctuations on small capillary waves.

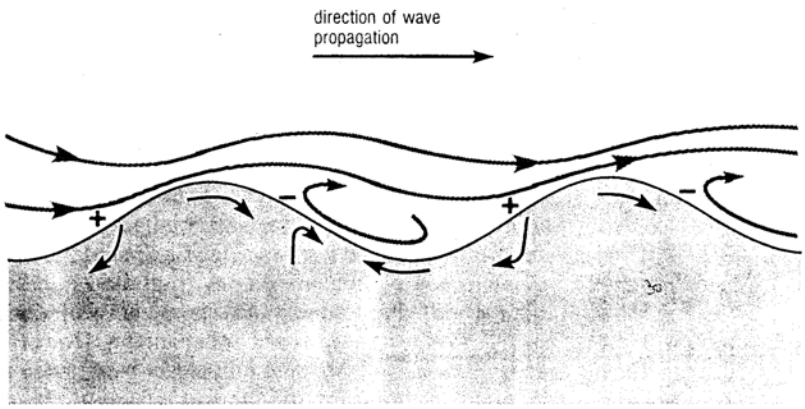


Figure 1.3 Jeffreys' 'sheltering' model of wave generation. Curved lines indicate air flow; short, straight arrows show water movement, which will be explained more fully in Section 1.2.1. The rear face of the wave against which the wind blows experiences a higher pressure than the front face, which is sheltered from the force of the wind. Air eddies are formed in front of each wave, leading to differences in air pressure. The excesses and deficiencies of pressure are shown by plus and minus signs respectively. The pressure difference pushes the wave along.

As in flow over topography, the wave causes air pressure fluctuations and eddies to form on the downwind side of the wave. Higher pressure on the upwind side of the wave creates a pressure gradient force on the wave and causes them to grow. As the waves grow, they steepen and non-linear effects become increasingly important and the waves break. In *deep water*, wave breaking tends to happen when $a/\Lambda = 1/12$.

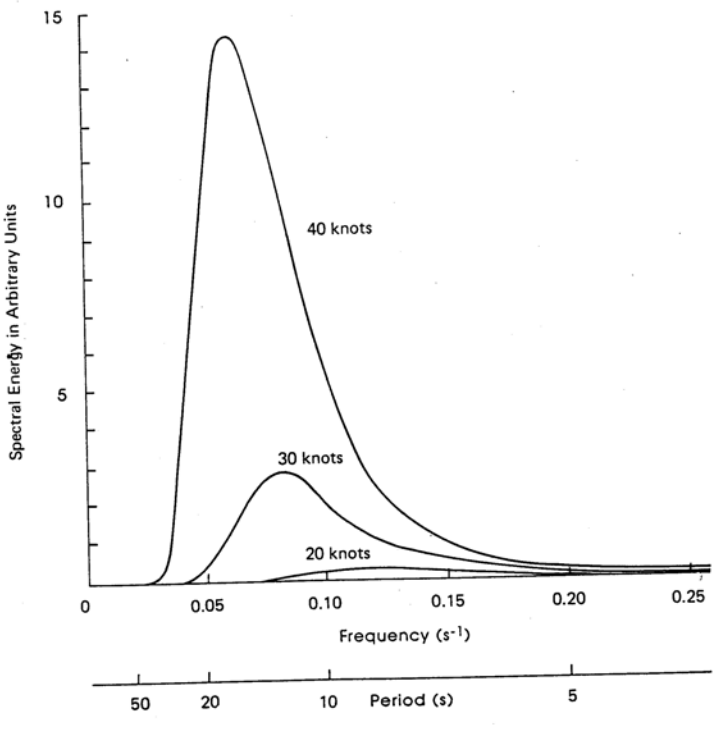
Now how does the speed of the wind effect the wave spectrum? First we need a definition for a *fully developed sea*. A fully developed sea occurs when the input by the wind is balanced by breaking of the waves.

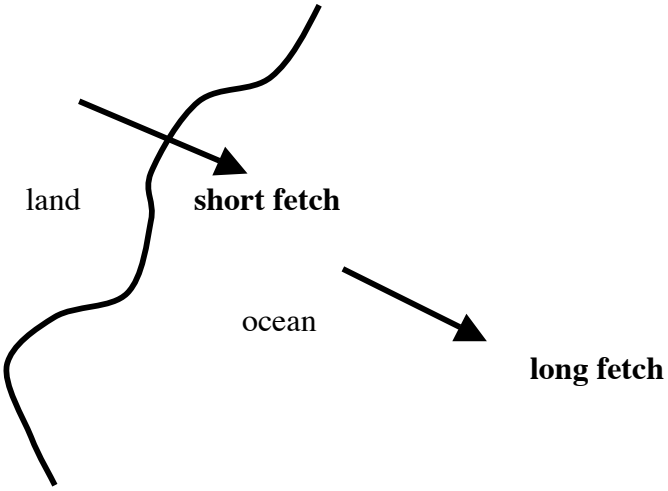
Wind energy in → Waves → Wave energy out (breaking)

The wind must blow as fast, if not faster, than the phase speed C of the wave to impart energy to it, where

$$C = \frac{\omega}{k} = \frac{\omega}{\omega^2/g} = \frac{g}{\omega} = \frac{gT}{2\pi}$$

Therefore, for a fully developed sea, the greater the wind speed, the longer the period of the most energetic waves (the peak in the spectrum). Also, since $\omega^2 = gk$, the longer the period T, the lower the frequency, and the longer the wavelength.





However, a fully developed sea does not always occur. Whether it does depends on the *fetch* (the distance over which the wind blows) and the *duration* (the length of time the wind blows) of the storm. *Young seas,* those with limited duration or fetch will tend to be peaked at shorter wavelengths. Waves tend to grow exponentially so that the seas quickly come into equilibrium with the winds, which is why the Beaufort scale is useful. See figure 9.12 in Knauss that shows the minimum fetch and duration required for a fully developed sea as a function of wind speed. In general, the *stronger the wind, the larger fetch and duration is needed for a fully developed sea to form.* Figure 9.13 shows the spectrum for a fully developed sea and for ones with more limited fetches.

Aside. The speed with which the ocean waves come into equilibrium with near-surface winds makes possible the measurement of winds using satellite-mounted radars called "scatterometers." The radar signal is scattered back from the ocean surface by waves with wavelengths of a few centimeters – their resonant backscatter, called "Bragg scatter", is used to estimate the speed of the wind that produces the short waves. By varying the look angle of the radar, wind direction can also be obtained.

Example: A storm is generated offshore of Washington. We measure the energy spectrum of surface gravity waves at Astoria on February 1 at noon and then again on February 3 at noon.

a. The peak energy occurs at a period of 12s on February 1, and 6 s on February 3. What is the wavelength for each of those waves?
We know that

$$\omega^2 = gk$$

Rearranging we have

$$\omega^2 = \frac{g2\pi}{\Lambda}$$

$$\Lambda = \frac{g2\pi}{\omega^2} = \frac{gT^2}{2\pi}$$

So plugging in for T we have 224 m for the 12 s wave and 56 m for the 6 s wave

b. What is the phase velocity and group velocity for each of the waves found in b?

$$C = \sqrt{g/k} = \sqrt{g\Lambda/2\pi}$$

18.7 m/s for the 12 s wave
9.35 m/s for the 10 s wave
The group velocity will be half that: 9.35 m/s and 4.68 m/s respectively.

c. Estimate *when* the storm occurred. Let d be the offshore distance (unknown, but the same for both cases)

$$d = C_1 t_1$$

$$d = C_2 t_2$$

and

$$t_2 = t_1 + 48 hours$$

where C_1 and C_2 are the group velocity for the 12s and 6 s waves, respectively. Then

$$C_1 t_1 = C_2 t_2 = C_2 (t_1 + 48 hours)$$

$$(C_1 - C_2) t_1 = C_2 48 hours$$

$$t_1 = \frac{C_2}{(C_1 - C_2)} 48 hours = 48 hours$$

d. Estimate *where* the storm occurred.

$$d = C_1 t_1 = 9.35 * 48 * 60 * 60$$

$$d = 1616\ km$$

Tests on Superconductor Gravitational Effects

by Alexander V. Frolov

1. Theoretical background

The high density fluctuations in Bose condensate is laboratory scale case to confirm theoretical conclusions about gravitational field cut-off frequency [1]. This experimental work was organized to examine if some resonance effects in 10-100 MHz range can be detected as mass (weight) anomalies.

Alexander V. Frolov is owner and director of research firm Faraday Lab, Russia, since 2001. He develops alternative energy and advanced aerospace projects. The publication of this article can be useful to find partners and investors for next stage of experiments. Contact email a2509@yahoo.com

2. Previous experimental data

Basically experimental approach in this area of research was described in [2] by Podkletnov:

1. Superconductor material was YBa2Cu2O7-x disk of 145 mm diameter and 6 mm high.
2. The effect is detected as 0.05% - 0.07% mass (weight) changes. It was detected for the case of non-rotating high temperature conductivity superconductor (HTCS) disk, which is leviting in 50-106Hz EM field.
3. Rotation of the disk increase the effect. Important fact is that during change of rotation velocity of the HTCS disk the effect was about 2-4% that is maximum data.
4. In the case of constant rotation velocity (about 5,000 rpm) the effect was detected about 0.3% - 0.5% change of the weight.
5. The effect was detected also for the case of rotation of the HTCS disk after EM field of solenoids was off.

Other experiment of 1995 was described by Podkletnov [3]. Two-phase material of the disk: in the operational mode the upper layer of the disk is superconductive the layer below is not superconductive. So, in this case the area of the phase transition between two layers was created especially.

One more important step in understanding of the effect was made by G. Modanese [4], who assumed that mechanical rotation of the HTCS disk produce motion of Bose condensate like electric current in HTCS material.

Next experiment by Podkletnov and Modanese was described as “impulse gravity generator” [5]. They used 50,000 A and 1MV electric discharge onto HTCS target to create non-dissipative “force beam” or gravity wave. This experiment is new step in understanding of process since

Podkletnov's idea of "shielding of gravity" is changed to conception of force action against gravity. This action is possible as result of artificial gravitational wave or impulse.

Static tests mainly were not effective but important example is experiment by John Schnurer [6]. The effect was detected in the case on non-rotating HTCS disk, which was leviting above permanent magnet. The effect was detected only during change of HTCS material phase from superconductor to non-superconductor phase (heating above Tk). This phase transition usually takes several seconds (2-3 seconds) when the effect can be detected.

Experiment with rotating HTCS ring described in [8] is example of gravimagnetic field produced by spinning superconductor. The results were presented at a one-day conference at ESA's European Space and Technology Research Centre (ESTEC), in the Netherlands , 21 March 2006. This experiment is the gravitational analogue of Faraday's electromagnetic induction experiment in 1831.

One more important aspect of experimenting with HTCS materials is their low temperature in superconductive state. This temperature is much low than environmental temperature and by this way the intensive heat transport present in all experiments. For the case of precise measurements flows of air produced by the temperature difference can be screened but there is aspect named as thermogravitation. For example, in Dotto ring [9] experiment it was demonstrated that intensive heat transfer along the ring produce gravimagnetic effects. For present experimental task it is not critical aspect since this effect is static i.e. it produce permanent force.

3. Related theories

Analysis of previous experimental and theoretical data allows to assume that gravity related effects resulting from changes of density of the Bose condensate. Maximum effect can be estimated for the case of correct frequency of oscillations of the external field, which resonate with natural high-density fluctuations in Bose condensate. In the case of correct frequency we can estimate full compensation of natural gravity field. Assume that the natural gravity field is not single frequency oscillation process. Complex frequency structure of the natural gravity field requires determine several main resonance frequencies to obtain full compensation.

Single phase transition in HTCS material [6] also is the case of change of the Bose condensate density (from maximum value to zero). Since in this case the change of the phase from superconductor to non-superconductor is gradual then the effects is weak and detected during several seconds. Experiment described in [5] is one of methods to produce rapid change of the phase in all Bose condensate of the HTCS target to create short but powerful gravitational pulse.

The nature of this gravitational pulse can be described here as longitudinal wave in aether. By this approach we can see analogy with Tesla experiments. Also we can see that impulse gravity generator by Podkletnov and Modanese [5] is development of Morton beam generator [7], which used electric spark between charged ball and metal plate to produce "Morton force beam". Powerful force effect in HTCS case [5] can be explained by coherent behavior of Bose condensate that produce "laser effect" since it is similar to coherent photon emission in laser.

Analysis of experimental data allows assume that:

1. Bose condensate currents in stationary HTCS disk involve aether in motion relative lattice in matter of the HTCS disk. This **relative motion** generate gravimagnetic field, which is responsible for the weight changes.

2. Rotation of the HTCS disk with Bose condensate currents produce more powerful effects due to **increase of the relative velocity** between Bose condensate and lattice of the matter of the disk.

3. **Change of rotation velocity** of the HTCS disk (i.e. **deceleration or acceleration**) produce maximum relative velocity between matter lattice and moving Bose condensate due to its inertial properties. Here is clear analogy with electromagnetic induction effects.

4. **Phase transition** from HTCS condition to non-superconductive phase is the case of maximum change of the Bose condensate density (zero – maximum or maximum – zero) that is responsible for generation of single **aether density wave.**

5. Special material of the HTCS disk [3] with **two-phase layers** demonstrated more powerful effects. It can be explained since in such disk there is **boundary layer** between superconductive and non-superconductive areas. External electromagnetic field make this layer produce **high frequency phase transitions** that generate high frequency aether density waves.

6. Impulse gravity generator [5] produce more powerful effect than Morton beam generator due to coherent behavior of the Bose condensate. The nature of this effect is the same **longitudinal aether wave** discovered by Tesla.

7. Experimental data from ESTEC [8] is confirmation of the above suggestions. Any rotation of mass by Einstein produce **gravimagentic field** that can be explained by aether dynamical theory. Spinning superconductor produces more powerful effect than non-superconductive matter due to physical properties of Bose condensate.

4. Conclusions

Considering matter as vortexes in aether it is possible to explain most of gravitational phenomenon. For example, inertial property of mass can be explained by behavior of aether, which is connected with this mass. Old theory [10] by Fatio (1690) and Le Sage (1700) can be confirmed in modern experiments. So called “gravitational waves” or “gravitational impulses” can be created as aether density waves, which are longitudinal waves. Bose condensate in superconductor can be presented as special physical state of matter when matter is connected with aether in different extent than usually. Phase transition of matter between superconductive state and non-superconductive state release or connect (join) some amount of aether and this phase transitions can be organized with high frequency to generate high frequency aether density waves. In the case of resonance (predicted in [1] range of frequencies is 10-100MHz) compensation of natural gravity forces can be obtained experimentally.

5. **Organization of tests**

HTCS disk was ordered from CAN superconductor producer [11]. Material is melt textured $YBa_2Cu_3O_{7-x}$ with Y_2BaCuO_5 excess. Critical temperature 90 K. Diameter 56 mm height 16 mm , Fig.1.

Fig.1 HTCS disk

Cooling of the HTCS was organized by liquid nitrogen, the HTCS disk was placed in plastic tank and immersed in nitrogen vapors, Fig.2.

Fig.2 One of the plastic tanks with the HTCS disk

Fig. 3 Cooling by liquid nitrogen

Detection of weight changes was made by digital scales HL-100 with accuracy 0.01 g . Balance rod with mass difference about 20g was organized in stable place of laboratory where any vibrations were minimized. The loads are 50g and 70g. In other experiment two loads were equal to 500g and balanced with small (about 20g) difference Fig.4. The loads made of plastic.

Fig. 4 Balance scales

Rotation of HTCS disk was organized mechanically by 3.000 rpm electromotor, Fig.5

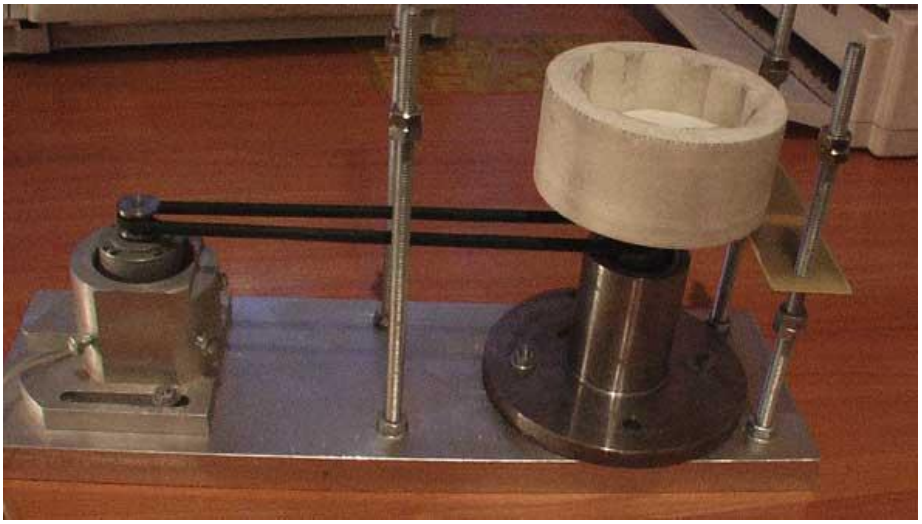

Fig.5 Electromotor and rotating plastic tank for HTCS disk

In this experimental setup the HTCS disk placed in the rotor and cooled by liquid nitrogen can be used in superconductive state only during 20-30 seconds. Due to this problem many measurements on rotational tests can not be reported here as reliable data.

6. **Logbook**

June 23, 2007. Reproduction of Schnurer experiment with balance scales. There are not visible effects for the phase transition from superconductive state to non-superconductive.

It was planned to build more precise rotational detector for more precise measurements. Production of low frequency and high frequency generators and experimental setup to rotate HTCS disk was started.

Other experiment was organized June 23: high voltage discharge to HTCS disk, which was immersed in liquid nitrogen, Fig.6.

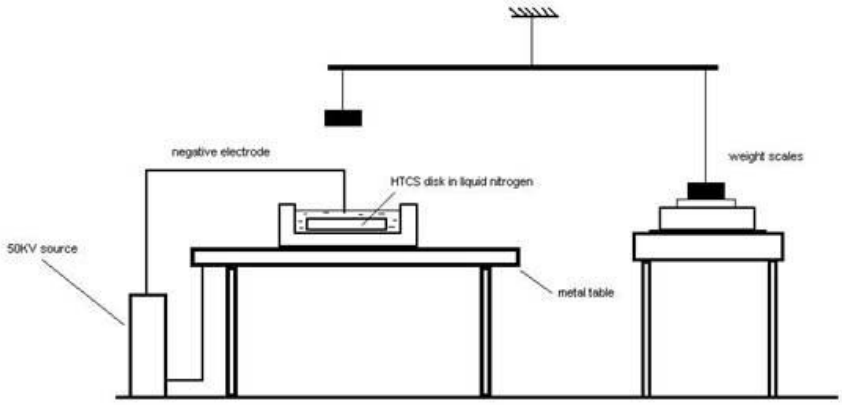

Fig.6

Initially significant weight changes (up to 0.3 g) were detected for the case of negative electrode connection to HTCS disk, which was immersed in liquid nitrogen. But future testing without HTCS disk also produced effects, which were identified as electrostatic interference to digital weight scales.

June 30, 2007. Test with rotational detector, Fig.7

The detector is made of wooden rods and plastic loads. Small glass plate in central point of the horizontal rod reflect red laser beam to the wall of the laboratory placed in 2 m distance that allow to detect small angle oscillations of the horizontal rod. Vertical axis is made of tungsten wire 0.05 mm diameter. All parts of the detector are placed under glass bell to avoid air flow interferences.

Experiment: cooled in plastic tank HTCS disk was placed near the detector. After 30-40 seconds when the disk is changing to non-superconductive state **the attraction of mass to the disk was detected.** After 3-5 min the detector is turning back to previous stable position. Maximum of the effect was measured if the HTCS disk was oriented by its flat side to the detector. Experiment was reproduced 4 times.

It seems to be impossible provide any quantitative data on this effect and future testing is necessary.

Possible mistakes here related with heat and cold flows, i.e. thermogravitation theory. To confirm or disprove this idea new tests with cold non-superconductive mass was organized. Metal disk of mass, which is equal to mass of tested HTCS disk, was cooled by liquid nitrogen and placed near of the rotational detector. Small effect of attraction of the load to the cold mass also was detected in this case. Values of effects for HTCS disk and simple metal disk are different. Conclusion: future testing is necessary to confirm if phase transition in superconductor generate gravity wave and produce attraction/repulsion of the detector.

Fig.7 Rotational detector

July 2, 2007. Experiment with permanent magnet installed near of rotating HTCS disk.

This experiment was planned to test if Lorenz force can be reason of gradient in Bose condensate that change its density and generate gravity wave. Fig. 8 is the case of radial magnetic field and Fig.9 show axial superposition of the permanent magnet (Faraday disk).

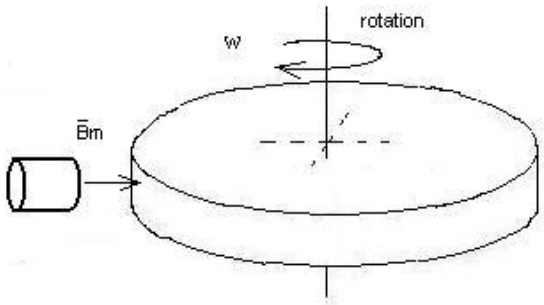

Fig.8 Superconductive disk and radial magnetic field

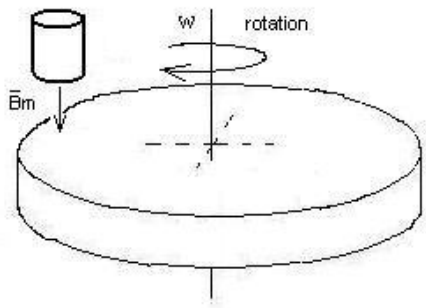

Fig.9 Superconductive disk and axial magnetic field

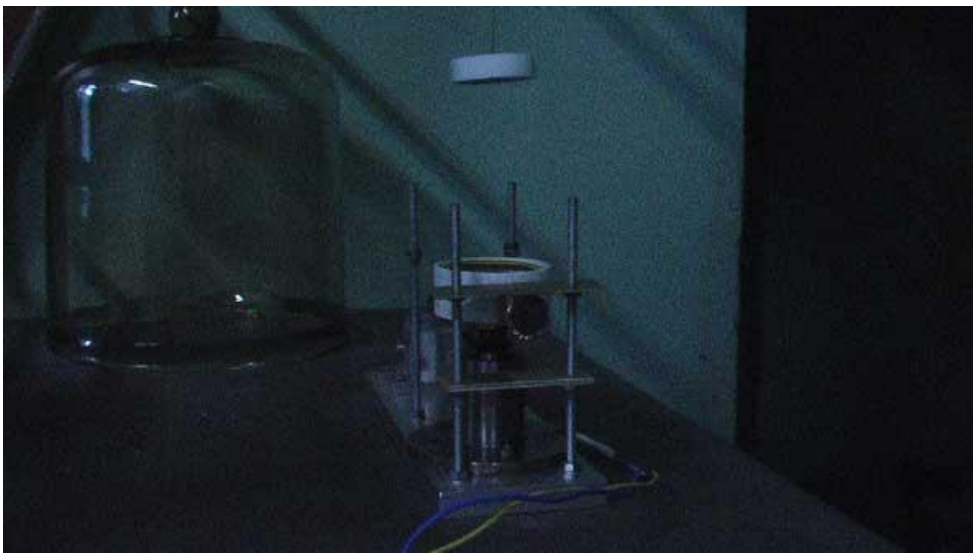

Fig.10 Radial permanent magnet installed near rotating HTSC disk.

Mass of the loads for this case was 50g (above the HTCS disk) and 70g (on the weight scales). Rotation velocity about 2000 rpm. Magnet of 1T field is made of NdFeB material, cylinder of 25 mm diameter and 24 mm height. Distance from magnet to HTCS disk is about 7 mm.

Weight changes were detected as 0.02 g only in experiments with axial superposition of the magnet (Fig.9). It is equal to 0.04% mass change that is too small to be considered as reliable data.

June 04, 2007

Tests with low frequency magnetic field was organized both for the case of stationary HTCS disk and for the case of rotation of the disk. Sinusoidal input signal with frequency from 10Hz up to 1KHz was connected to transistor current amplifier loaded on output coil. For frequencies between 10Hz – 100Hz the coil was made as 500 turns of 1 mm wire on U-shape transformator metal core, Fig. 11.

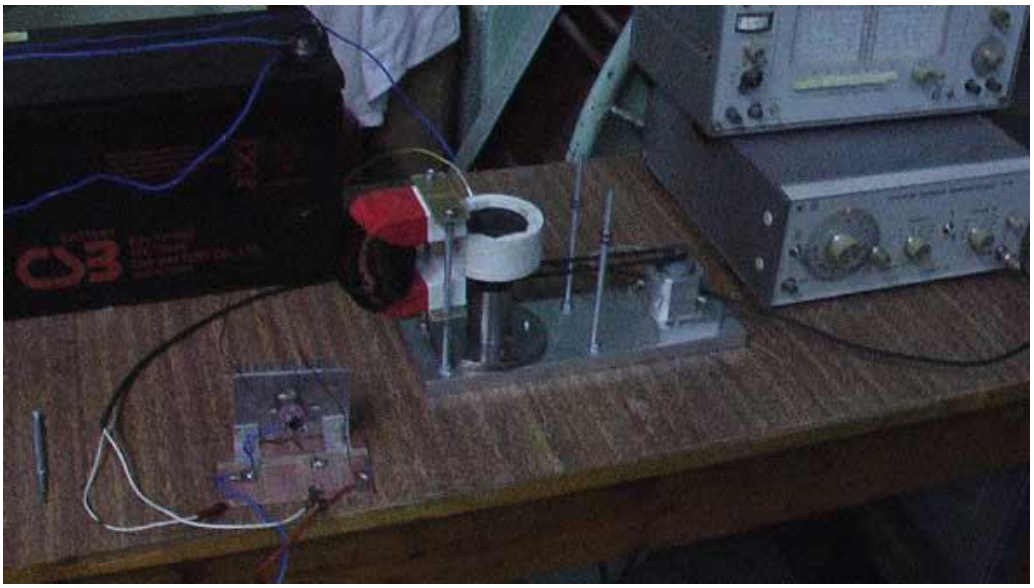

Fig.11 Low frequency tests

Frequency from 100Hz up to 10KHz was tested with other output coil and ferrite core, Fig.12 and Fig.13.

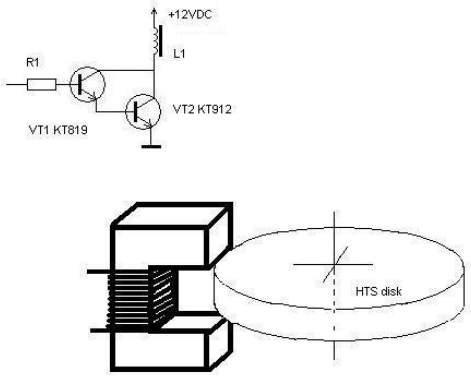

Fig.12

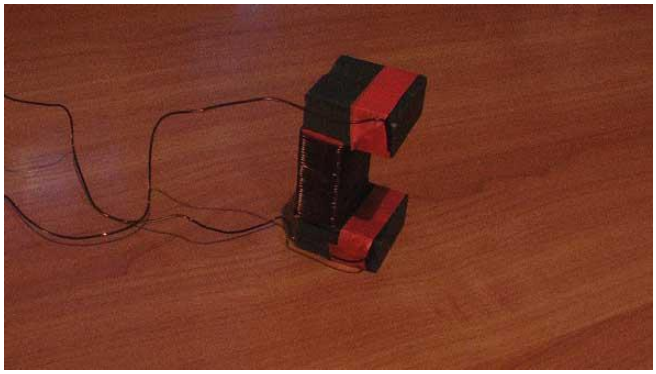

Fig.13

Small positive result was detected for the case of rotation in the field of 1kHz frequency. Weight changes was detected as 0.02 g for mass of the load 500g. Probable it was measurements mistake since percent ratio of the mass changes here is 0.004% only.

July 09, 2007

Tests for frequencies from 10KHz up to 3MHz were organized with air core output coil placed above HTCS disk, Fig. 14 and Fig.15.

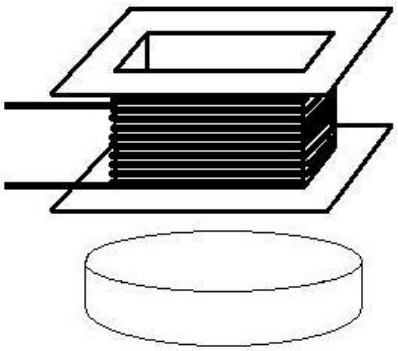

Fig.14

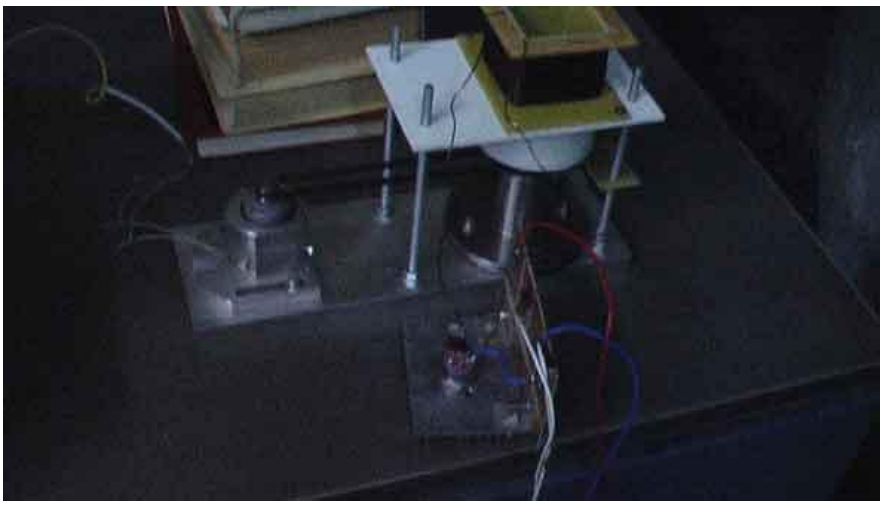

Fig.15

All tests in this case were negative, i.e. it was not confirmed that electromagnetic field in this case produced significant weight changes. Both stationary and rotational HTCS disk were tested.

July 12, 2007

High frequency generator was designed, Fig. 16 – Fig.17 for tests of 3MHz – 40MHz frequency band. Output power is about 10-30Wt.

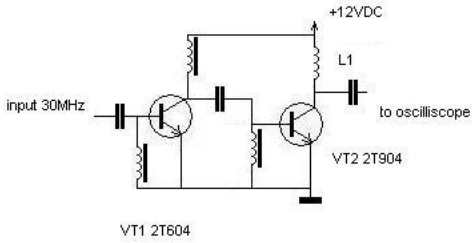

Fig.16

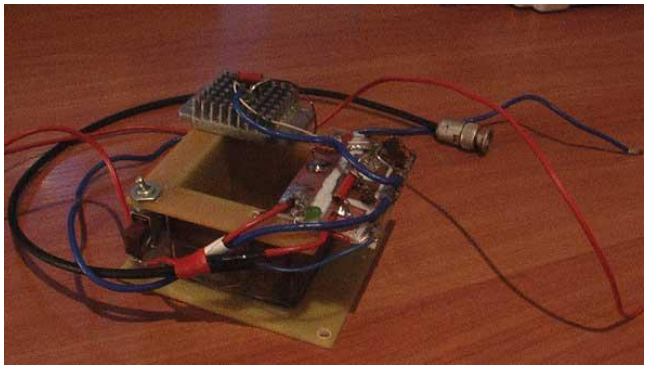

Fig.17

Weight changes were detected as 0.06 g for the case of stationary disk and frequency about 30MHz. High frequency generator was installed above HTCS disk, which was immersed in liquid nitrogen. It seems to be strange that the weight change were stable after the electromagnetic generator was OFF. Quantitative data: this weight change is about 0.01% only.

The case of rotation of the disk in high frequency electromagnetic field also was testes but without estimated effects, Fig.18. Perhaps that in this case important data was missed due to short time of superconductive state of the disk placed in the rotor. Other possible reason is that high frequency electromagnetic field was dissipated in metal parts of the rotor.

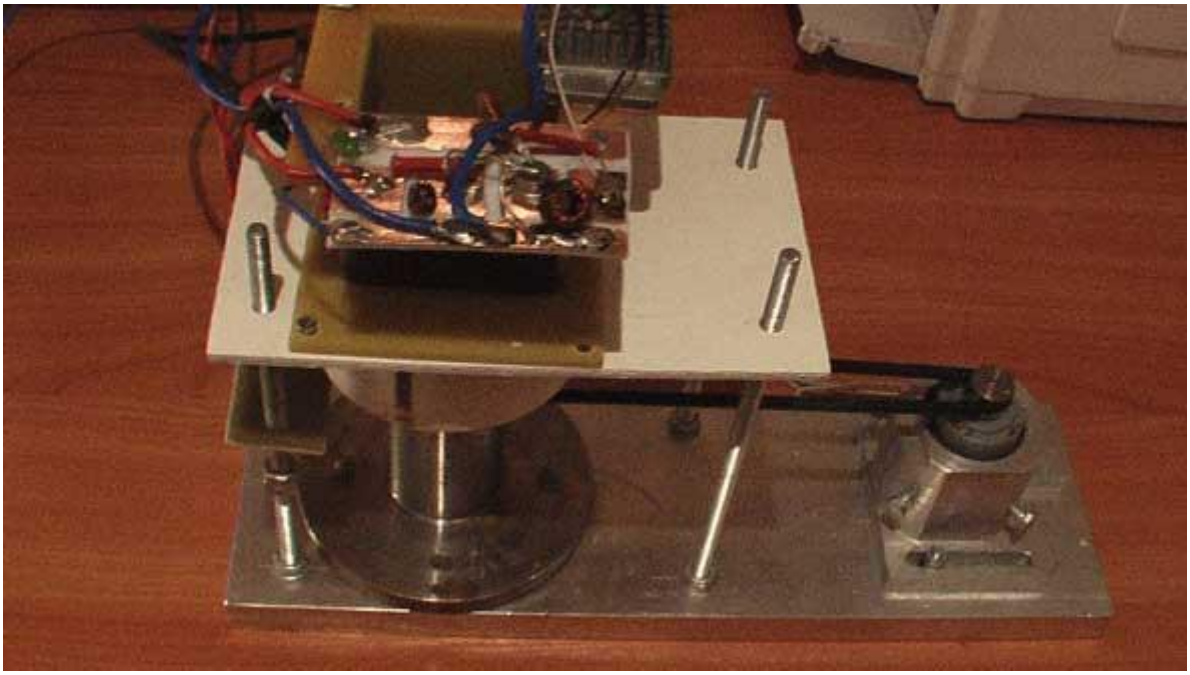

Fig.18

7. Conclusions

7.1. Experiments were organized with low power electromagnetic field. Due to short time of superconductivity state of rotating HTCS disk, reported effects for rotation tests can not be considered as reliable data and additional experimenting can be necessary.

7.2. There is positive effects in the case of rotation of the HTCS disk in permanent magnet field oriented cross the disk axially. If this effect is not a mistake then it can be explained by consideration of conditions created by this design for local gradient of Bose condensate density in the disk due to Lorenz force. Oscillations of this density due to rotation for the disk can generate gravity wave in axial (vertical) directions above and below the permanent magnet.

7.3. Main task of the project was to find resonance effects in 10-100MHz frequency range. Some effects were detected for 1KHz and 30MHz frequencies. To get more reliable data it is necessary to increase power of electromagnetic field.

8. **Planning of the future experiment**

Rotation or motion of HTCS matter in future tests is not planned. It is planned to test superconductor films instead of solid state disk. Instead of high frequency electromagnetic field producing induction currents in HTCS it is planned to use high frequency electric fields, which allow to create high frequency oscillations of Bose condensate and by this way to change its density to find reliable experimental data on resonance frequencies predicted in [1].

GravWave® LLC TEAM

(A group of individuals in the United States and abroad who have a common interest in
High-Frequency Gravitational Waves)

Robert M L Baker, Jr., PhD

Principal Investigator and Project Manager

Robert M L Baker, Jr. was born in Los Angeles on September 1, 1930. He has been married to his wife Bonnie since 1964 and has three grown children. Baker earned a bachelor's degree in Physics at UCLA with highest honors (*summa cum laude* – first in his class) was elected to *Phi Beta Kappa*, earned a master's degree in Physics and a Ph.D. in Engineering at UCLA—the Ph.D. degree with a specialization in space navigation was, according to UCLA officials, the first of its kind to be granted in the United States. Dr. Baker was on the faculty of the Department of Astronomy at UCLA from 1959 to 1963 and the Department of Engineering and Applied Science at UCLA from 1963 to 1971 as a Lecturer and Assistant Professor. During that time he was a Lecturer at the *United States Air Force Academy.* While on a two-year tour of active duty in the Air Force he worked on a variety of classified aerospace projects. He was the head of the Lockheed's *Astrodynamics Research Center* in Bel Air, California and in 1964 joined *Computer Sciences Corporation* as the Associate Manager for Mathematical Analysis. In 1980 he was elected President of *West Coast University*, an accredited university for the adult learner (Western Association of Schools and Colleges

or WASC and Accreditation Board for Engineering and Technology or ABET) now operating under the auspices of *American Career College* in Los Angeles. After retiring from West Coast University in 1997 as President and Professor of Engineering, Dr. Baker became the Senior Consultant for *Transportation Sciences Corporation* and *GRAVWAVE© LLC*. He won the UCLA *Physics Prize*, was recipient of the *Dirk Brouwer Award* for outstanding contributions in astrodynamics and orbital mechanics, was a recipient of the *Outstanding Man of the Year* Junior Chamber of Commerce award in 1965 presented to him by Ronald Reagan and the 2011 "Outstanding Lifetime Achievement in the Field of High-Frequency Gravitational Waves" Awarded during the joint Conference of the International Institute of Information and Systems (IIIS), International Conference on Information and Communication Technologies and Applications: ICTA 2011, the International Institute for Design Marketing in Science, Education and Technology (DeMset) and the 17th International Conference on Information Systems Analysis and Synthesis: ISAS 2011.. He is a *fellow* of the *American Association for the Advancement of Science.* He was national chairman of the Astrodynamics Technical Committee of the *American Institute of Aeronautics and Astronautics* (AIAA) from 1961 to 1964, was Editor of the *Journal of the Astronautical Sciences* from 1963 to 1975, was appointed by William Bennett to the *National Advisory Committee on Accreditation and Institutional Eligibility* of the Department of Education from 1987 to 1989, was appointed to the *Academic Review Committee on Gravitational Research* with the U. S. Army from 2001 to 2003, Vice Chairperson of the first International HFGW Workshop at the MITRE Corporation in 2003, Honorary Chairman of the second International HFGW Workshop in Austin Texas in 2007, Chairman of the third International HFGW Workshop in Huntsville, Alabama in 2009 , cochairman of the High-Frequency Gravitational Wave Symposium at the Johns Hopkins University Applied Physics Laboratory in 2010. and coauthor of papers presented at the Space Technology Applications International Forum in 2012. Dr. Baker is an Advisory Professor *Chongqing University*, China 2004, and was the author of several textbooks and over one hundred company reports, symposium papers, and journal articles in the area of astrodynamics, unmanned sailcraft, celestial mechanics, and High-Frequency Gravitational Waves (HFGWs) including *An Introduction to Astrodynamics* (1960) with Maud W. Makemson and *Astrodynamics: Applications and Advanced Topics* (1969). Dr. Baker has been Project Manager on three prototype development, fabrication, and test projects under contract to the U. S. Navy and Principal Investigator on several NASA and USAF projects while head of Lockheed's *Astrodynamic Research Center*. As President of *West Coast University* Dr. Baker coordinated the activities of six groups of scientists and engineers spread throughout Southern California. Dr. Baker has been interested in the dynamics of gravitational fields since the 1950's and in high-frequency gravitational-wave (HFGW) research since the early 1960's. He is the inventor of the Li-Baker HFGW detector and the double-helix HFGW generator/transmitter and holds six patents and several pending patents in the United States, Europe, Russia, and China in the area of gravitational-wave generation and detection in the laboratory. You are invited to visit: www.DrRobertBaker.com.

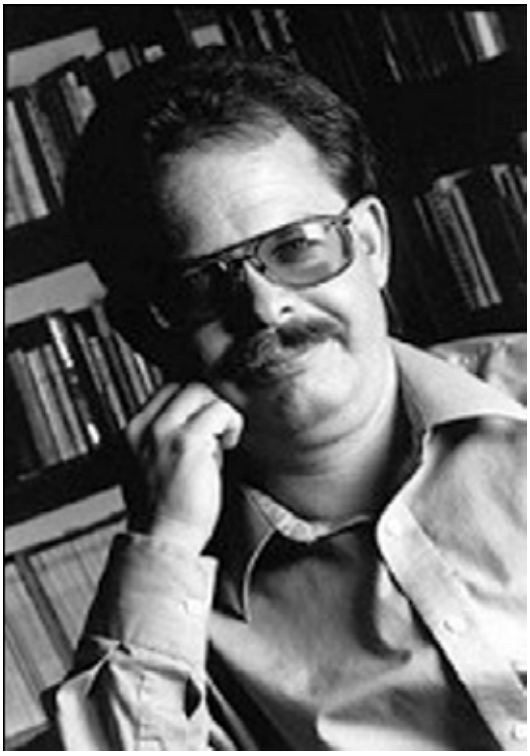
Roger Clive Woods, M.A., D.Phil., D.Sc. (Oxford), FIET

Senior Scientific Investigator

R. Clive Woods was born in Leicester, England on May 18, 1955. Currently he is Department Chairman and Voorhies Distinguished Professor, Department of Electrical and Computer Engineering, *Louisiana State University*. Woods earned a Master's degree and Doctorate at New College, *University of Oxford*, 1976 and 1980, for work on magnetic resonance in rare earth metal alloys in the Solid State Physics group of the Clarendon Laboratory in the *University of Oxford*. Dr. Woods was a Senior Scientist and Project Manager at Plessey Research (Caswell) Ltd. from 1982 to 1983, and Lecturer and Senior Lecturer on the faculty of the Electronic and Electrical Engineering Department of the *University of Sheffield* from 1983 to 2001. During this period he managed projects on the design, development, and test of microwave acoustic devices, III-V heterojunction bipolar transistors, avalanche photodiodes, high-temperature superconductors, and other solid-state devices. In 1989 he was appointed as a *British Association Media Fellow* and in 1995 he was Professeur Invité at the Laboratoire de Physique de la Matière, *Institut National des Science Appliquées* de Lyon, France. From January 2002 to June 2006 Dr. Woods was a Full Professor of Electrical and Computer Engineering at *Iowa State University*, Ames, Iowa. During 1992-1995 he was a Member of IEE Professional Group Committee S8 (Electromagnetics); 1999-2002 a Member of IEE Professional Group Committee E3 (Microelectronics and Superconductor Devices); 1999-2002 an Associate Editor of *IEE Electronics and Communication Journal*, and in 2003 a Member of the *National Science Foundation* SBIR/STTR Photonics (Lasers and

LEDs) panel. Dr. Woods has consulted for Barnsley Business and Innovation Centre Ltd., McLarens Ltd., Price Waterhouse, John Lovell Associates, Halpern & Ward Associates, the European Commission in Brussels, and Ashton Brown Associates Ltd. among others. He has authored over 70 technical papers and the book "Digital logic design" (with B. Holdsworth), Butterworth-Heinemann, 2002. Dr. Woods has been interested in the research associated with gravitational-waves for over a decade and participated in the first International HFGW Workshop at the MITRE Corporation in2003, the second International HFGW Workshop at Austin, Texas in 2007, the third at Huntsville, Alabama in 2009 and the High-Frequency Gravitational Wave Symposium at the Johns Hopkins University Applied Physics Laboratory in 2010. You are invited to visit: http://myprofile.cos.com/cwoods

Eric W. Davis, PhD



Senior Scientific Investigator

Eric Davis received his bachelor's degree in Physics in 1983 and a Ph.D. in Astrophysics with a specialization in the theory of relativity from the *University of Arizona* in 1991. His fields of specialization include relativity theory and cosmology, space mission engineering, gravitational-wave research, and the NASA Breakthrough Propulsion Physics program. Dr. Davis is a Senior Scientist at *The Institute for Advanced Studies at Austin.* He also participates in and serves as a consultant to the NASA Breakthrough Propulsion Physics program. For nearly six years Dr. Davis served as a research scientist and S&TI analyst at the National Inst. for Discovery Science-Bigelow Aerospace Co. where he conducted phenomenology research and forensic

investigations into transient optical phenomena and manned spaceflight research projects. Dr. Davis began his graduate work as a mission support and research assistant with the Infrared Astronomical Satellite group at the *Steward Observatory* in Tucson, AZ. In 1985, he joined the Voyager Ultraviolet Spectrometer Experiment group at the Lunar & Planetary Lab in Tucson where he conducted research on Jupiter's magnetosphere, the Uranus and Neptune planetary encounters, and participated in the Voyager 1 & 2 space mission support. Following completion of his doctorate, he became an associate faculty and interim director for the Arizona Astronomy Education Center at *Pima College* in Tucson. In 1995 Dr. Davis was appointed to the faculty of physical/computer sciences & mathematics, where he was involved with Air Force sponsored space mission engineering and Korean theater space reconnaissance training, at the *University of Maryland* Asian Division while he was stationed at the 8th Fighter Wing in Kunsan, South Korea. Dr. Davis developed experiment designs and cost estimates supporting the AFRL Advanced Concepts Office He has also been recognized by the *American Institute of Aeronautics and Astronautics* in their 1993-94 Public Policy Award for outstanding contributions to national defense and space public policy, and received recognition from the State of Arizona Economic Conversion Council for contributions to commercial conversion of small-medium space and defense businesses in Arizona. Dr. Davis is a Fellow of the *British Interplanetary Society*, senior member of the *American Institute of Aeronautics & Astronautics*, member of the *Association of Former Intelligence Officers*, and member of the *American Astronomical Society.* Dr. Davis participated in the first International HFGW Workshop at the MITRE Corporation in 2003 and the second International HFGW Workshop at Austin, Texas in 2007.

Andrew Beckwith, PhD

Scientific Investigator

Andrew (Andy) Beckwith was born on December 15, 1954. He has studied astrophysics, theoretical Physics and superconductivity. He received his PhD from the Texas Center of Superconductivity on June 5th, 2002. Dr. Beckwith is currently working in condensed matter CDW/ Domain wall physics problems, and early universe models of emergent gravity/ entropy generation. He joined *Fermi National Accelerator*

Laboratory (FNAL) in August of 2002, is a member of the American Institute of Beam Energy and was appointed senior scientific researcher for GravWave® LLC in February, 2009. Dr. Beckwith is a Fellow of the Space Physics Committee on Space Research (COSPAR) and on their Committee for Space Astrophysics as well as a Life Member of the American Institute of Beamed Energy Propulsion (AIBEP). He has attended several astrophysics conferences in the last few years (2008) including the following: *Space Technology Application International Forum (STAIF)* 2007 and 2008 (HFGW sessions), Quantum Atomic and Molecular Tunneling in Solids (QAMTS) 2007 (Texas), 23rd International Conference On Neutrino Physics And Astrophysics (Neutrino 2008) (New Zealand), and European Committee for Future Accelerators (ECFA) 2008 on behalf of *Fermi National Accelerator Laboratory (Poland).* He is also currently doing work in several areas including topics concerning the early universe and relic HFGWs. Dr. Beckwith participated in the third HFGW International Workshop at Huntsville, Alabama in 2009 and the High-Frequency Gravitational Wave Symposium at the Johns Hopkins University Applied Physics Laboratory in 2010.

.

Gary V. Stephenson

Scientific Investigator

Gary Stephenson received his Bachelor's of Science Degree in Physics at Montana State University in 1983, and his Masters of Engineering in Space Systems Engineering at Stevens Institute of Technology in 2011. From 1983 to 1986 he was a Member of the Technical Staff at Hughes Aircraft Company where as a systems engineer in optical and radar systems. In 1986 Mr. Stephenson joined the Aerospace Optical Division of ITT where he performed systems design of space borne meteorological Infrared imagers. In 1989 through 1997 he returned to Hughes as a Systems Engineer where he was responsible for the electro-optical systems engineering and on-site support of AST, an airborne infrared tracking sensor for the US Army. From 1997 to 2010 he was a

Systems Engineer at The Boeing Company where he performed the systems design of electromagnetic and electro-optical mission equipment, including TAPLOC, (TENCAP AWACS Precision Location), the satcom system for Connexion by Boeing, and several proprietary satellite projects. Mr. Stephenson is named as inventor or co-inventor in six US patents in satellite communications. Since 2010 he has been with LinQuest, and as a government crew chief manages the integration of a number of GPS II-F spacecraft for the US Air Force. Since 1989 Mr. Stephenson has also been the president and chief investigator for Seculine Consulting, an applied physics consultancy. He has several publications in the communications applications of high-frequency gravitational waves, including the possible application of the Gertsenshtein effect. He has participated in the first International HFGW Workshop at the MITRE Corporation in 2003, the second International HFGW Workshop at Austin, Texas in 2007, as cochairman of the third at Huntsville, Alabama in 2009, and as cochairman of the High Frequency Gravitational Wave Symposium at the Johns Hopkins University Applied Physics Laboratory in 2010.

Lawrence S. Moy, M.D.

Medical/Biological Investigator

Lawrence Moy graduated from Medical School at the University of California at Los Angeles in 1981 and was certified by the American Board of Dermatology. For the last several years Dr. Moy has worked with Dr. Baker on the applications and influences of high-frequency gravitational waves on biological matter especially on the muscles underlying the skin. They have jointly published peer-reviewed scientific papers on the subject.

Colby Harper

Telecommunications Specialist

Colby Harper graduated from the *University of Washington* with a BA with College Honors in Economics in 1993 and from 1996 to 1997 performed graduate studies *University of Washington Graduate School of Business Administration.* In 1993 he was the recipient of the Certificate in International Economics from the *University of Washington*. Between 1985 and 1990 Mr. Harper was in contract software development and network design and administration for companies including *Westinghouse Corporation*. He was involved in systems engineering at *Digital Communications Associates* in 1990-1991, was Senior Architect, Project Manager and Network Engineer at *Energy Northwest* from 1991 to 1995 and in late 1995 he served in the National Telecommunications and Information (NTIA) branch of the United States Department of Commerce and was a contributor to the Telecommunications Act of 1996. From 1996 to 2001 Harper was the National Director, Wireless Internet Service Provider & Technical Infrastructure at *Inteliant Corporation*, and in 2002 he joined *Washington Mutual* as a Product Manager involving, among other tasks, network systems and information handling. Harper is an IBM-Certified Client/Server Integration Specialist. In summary Mr. Harper is a hands-on wireless telecommunications executive having in-depth technology, operations, and process–improvement experience. In cooperation with Paul Murad he prepared a future concepts paper entitled: “Cost-based Global Optimization of Tomorrow’s High-Frequency Gravitational Wave (HFGW) Communications System: Value-added HFGW Device Requirements for Today,” and coauthored with Gary Stevenson a paper presented at the Space Technology and Applications International Forum (STAIF2007), sponsored by the American Institute of Physics, entitled “The

Value Estimation of an HFGW Frequency Time Standard for Telecommunications Network Optimization."

Buzz Aldrin, Sci. Dr.

Senior Scientific Advisor

Edwin "Buzz" Aldrin was educated at *West Point*, graduating with honors in 1951, and was third in his class. He earned a Doctorate in Astronautics from the *Massachusetts Institute of Technology* in Manned Space Rendezvous. On July 20, 1969, Buzz and Neil Armstrong made their historic Apollo XI moon walk, thus becoming the first two humans to set foot on another world. Since retiring from *NASA*, the *Air Force*, and his position as Commander of the Test Pilot School at Edwards Air Force Base, Dr. Aldrin has remained at the forefront of efforts to ensure a continued leading role for America in manned space exploration. He has been interested in High-Frequency Gravitational Waves since 1999 when he was briefed on the subject by Dr. Baker. Dr. Aldrin heads *Starcraft Boosters, Inc.,* Starcraft *Enterprises* and the *ShareSpace Foundation,* and is Chairman of the *National Space Society.* In 2011 he was awarded the Congressional Gold Medal, the United States highest civilian award. You are invited to visit: www.buzzaldrin.com.

Jerah D. Cameron

Senior Systems Engineer

Jerah Cameron attended the *University of Northern Colorado* and *CCU* and was awarded a Bachelors of Science degree in Computer Information Systems-Management in 2002. He has Certification as a *Microsoft Systems Engineer* (MCSE NT/2000/2003/2010), *Microsoft Professional Internet* (MCP+NT/2000/2001) and *Microsoft Office SharePoint Server* [SharePoint Server 2007 and 2010 (MCTS)]. He is designated as a Senior Systems Engineer, Solutions Architect & Web Design/Programmer. At *Raytheon*, from 2003 to 2005, Mr. Cameron was a Systems Administrator/ Integration Specialist (SSB!/Top Secret Clearance). At *IBM*, from 2005 to 2006, he was a Senior Systems Administrator and SharePoint Architect, At *Newsgator Technologies,* from 2006 to 2011; he was Solutions Architect/Senior Systems Engineer. Most recently, 2011, Mr. Cameron is Solutions Architect/Level V Senior Technical Consultant for Hewlett Packard. He provides the technical direction required to resolve complex issues to ensure the on-time delivery of solutions that meet customer expectations. He regularly leads large functional teams to include technical management of client staff assigned to the implementation team in the completion of one or more solution requirements, architecture or implementation deliverables. Mr. Cameron works with peers outside his immediate organization to define and characterize complex technology or process problems and/or develops new solutions, yet he works independently from others to drive technical problems to a solution.

Recently (2012), he has become very interested in theories and research in the area of high-frequency gravitational waves and its applications to Information Technologies (IT).

Peter Guernsey

Engineering Specialist

Peter Guernsey was born in Kansas City, Kansas, youngest of five children. His father was an executive in the aerospace reprographics industry. In 1967, the family moved to Southern California where Peter spent his grade school years. In high school he focused on shop classes, photography, auto mechanics, wood shop, metal shop, photo offset lithography, photography, astronomy, and horticulture. During his high school tenure Peter was introduced to optical coating. Learning basic principals of vacuum pumps and ultra high vacuum pumps, and the deposition of simple materials such as aluminum, gold, SIO, for the application of astronomical mirrors and optics for precision instruments such as mirrors for galvanometers for seismic measurements. In 1982, he founded Guernsey Coating Laboratories, Inc. (GCL) in Ventura, California, as CEO and President. For the past 27 years GCL has specialized in precision optical coatings for lasers, medical instruments and military applications. GCL is currently involved in the manufacture and deposition of ION beam assisted, ION beam sputtered; electron beam deposited, and thermally deposited films for the optical and industrial community. Mr. Guernsey is most interested in gravitational-wave detection and, in particular, in the highly absorbent material coating to minimize microwave noise in the Li-Baker detector.

His interest In Einstein's general theory of relativity has intrigued him since early child hood along with the grail of physic's, which is to combine particle and wave theory.

Robin Fell

International Business Specialist

Robin Fell received her Bachelor of Arts degree in Political Science at the *University of California at Berkley* in 1990, Certificate at the *American University in Paris* in 1989, and a MBA in International Business at *Loyola Marymount University*, Los Angeles in 1997. She was the Night Reporter at television station *KMIR* in Palm Springs, California in 1990, directed domestic video distribution at *Vidmark Pictures* 1992-1994, and Director of International Sales at *Rysher Entertainmen*t 1994-1998. Robin is an inventor (of "Drip Free"), an entrepreneur and an international marketing and manufacturing specialist. She has made numerous sales trips to Europe and Southeast Asia and is the Media Director for GravWave® LLC..

Thomas R. Lane

Scientific Advisor

Thomas R. Lane received his BS *cum laude* in Physics at the *United States Air Force Academy* in 1988. He completed Squadron Officer School in 1994 and graduated from Air Command and Staff College in 2002. From 2000 to 2004 he was Assistant Director of Operations and from 2004 to his retirement was Chief of Plans at the 28th Bomb Squadron in the *United States Air Force*. Lane is a B-1/T-37 Instructor Pilot and holds a Top Secret security clearance. In 2004 he assisted Dr. Baker in the preparation of the "Layperson's Description of High-Frequency Gravitational Waves (HFGWs)" and has been an active, although unofficial, contributor to HFGW research since that time. He and his wife Cathy live in Abilene, Texas. Currently Mr. Lane is a member of J9 Future Capabilities Division, Force Management Directorate, U.S. Special Operations Command.

Frederick W. Noble

Prototype Analyst

The co-inventor with Dr. Baker of the parent patented HFGW invention, Frederick W. Noble, was born in Oak Park, Illinois, May 1, 1939. He earned a bachelor's degree at *UCLA* with a major in English and a minor in Naval Science. In the *United States Navy* from 1961 to 1963 he served as a junior officer on a destroyer based in Japan. In 1966 he earned a Doctor of Law degree from the *UCLA School of Law* and is a Member of the California and Federal Bar. Mr. Noble was a practicing attorney from 1966 to 1978. From 1979 to the present he is President and CEO of Frederick W. Noble, Inc., a personal investment company. From 1982 to the present he is President and CEO of *Wintec Energy*, Inc. and its affiliates, which operate wind farms in Palm Springs, California and in the Altamont Pass area in Northern California. In July of 2001 he co-founded GRAVWAVE® LLC with Dr. Baker. Mr. Noble's *Wintec* corporation owns a one-thousand-acre property in Palm Springs, California, with some 600 wind turbines. The property has available several 10-acre to 40-acre flat, vacant sites for the construction of the prototype embodiments of the HFGW generator/detector in the US. Mr. Noble and *Wintec* can make available several civil and electrical engineers and construction personnel for HFGW prototype fabrication and test.

Bonnie Sue Baker

Scientific Investigator

Bonnie Sue Baker was born in Dunsmuir, California on August 17, 1942. She attended *Glendale City College* 1960-61, studied Physics at *San Jose State College* 1962, Certified Microsoft Office Specialists 2012. She was Technical Assistant *Lockheed Astrodynamics Research Center* 1962-1963 (where she first became interested in high-frequency gravitational waves or HFGWs), Technical Associate, *Planning Research Corporation* 1963-1965, Scientific Associate, *Astrophysics Research Corporation* 1965-1968, Scientific Investigator, *Online Data Processing* 1968-1980, Director of Special Scientific Projects, *West Coast University* 1981-1986 and Scientific Associate *Transportation Sciences Corporation* 1987 to date. Attendee of the first International HFGW Workshop at the *MITRE Corporation* in 2003, the second International HFGW Workshop in Austin Texas in 2007, the third International HFGW Workshop in Huntsville, Alabama in 2009 , the High-Frequency Gravitational Wave (HFGW) Symposium at the *Johns Hopkins University Applied Physics Laboratory* in 2010 and coauthor of a paper on HFGW Global Communications at the the 17th International Conference on Information Systems Analysis and Synthesis: ISAS 2011.in Orlando, Florida, 2011 .and coauthor of papers presented at the Space Technology Applications International Forum in 2012.. She is the co-inventor of two high-frequency gravitational wave United States Patents and coauthor of several high-frequency gravitational wave technical papers.

Christine Black

Scientific Associate

Christine Black graduated from *The University of Michigan* in 2009 majoring in Astronomy and Astrophysics with an interdisciplinary major in Physics. She has taken courses in EM Theory, Quantum Mechanics, Celestial Mechanics (Stars and Galaxies), Optics, Special Relativity and Astronomical Techniques. She has carried out research with at the University of Michigan involving variable stars in the nearby galaxy Carina and accomplished graduate research at the *University of Tasmania*. Ms Black was involved in research projects at the UCLA Astronomy Department in 2011. She is currently pursuing post-graduate studies in the Department of Physics and Astronomy at *Dartmouth College*. She has a keen interest in HFGW research and has been an assistant of Dr. Robert M L Baker, Jr. as a Project Scientist at *GravWave® LLC* since 2007 and presented a paper with him concerning high-frequency gravitational waves at the third HFGW Workshop in February, 2009 at Huntsville, Alabama..

Andrew Moe

Student Apprentice

Andrew Moe is an undergraduate student at *North Dakota State University*, with a major in Mechanical Engineering. Andrew takes an interest in some of the more obscure fields of science and is especially interested in the creation and application of HGFWs. He believes that they are going to become a key technology in the future. Andrew plans on testing the theories of the GravWave Team with the intention of engineering practical, and useful devices.

Jeff Schuss

Student Apprentice

Jeff Schuss is an undergraduate (2007) at *Loyola Marymount University*, with a hybrid major of Engineering Physics (EE/Physics). Besides having “gone the extra mile” in investigating many principles and theories that would have been otherwise briefly mentioned in a class, Mr. Schuss plans on taking classes in **pending**. He is fascinated by the work being done with HFGW and looks forward to broadening his horizons. He is also the grandson of Dr. Buzz Aldrin.

Maximilian Collins

Student Apprentice

Maximilian Collins (Max) is a 14 year old student in *Midlothian, Virginia*. He has loved science since the age of four months when he would stare fixatedly at the gears of the baby swing. He has been home schooled since the 6th grade and is currently enrolled in a nearby junior college. He will finish high school by the end of next year and plans to attend a four-year university in the fall of 2009. He first came across the subject of HFGWs in a scientific forum and began studying them. As a profession, he hopes to be a particle physicist, a research chemist, or a HFGW researcher.

IN MEMORIUM

One of the most important and intelligent members of the GRAVWAVE® Team has passed away. Bob Anderson was a Captain of Industry, perceived to be assertive, even gruff on the outside, but gentle, kind and generous on the inside – we will miss his business acumen and advice.

Robert Anderson
Senior Management Advisor

Robert Anderson was the Chairman of the Board, President, and CEO of *Rockwell*. He received his bachelor's degree in mechanical engineering from *Colorado State* University in 1943. He was a knowledgeable and aggressive business man who was an expert in defense and commercial applications of new technology. He has been referred to as "... the father of the B-1 Bomber." In fact, in 1977 he accepted the prestigious *Robert J. Collier* Trophy for Rockwell International's work on the B-1 bomber. Mr. Anderson was a Lifetime Trustee of the *California Institute of Technology* and was a Consulting member of the Caltech Board of Trustees Committee on the *Jet Propulsion Laboratory.*

INTERNATIONAL CORRESPONDING SCIENTIFIC ADVISORS

Giorgio Fontana, PhD

Senior Scientific Advisor, Italy

Giorgio Fontana was born in Trento, Italy on June 11, 1957. He received his doctorate with a specialization in electronics at the *University of Padua* in Italy. In 1984 Dr. Fontana became the Head of the Electronics Laboratory of the Department of Physics of the *University of Trento*. In 1995 he became the head of the computer center of the Faculty of Science (physics and mathematics) of the *University of Trento* and in 2000 he was advanced to the Head of the Electronics Laboratory of the Department of Information and Communication Technology at the *University of Trento*. Dr. Fontana has developed scientific instrumentation in the field of laser measurement and characterization of materials, ion transport and analysis, superconductors and related devices, cryogenic semiconductor electronics, optics, gravitational-wave Weber bar detectors and computer systems. Recently he has been involved in the development of technologies for atomic time transfer and synchronization, high speed data switching and fiber optic amplifiers and sensors. Dr. Fontana is interested in the development of new technologies for space travel with gravitational waves and is involved in the development of a suitable theoretical/engineering model for FTL travel through the Hyperspace. Currently he instructs in computer simulation and electronic circuit courses at the *University of Trento.* Dr. Fontana is a member of the *Istituto Nazionale di Fisica Nucleare (INFN).* He has authored well over a dozen scientific papers related to High-Frequency Gravitational Waves (HFGW) in internationally recognized technical journals. He participated in the first International HFGW Workshop at the MITRE Corporation in 2003, the second International HFGW Workshop at Austin, Texas in 2007 and the third at Huntsville, Alabama in 2009.

Gloria Garcia-Cuadrado

Scientific Advisor, Spain

Gloria Garcia-Cuadrado was born in Barcelona, Spain on January 14, 1974. She received a Master in Theoretical Physics (Research Proficiency) by the Physics Faculty of the *University of Barcelona*, SPAIN; in 2002 she was awarded a Diploma in Space Studies by the *International Space University; Polytechnical University of Pomona*; California; USA and in 2000 received a Bachelor in Physics by the University of Barcelona; SPAIN. Director of the Catalan Aerospace Cluster BAIE (*Barcelona Aeronautics & Space Association*), gathering up to 90 members devoted to Aerospace Research & Technology in Catalonia and Spain, including Universities and other Research Centres, Companies, Financing Institutions and Government (both at regional level in Catalonia and at national level, in Spain). The Area focuses also in identifying advanced concepts and technologies to pursue. Projects carried out so far include Space Tourism; Life Support Systems for Human Spaceflight and Gravitational Wave research. As Head of Communication main responsibilities include: representation of the Centre; science outreach; institutional and governmental relations; and media relations and networking. She received a grant by the *European Space Agency* (ESA) to design, implement and conduct an experiment in microgravity conditions on board an Airbus 300; and a joint grant from ESA and the Government of Catalonia - Generalitat de Catalunya - to attend the *International Space University* Course, ending in the attainment of the Diploma in Space Studies; California – USA. Ms. Garcia-Cuadrado has expressed a great interest in High-Frequency Gravitational Wave research and she has been previously involved with low frequency Gravitational

Wave projects such as LISA and LISA Pathfinder. She was a participant in the third International HFGW Workshop at Huntsville, Alabama in 2009.

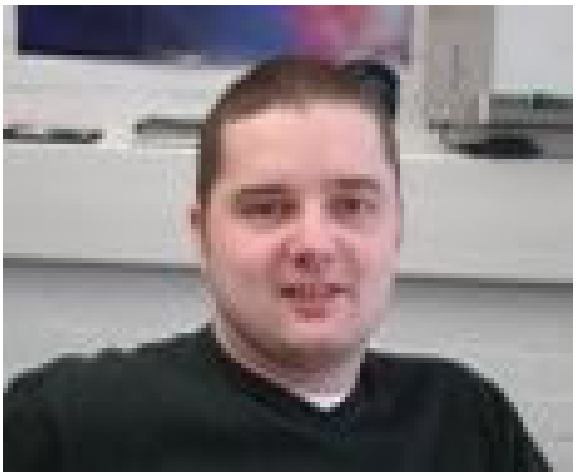
Christian Corda, PhD

Scientific Advisor, Italy

Christian Corda was born in Nuoro Italy on the March, 7, 1969. He obtained a Graduate Degree in Physics at the *Pisa University* in the 2001 and a specialist degree in Physical Sciences at the Pisa University in the 2003. He received his Ph.D in Physics at the Pisa University in 2003-2007, obtaining a research contract (Scientific Association) from the *Istituto Nazionale di Fisica Nucleare* (INFN) within the INFN-Pisa Section. Dr. Corda is a life member of the "Società Italiana della Relatività Generale e della Gravitazione" (SIGRAV). In 2007 Dr. Corda was the invited researcher at the *Albert Einstein Institute for Gravitational Physics*, in Hannover, Germany and invited Visiting Professor at the *Instituto de Cosmologia, Relatividade e Astrofisica* (ICRA-BR), Centro Brasilero de Pesquisas Fisicas, in Rio de Janeiro, Brazil. At the present time, Dr. Corda works within the Virgo Collaboration. He is Chairperson of the "Scientific Association Galileo Galilei", in Prato near Florence, Italy. He is also First Investigator of the Cosmology, Astrophysics and Gravitation Program of the *Centro di Scienze Naturali,* in Prato. Dr. Corda is author of more than 40 scientific publications in international journals in the fields of gravitation, gravitational-waves, astrophysics and cosmology. In 13 of these publications he is the sole author. Dr. Corda is also author of a number of scientific talks at various international conferences and/or workshops. At the end of the 2007, Dr. Corda became the world's most cited author in the *Official Astroparticle Publication Review* of ASPERA with 13 citations. ASPERA, the network of national government agencies responsible for coordinating and funding national research efforts in Astroparticle Physics. The Mayor and the city council of Nuoro will award Dr. Corda a solemn encomium in 2008 and also the nomination of world international ambassador for the city of Nuoro. Because of his recent research on the "magnetic" component of gravitational waves and on the stochastic background of relic gravitational

waves, Dr. Corda is strongly interested in the high-frequency gravitational waves.

Richard Ingley, PhD



Scientific Advisor, England

Richard Ingley received his Ph D in 2005 at *Birmingham University*, Birmingham, England. His thesis was entitled: “Implementation and Cross Correlation of Two High Frequency Gravitational Wave Detectors” and reports on his fabrication of the first High-Frequency Gravitational Wave (HFGW) detector. The detector was based upon the concept of Mike Cruise who found that in the presence of a gravitational wave, an electromagnetic wave will experience changes in its amplitude, frequency, direction of propagation and polarization. If an electromagnetic wave is confined to move in a circular path in the presence of a gravitational wave, then a resonant condition exists where the *polarization shift* is cumulative with successive passes of the path circumference and thus the HFGW can be detected. Dr. Ingley has published several peer-reviewed papers concerning HFGWs, presented papers at the Amaldi Conferences and was an invitee to the first International HFGW Workshop at the MITRE Corporation in 2003 and the second International HFGW Workshop at Austin, Texas in 2007. He is now associated with the Centre for Electronic Imaging School of Engineering and Design, *Brunel University*, Uxbridge Middlesex, England.

Fangyu Li, PhD

Senior Scientific Advisor, China

Fangyu Li was born on October 28, 1943. He was a student in the department of Physics at *Northwestern Normal University*, China from 1961 to 1965. From 1978 to 1990 he was a Lecturer. Associate Professor in the Department of Physics at *Chongqing University,* China and from 1990 to 1991 he was a visiting Scientist at the Gravitational Laboratory of the Sternberg State Astronomical Institute of the Moscow University in Russia. He was an Associate Professor, Department of Physics, *Chongqing University* from 1991 to 1994, was appointed Head of the Physics Department of *Chongqing University* from 1996 to 1998, and was appointed Dean of the college of Science at *Chongqing University* during the period 1998 to 2000. From 1994 to date, he has been a professor of Physics and Doctorate Tutor at the University. Now he is a member of the Council of the Chinese Physics Society, a member of the Council of the Chinese Gravitational and Relativity Astrophysical Society, a member of the World Laboratory, Chairman of *Chongqing Physics Society*, China and Head of the *Gravitational Physics Institute of Chongqing University*. His research fields include General Relativity and gravitation, classical and quantum electrodynamics in curved spacetime, theories of gravitational waves and gravitational radiation, positive definite problems of energy-momentum tensor of gravitational field, exact and approximate wave solutions of the Einstein field equations, gravitational perturbation effect in topological phonon space, interaction of gravitational waves with electromagnetic fields, and detection of high-frequency gravitational waves. Dr. Li has published more than sixty papers concerning gravitational waves in internationally recognized scientific journals and authored a paper at the first International HFGW Conference and

Workshop at The MITRE Corporation in 2003 participated in the second International HFGW Workshop at Austin, Texas in 2007.

Zhenyun Fang, PhD

Senior Scientific Advisor, China

Zhenyun Fang was born in Anhui China on May 4, 1945, graduate from Sichuan University in 1967 in Physics, received master's degree in Physics in 1982 at *Chongqing University (CQU)*. From 1983 to 1987 performed graduate studies at the *Unversite Catholique de Louvain (UCL)* in Belgium, and earned the PhD in Physics in 1987. From 1987 to 1990, was on the faculty of Department of Physics at Chongqing University (CQU) as an Associate Professor and Professor. From 1991, once as the Dean of the Graduate School, Assistant President of CQU. Currently, has been the Director of Institute of Theoretical Physics of CQU, Managing Director of *High Energy Society* of China, and has been interested in theoretical Physics, especially, in the research associate with the particle physics and related issues such as QED_QCD_SM (Standard Model) and beyond of electro-weak gauge-interaction, and high frequency gravitational-wave research, etc. for several decades. Dr. Fang participated in the second International HFGW Workshop at Austin, Texas in 2007.

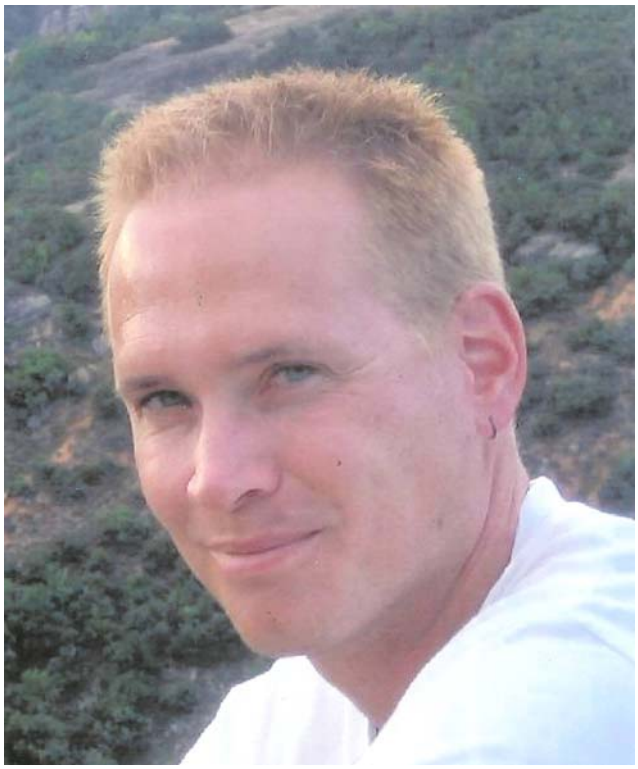
Ammar Sakaji, PhD

Senior Scientific Advisor, UAE

Ammar Sakaji was born in Jordan on August 28, 1967. Graduated from the *University of Jordan* with bachelor's degree in Physics in 1989 (first in his class), and Master Degree which was a research degree at that time in Theoretical Condensed Matter Physics in 1994 (first in his class), and finished the PhD course work and research on Theoretical Physics. He was a faculty member (lecturer and senior lecturer) in the physics department at *Zarqa Private University* and *Hashemite University* in Jordan, he came to UAE as a visiting professor at *Ajman University*, and then faculty member at Naval College. He is author or co-author of dozens of articles on Theoretical and Mathematical Physics, and editor or co-editor of several books and projects such as; "Majorana Legacy in Contemporary Physics," Di Renzo, Roma 2006, "Physics Of Emergence and Organization," World Scientific Publishing Company 2008, "Lev Davidovich Landau and his Impact on Contemporary Theoretical Physics" (Horizons in World Physics, Volume 264), Nova Science Publisher 2008, and "Quantum Field Theory," Springer 2009, and Quantum Information Science Project 2009. He also actively participated in several international conferences and workshops in the fields of Theoretical Physics, Quality Assurance in Higher Education, Intellectual Property, and E-Commerce and Legal Vacuum. He is the Editor in Chief of the *Electronic Journal of Theoretical Physics* (EJTP) www.ejtp.com, member of the *International Association of Mathematical Physics* (IAMP), member of the International Network for Quality Assurance Agencies in Higher Education (INQAAHE), referee of the *International Journal of Theoretical Physics*, he is a member of the *Planetary Society Berkeley*,

Jordan Physics Society, *American Institute of Physics*, and member of *Majorana Prize Committee* (Email: info@ejtp.com).

Harald Dimmelmeier, PhD



Senior Scientific Advisor, Germany

Harry Dimmelmeier was born in 1972 in Regensburg, Germany. He received his PhD in Physics from the Technical University Munich in 2001. He worked as a student at the Max Planck Institute for Gravitational Physics (Albert Einstein Institute) in Potsdam and as a post-doctoral scientist at the Max Planck Institute for Astrophysics in Garching. There he conducted research on numerical simulations of compact objects like stellar cores, neutron stars and black holes as astrophysical sources for gravitational waves. He received a Marie Curie fellowship from the EU to work at the Aristotle University in Thessaloniki on gravitational wave asteroseismology. He was also a part time technical editor for the free electronic scientific journal 'Living Reviews in Relativity'. He published many peer-reviewed papers on the numerical modeling of gravitational wave sources, participated in numerous international conferences on that subject, and closely collaborated with scientists working in data analysis for the large gravitational wave interferometer detectors. In 2002 he sponsored Dr. Baker's Lecture at the Max Planck Institute for Gravitational Physics (Albert Einstein Institute) in Potsdam. He recently moved to a position in industry and now works as a computational

engineer at AREVA NP in Erlangen in the field of safety analysis for nuclear power plants.

Kai Lin

Scientific Associate, China

Kai Lin was born in March, 1984 in P.R. China. In July 2006 he received a Bachelor of Science, in Physics at China West Normal University and in ·July 2009 he was awarded a Master of Science in Physics also at China West Normal University. Currently Mr. Lin is a doctorial student of Professor Li Fangyu and Professor Fang Zhenyun at the Institute of Theoretical Physics of Chongqing University and a visitor at Baylor University. His interests include: gravitational wave's theory and detection, cosmology, black hole thermodynamics, perturbations of black holes and computational physics. He has published in Physics Review D, Physics Letters B, Europhysics Letters, Modern Physics Letters A as well as other journals and is a member of the Chinese Physics Society.

CHAPTER

17 Gravitational Waves

Edmund Bertschinger & Edwin F. Taylor *

A modern physicist is a quantum theorist on Monday, Wednesday, and Friday, and a student of gravitational relativity theory on Tuesday, Thursday, and Saturday. On Sunday the physicist is neither, but is praying to his God that someone, preferably himself, will find the reconciliation between these two views.

—Norbert Wiener

I ask you to look both ways. For the road to a knowledge of the stars leads through the atom; and important knowledge of the atom has been reached through the stars."

—Arthur Eddington

1 INTRODUCTION

Gravity wave: a tidal force that propagates through spacetime.

General relativity differs from Newtonian gravity in several important ways. One way is in the behavior of light and matter in strong gravitational fields, especially near black holes. The black hole was predicted by Michell and Laplace on the basis of Newtonian gravity more than a century before Schwarzschild discovered his famous metric. However, the event horizon, singularity, and no-hair theorems are all consequences of general relativity that could not have been predicted from Newtonian physics.

Newton: Gravity propagates instantaneously.

Gravitational radiation is another phenomenon that has no counterpart in Newtonian physics. According to Newton, the gravitational interaction propagates instantaneously: When the Earth moves around the Sun, the Earth's gravitational field changes all at once throughout space, according to Newton.

Einstein: No signal propagates faster than light.

When Einstein formulated special relativity and recognized its requirement that no information can travel faster than the speed of light, he

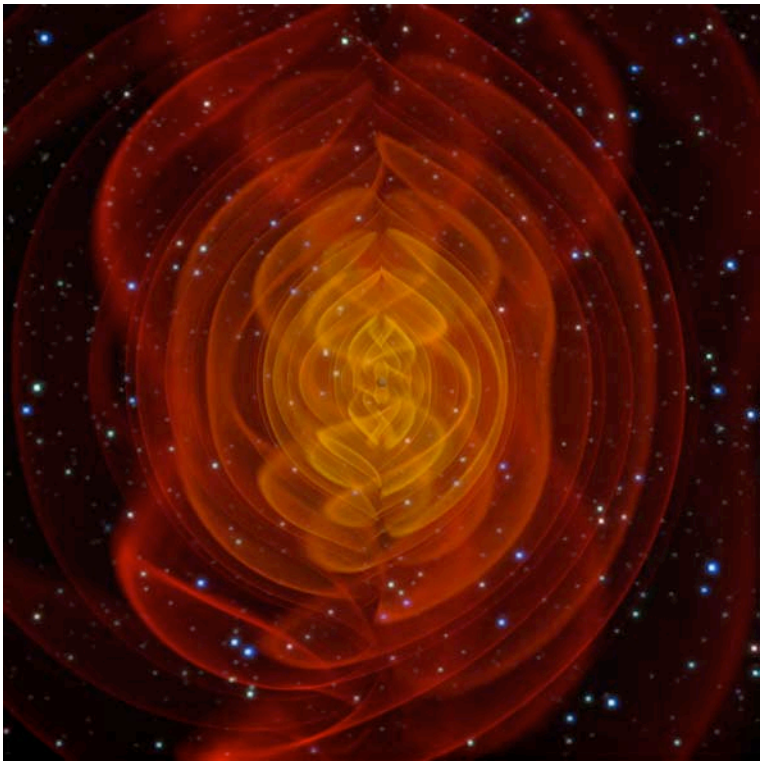

FIGURE 1 Computed emission of gravity waves. The tiny dot at the center of this image is two black holes churning spacetime as they combine into one. The swirling patterns represent distortions of spacetime that propagate outward as gravity waves. Close to the coalescing black holes, the gravity waves—essentially nothing but traveling tidal forces—are lethal. In contrast, we expect that gravity waves that could be detected on Earth are extremely small.

realized that Newtonian gravity would have to be modified. Not only would static gravitational fields differ from the Newtonian prediction in the vicinity of compact masses, but also time-varying fields would have to propagate. He showed that these fields would move with the speed of light, so gravity could not be used to send information faster than the speed of light, which would have destroyed the fundamental basis of all relativity.

Gravity waves like electromagnetic waves?

Einstein had a conceptual prototype for gravity waves: electromagnetic radiation. James Clerk Maxwell predicted electromagnetic radiation in 1873 and Heinrich Hertz demonstrated it experimentally in 1888. (Einstein was born in 1879.) When he grew up, Einstein quickly realized that a general relativity theory based on curved spacetime would not look like Maxwell's electromagnetic theory. After his theory was completed, Einstein and others were able to compute how gravitational fields propagate.

Gravity waves are essentially tidal forces that vary with time and position; that is all they are. As a gravity wave passes over you, you are alternately stretched and compressed in ways that depend on the particular form of the

wave. In principle there is no limit to the size of gravity waves. Figure 1 pictures the calculated result of two black holes emitting gravity waves as they combine into one. In the vicinity of the coalescence, gravity-wave-induced tidal forces would be dangerous to life.

We predict that gravity waves from various sources are continually sweeping over us on Earth's surface. Sections 3 and 7 describe some of these sources. Basically we hope to observe these waves by detecting changes in separation between two test masses suspended near to one another—changes in separation caused by the traveling tidal force that constitutes a gravity wave. We expect this change in separation to be *extremely* small for gravity waves detectable on Earth.

Gravity wave on Earth: An extremely small traveling tidal force.

Current gravity wave detectors on Earth are interferometers in which light is reflected back and forth between free test masses along two perpendicular directions, and the time difference measured between round-trip times in the two directions. The "free" test masses are hung from wires that are in turn supported with elaborate shock-absorbers so as to minimize the vibrations due to passing trucks and even waves crashing on a distant shore. But the back-and-forth pendulum-like motions of these test masses are free enough to permit measurement of their change in separation due to tidal effects resulting from a passing gravity wave, caused by some gigantic distant gravitational event, for example the coalescence of two black holes modeled in Figure 1.

Does the change in separation induced by gravity waves affect everything, for example a meter stick or the concrete slab on which a gravity wave detector rests? Answer: Only by an amount that is entirely negligible. The structure of meter sticks and concrete slabs is determined by electromagnetic forces mediated by quantum mechanics. The two ends of a meter stick are not freely-floating test masses. The tidal force of a passing gravity wave is much weaker than the internal forces that maintain the shape of solids. The meter stick—or the concrete slab underlying the vacuum chamber and detectors of a gravitational-wave observatory—is stiff enough to be negligibly affected by a passing gravity wave.

2. GRAVITY WAVE METRIC

Tiny but significant departure from the inertial metric

Our analysis uses a particular gravity wave: a certain kind of plane wave arriving from a very distant source and moving in the z-direction. This wave (and almost all of the gravity waves we discuss in this chapter) represents a very small perturbation of flat spacetime. Here is the timelike metric for such a particular wave that propagates along the z-axis.

Gravity wave metric

$$d\tau^2 = dt^2 - (1+h)dx^2 - (1-h)dy^2 - dz^2 \qquad (h \ll 1) \tag{1}$$

In this metric h is a dimensionless function of time and space. *Numerically, h is a fractional deviation from the flat-spacetime coefficient of dx^2 or dy^2 in the metric.* Another name for fractional deviation of length is **strain**, so h is also

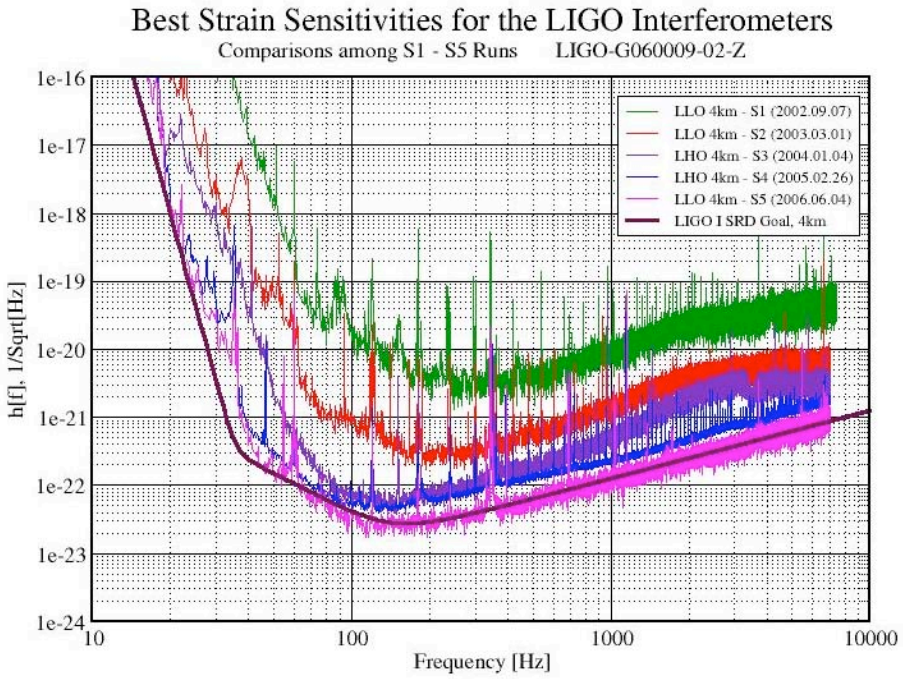

FIGURE 2 Progressive improvements in sensitivity of LIGO interferometers. On the vertical axis 1e-19, for example, means a fractional change in separation of 10^{-19} between test masses. The bottom solid line is the current goal. Spikes occur at frequencies of electrical or acoustical noise. To be detectable, gravity wave signals must cause greater displacement than what is represented by these noise curves. As of mid-2009, gravity wave signals have yet to be detected. FIND MOST RECENT UPDATE THAT SHOWS EVOLUTION OF SENSITIVITY: SCOTT HUGHES?

h = gravity wave strain

called the **gravity wave strain**. The wave leading to (1) is a transverse wave, since h describes a perturbation of space only in the x and y directions transverse to the z-direction of propagation. The strain h varies with both position and time. Its maximum value is very much less than one. Let two free test masses be at rest a distance D apart in the x or y direction. When a z-directed gravity wave passes over them, the change in their separation, called the **displacement**, equals hD, which follows directly from the definition of h as a "fractional deviation."

FOLLOWING IS NUMERICALLY INCONSISTENT. GET LATEST LIGO PARAMETERS AND SENSITIVITIES. One can use Einstein's field equations to make predictions about the magnitude of the function h in equation (1) for various kinds of astronomical phenomena. Currently, gravity wave detectors use laser interferometry and go by the full name **Laser Interferometer Gravitational Wave Observatory** or **LIGO** for short. The first-generation LIGO, called Initial LIGO, was able to detect waves with (approximately) $h > 10^{-19}$ for frequencies within a range of about 100 hertz.

LIGO gravity wave detector

(Abbreviation: Hz. Recall that one hertz is one cycle per second.) The second-generation LIGO, called Advanced LIGO, is about 10 times more sensitive; it is planned to be operational around 2014. Advanced LIGO can also be tuned in frequency to achieve higher sensitivity in frequency bands of interest.

LIGO sensitivity

Figure 2 compares the gradually-improving sensitivities of LIGO over time. The displacement sensitivity is expressed in the units of meter/$(\text{hertz})^{1/2}$ because the amount of noise limiting the measurement grows with the frequency range being sampled. Note that the instruments are designed to be most sensitive near 150 hertz. This frequency is determined by the different kinds of noise faced by experimenters: Quantum noise limits the sensitivity at high frequencies, while seismic noise is the largest problem at low frequencies. If the range of sampled frequencies—*bandwidth*—is 100 hertz, then the best sensitivity is about $10^{-22} \times 100^{1/2} = 10^{-21}$. This means that along a length of 4 kilometers $= 4 \times 10^3$ meters, the change in length is approximately $10^{-21} \times 4 \times 10^3 = 4 \times 10^{-18}$ meters, which is approximately one thousand times smaller than a proton, or a hundred million times smaller than a single atom!

Hold on! Your gravity wave detector sits on Earth's surface, but equation (1) says nothing about curved spacetime described, for example, by the Schwarzschild metric. The expression $2M/r$ measures departure from flatness in the Schwarzschild metric. At Earth's surface, $2M/r \approx 1.4 \times 10^{-9}$, which is 10^{13}—ten million million!—times greater than the corresponding gravity wave factor $h \sim 10^{-22}$. Why doesn't the quantity $2M/r$—which is much larger than h—appear in (1)?

First, the factor $2M/r$ is essentially constant over the size of LIGO, so we can ignore it. Second—and more important—the LIGO detector is "tuned" to detect a time-varying gravity wave of frequency near 150 hertz. LIGO is totally insensitive to the small *static* curvature introduced by the factor $2M/r$ at Earth's surface. For this reason, we simply omit static curvature factors from equation (1), effectively describing gravity waves "in free space" as well as for the predicted $h \ll 1$.

Einstein's equations become a wave equation.

In free space and for small values of h, Einstein's field equations actually reduce to a wave equation for h. For the most general case, this wave has the form $h = h(x, y, z, t)$. When x, y, z, and t are all in geometric units (for example meters), this wave equation takes the form:

$$\frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial y^2} + \frac{\partial^2 h}{\partial z^2} = \frac{\partial^2 h}{\partial t^2} \qquad \text{(free space and } h \ll 1\text{)} \tag{2}$$

For simplicity, think of a wave moving along the z-axis. The most general solution to the wave equation under these circumstances is

$$h = h_{+z}(z - t) + h_{-z}(z + t) \tag{3}$$

Assume gravity wave moves in $+z$ direction.

The expression $h_{+z}(z - t)$ means a function h of the variable $z - t$ and *not* some constant h *times* the quantity $(z - t)$. The function $h_{+z}(z - t)$ describes

a wave moving in the positive z-direction and the function $h_{-z}(z+t)$ describes a wave moving in the negative z-direction. In this chapter we deal only with a gravity wave propagating in the positive z-direction and hereafter use

$$h \equiv h(z-t) \equiv h_{+z}(z-t) \qquad \text{(wave moves in } +z \text{ direction)} \tag{4}$$

The argument $z-t$ means that h is a function of *only* the combined variable $z-t$. Indeed, h can be *any function whatsoever* of the variable $(z-t)$. The form of this variable tells us that, whatever the profile of the gravity wave at any given time; as time passes, that profile displaces itself in the positive z-direction with the speed of light (one in our units) .

LIGO sensitive 75 to 500 hertz

Figure 2 shows that the LIGO gravity wave detector has maximum sensitivity to gravity waves of frequencies between 75 and 500 hertz, with a peak sensitivity at around 150 hertz. Even at 500 hertz, the wavelength of the gravity wave is very much longer than the overall 4-kilometer dimensions of the LIGO detector. Therefore *we can assume in the following that at any given time the value of h is spatially uniform over the entire LIGO detector.*

QUERY 1. Uniform h?
Using numerical values, verify the claim in the preceding paragraph that h is effectively uniform over the LIGO detector.

Draw global map coordinates on rubber sheet.

It is important to understand the meaning of the coordinates in metric (1). These are global *map* coordinates; global coordinates are always fictions that we choose to reveal aspects of a spacetime we cannot visualize. For $h \neq 0$, these global coordinates are invariably distorted. Think of the three mutually perpendicular planes formed by pairs of space coordinates (x, y), (y, z), and (z, x). Draw a grid of lines on a rubber sheet lying in each corresponding plane. The gravity wave distorts the rubber sheet as it passes through it.

Glue map clocks to the intersections of these grid lines on the rubber sheet so that they move as the rubber sheet distorts. A gravitational wave moving in the $+z$ direction (Figure 5) passes through a rubber sheet lying in the xy plane, so that the grid ruled on the rubber sheet stretches and contracts in different directions within the plane of the sheet (Figures 3 and 4). The map clocks, glued at intersections of map coordinate grid lines, ride along with the grid as the sheet distorts,so that the map coordinates of any clock does not change.

Map time t read on clocks glued to the rubber sheet.

Think of two ticks on a single map clock. Between ticks the map coordinates of the clock do not change: $dx = dy = dz = 0$. Therefore metric (1) tells us that the wristwatch time $d\tau$ between two ticks is also map time dt between ticks. Therefore map time t corresponds to the time measured on the clocks glued to the rubber sheet, even when the strain h varies at their locations.

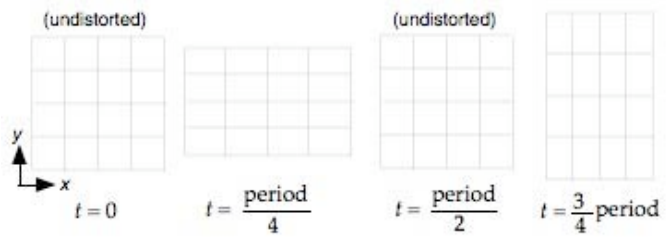

FIGURE 3 Change in shape (greatly exaggerated!) of the map coordinate grid at four times as a periodic wave passes through in the z-direction (perpendicular to the page). NOTE carefully!: The x-axis is stretched while the y-axis is compressed and vice versa. The areas of the panels remain the same.

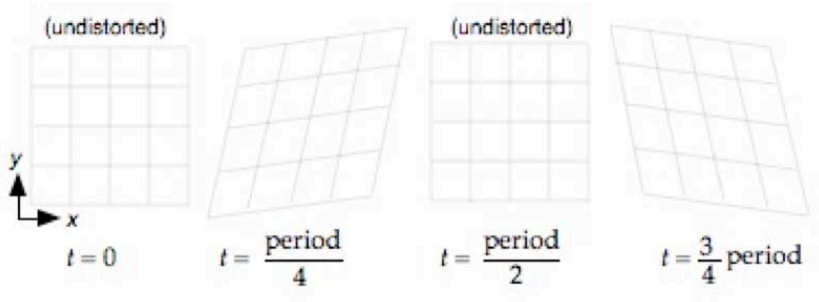

FIGURE 4 Effects of a periodic gravity wave with polarization "orthogonal" to that of Figure 3 on the map grid in the xy plane. Note that the axes of compression and expansion are at 45 degrees from the x and y axes. All grids stay in the xy plane as they distort. As in Figure 3, the areas of the panels are all the same.

Figure 3 represents the map time variation of the space distortion of the rubber sheet at a given location due to a particular polarization of the gravity wave. Although gravity waves are transverse like electromagnetic waves, the polarization forms of gravity waves are different from those of electromagnetic waves. Figure 4 shows the distortion caused by the wave "orthogonal" to that shown in Figure 3.

3 ■ SOURCES OF GRAVITY WAVES

Many sources; only one with clear prediction

Sources of gravity waves include collapsing stars, exploding stars, stars in orbit around one another, and the big bang. Neither electromagnetic waves nor gravity waves result from a spherically symmetric distribution of charge (for electromagnetic waves) or matter (for gravitational waves), even when that spherical distribution pulses symmetrically in and out. Therefore, *symmetric* collapses or explosions emit no waves, either electromagnetic or gravitational. The most efficient source of electromagnetic radiation is oscillating pairs of electric charges of opposite sign, the result technically called **dipole radiation**. But mass has only one "polarity;" there is no gravity dipole radiation from masses that oscillate back and forth along a line. Emission of gravity waves requires *asymmetric* movement or oscillation; the technical name for the simplest result is **quadrupole radiation**. Happily, most collapses and explosions are asymmetric; even the motion in a binary system is sufficiently asymmetric to emit gravitational waves.

We study here gravity waves emitted by a binary system consisting of two neutron stars—or a neutron star and a black hole—orbiting about one another (Section 6). All such pairs that we have detected are too far away to see directly; at least one neutron star needs to be a **pulsar** that emits a steady stream of pulses that we can receive at a great distance. Pulsars turn out to be extremely stable clocks. As the two objects orbit, they also emit gravity waves that cause the binary system to lose energy, so that the orbiting objects gradually spiral in toward one another. These orbits are fairly well described by Newtonian mechanics until about one millisecond before the two objects coalesce.

Binary system emits gravity waves . . .

Emitted gravity waves are nearly periodic during the Newtonian phase of orbital motion. As a result, these particular gravity waves are easy to predict and therefore easy to search for. When the two objects coalesce, they emit a burst of gravity waves (Figure 11). After coalescence the resulting structure vibrates ("rings down"), emitting more gravity waves as it settles into its final state as a black hole. Initial LIGO has already completed its efforts and would have been sensitive enough (Figure 2) to detect binary neutron star systems coalescing at a distance of about 26 million light years. Unfortunately, no such coalescences were detected during more than one year of observation. Advanced LIGO extends the detection radius to 200 Megaparsecs $\approx$ 650 million light years. The volume of space increases approximately as the cube of the distance, so the improved sensitivity will vastly increase the number of galaxies that can be "seen" by LIGO from about one thousand to millions, increasing the odds of success thousands of times.

. . . whose amplitude is predictable.

QUERY 2. Increased volume of detection

Use numerical values given in the preceding paragraph to calculate to two significant figures the increased "odds of success" of Advanced LIGO compared with Initial LIGO.

From other sources: hard to predict.

Binary coalescence is the only source for which we can currently make a clear prediction of the signal (and therefore of the detection distance limit). Other conceivable sources include supernovae and the collapse of a massive star to form a black hole—the event that triggers so called **gamma-ray bursts**. But we have only speculations about how far away any of these can be and still be detectable by either Initial LIGO or Advanced LIGO.

DETECTORS DO NOT AFFECT GRAVITY WAVES

We are used to the fact that metal structures can distort or reduce the amplitude of electromagnetic waves passing across them. Even the presence of a receiving antenna can distort an electromagnetic wave in its vicinity. The same is not true of gravity waves, whose generation or modification requires massive moving structures. Gravity wave detectors have negligible effect on the waves that they are designed to detect. Indeed, it is the smallness of the influence that gravity waves have on mechanical structures that makes gravity waves so difficult to detect.

QUERY 3. Electromagnetic waves *vs.* gravity waves. Discussion.
What property of electromagnetic waves makes their interaction with conductors so huge compared with the interaction of gravity waves with matter of any kind?

4 ■ MOTION OF LIGHT IN MAP COORDINATES

Light reflected back and forth between mirrored test masses.

The LIGO detector is an *interferometer* that employs mirrors mounted on "test masses" suspended at rest at the ends of an L-shaped vacuum cavity. The length of each leg of the L is 4 kilometers. Detection of the gravity wave is accomplished by measuring the relative round-trip *time delay* between light sent down one leg of the detector and light sent down the other, perpendicular leg.

LIGO is an interferometer.

Suppose that a gravity wave of the polarization illustrated in Figure 3 moves in the z-direction as shown in Figure 5 and that one leg of the detector lies along the x-direction and the other leg along the y-direction. In order to analyze the operation of LIGO, we need to know (a) how light propagates along the x and y legs of the interferometer and (b) how the test masses at the ends of the legs move when the z-directed gravity wave passes over them. In the present section we analyze the motion of light in map coordinates; Section 5 begins the description of the motion of test masses in map coordinates.

Motion of light in map coordinates.

With what map speed does light move in the x-direction in the presence of a gravity wave implied by metric (1)? To answer this question, set $dy = dz = 0$ in that equation, yielding

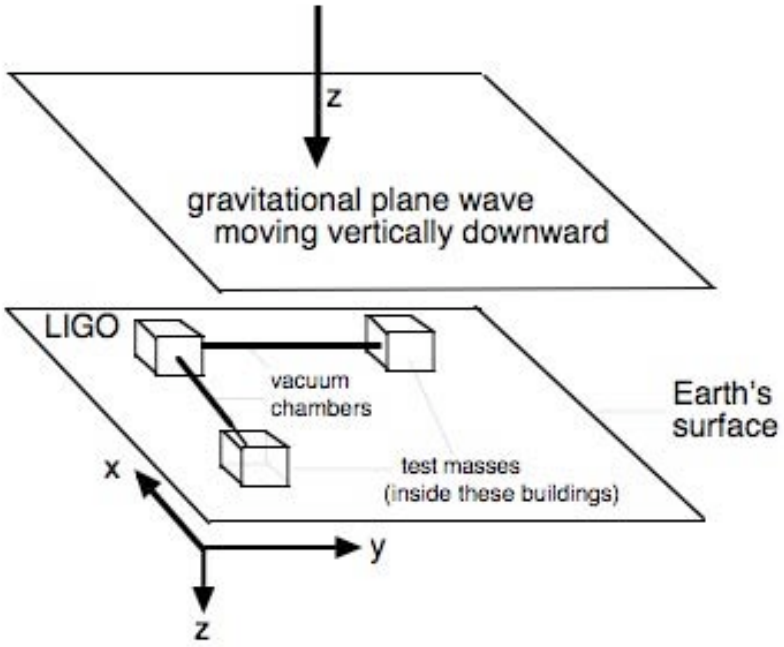

FIGURE 5 Perspective drawing of the relative orientation of legs of the LIGO interferometer lying in the x and y directions on the surface of Earth and the z-direction of the incident gravity wave descending vertically. [Illustrator: Rotate lower plate and contents CCW 90 degrees, so corner box is above the origin of the coordinate system. Same for Figure 10.]

$$d\tau^2 = dt^2 - (1+h)dx^2 \tag{5}$$

As always, the proper time is zero between two adjacent events on the worldline of a light pulse. Set $d\tau = 0$ to find the speed of light in the x-direction.

$$\frac{dx}{dt} = \pm(1+h)^{-1/2} \qquad \text{(light moving in } x \text{ direction)} \tag{6}$$

The plus and minus signs correspond to a pulse traveling in the positive or negative x-direction, respectively—that is, in the plane of LIGO in Figure 5. Remember that the magnitude of h is very much smaller than one, so we use the approximation inside the front cover. To first order:

$$(1+\epsilon)^n \approx 1 + n\epsilon \qquad |\epsilon| \ll 1 \text{ and } |n\epsilon| \ll 1 \tag{7}$$

Apply this approximation to (6) to obtain

$$\frac{dx}{dt} \approx \pm(1 - \frac{h}{2}) \qquad \text{(light moving in } x \text{ direction)} \tag{8}$$

Gravity wave modifies map speed of light.

In words, the map speed of light is changed (slightly!) by the presence of our gravity wave. Since h is a function of time as well as position, the map speed of light in the x-direction is not constant, but varies as the wave passes through. (Should we worry that the speed in (8) does not have the standard value one? No! This is a *map speed*—a mythical beast—measured directly by no one.)

By similar arguments, the map speeds of light in the y and z directions for the wave described by the metric (1) are:

$$\frac{dy}{dt} \approx \pm(1 + \frac{h}{2}) \qquad \text{(light moving in } y \text{ direction)} \tag{9}$$

$$\frac{dz}{dt} = \pm 1 \qquad \text{(light moving in } z \text{ direction)} \tag{10}$$

5 MOTION OF LIGO TEST MASSES IN MAP COORDINATES

"Obey the Principle of Maximal Aging!"

Consider two test masses with mirrors suspended at opposite ends of the x-leg of the detector. The signal of the interferometer due to the motion of light along this leg will be influenced only by the x-motion of the test masses due to the gravity wave. In this case the metric is the same as (5).

How does a test mass move as the gravity wave passes over it? As always, we answer this question with the Principle of Maximal Aging, maximizing the wristwatch time of the test mass across two adjoining segments of its worldline between fixed end-events. In what follows we verify the surprising result anticipated in Section 2 above, namely that a test mass initially at rest in map coordinates rides with the expanding and contracting map coordinates drawn on the distorting rubber sheet, so this test mass does not move with respect to map coordinates as a gravity wave passes over it. This result comes from showing that an out-and-back jog in the vertical worldline in map coordinates leads to smaller aging and therefore does not occur for a free test mass

Figure 6 pictures this idealized case: an incremental linear deviation from a vertical worldline from origin 0 to the event at $t = 2t_0$. Along Segment A the displacement x increases linearly with time: $x = v_0 t$, where the speed v_0 is a constant. Along segment B the displacement returns to zero at the same constant rate. The strain h has average values $\bar{h}_{\rm A}$ and $\bar{h}_{\rm B}$ along segments A and B respectively. We use the Principle of Maximal Aging to find the value of the speed v_0 that maximizes the wristwatch time along this worldline. We will find that $v_0 = 0$. In other words, the free test mass initially at rest in map coordinates stays at rest in map coordinates; it does not deviate from the vertical worldline in Figure 6. Now for the details.

Idealized case: Linear jogs out and back.

Write the metric (5) in approximate form for one of the segments:

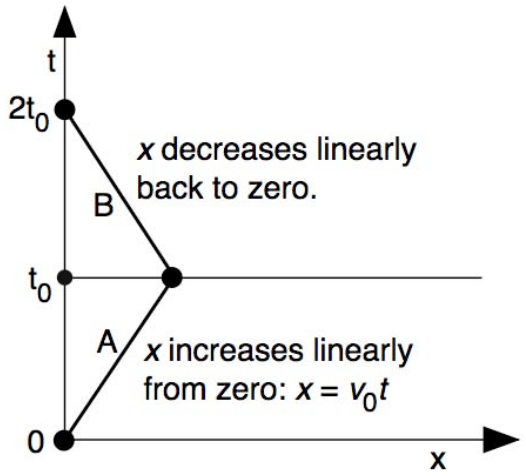

FIGURE 6 Trial worldline for a test mass; incremental departure from vertical line of a particle at rest. Segments A and B are very short.

$$\Delta\tau^2 \approx \Delta t^2 - (1+\bar{h})\Delta x^2 \tag{11}$$

where $\bar{h}$ is an average value of the strain h across that segment. Now we apply (11) first to Segment A in Figure 6, then to Segment B. We are going to take derivatives of these expressions, which will look awkward applied to Δ symbols. Therefore we temporarily ignore the Δ symbols in (12) and let τ stand for $\Delta\tau$, t for Δt, and x for Δx, holding in mind that these symbols actually represent increments, so equations in which they appear are approximations.
With these substitutions, equation (11) becomes, for the two adjoining worldline segments:

$$\tau_{\mathrm{A}} \approx \left[t_0^2 - \left(1+\bar{h}_{\mathrm{A}}\right)\left(v_0 t_0\right)^2\right]^{1/2} \qquad \text{Segment A} \tag{12}$$

$$\tau_{\mathrm{B}} \approx \left[t_0^2 - \left(1+\bar{h}_{\mathrm{B}}\right)\left(v_0 t_0\right)^2\right]^{1/2} \qquad \text{Segment B}$$

so that the total wristwatch time along the bent worldline from $t = 0$ to $t = 2t_0$ is the sum of the right sides of equations (12).

We want to know what value of v_0 (the out-and-back speed of the test mass) will lead to a maximal value of the total wristwatch time. To find this, take the derivative with respect to v_0 of the sum of individual proper times and set the result equal to zero.

$$\frac{d\tau_{\mathrm{A}}}{dv_0} + \frac{d\tau_{\mathrm{B}}}{dv_0} \approx -\frac{(1+\bar{h}_{\mathrm{A}})v_0 t_0^2}{\tau_{\mathrm{A}}} - \frac{(1+\bar{h}_{\mathrm{B}})v_0 t_0^2}{\tau_{\mathrm{B}}} = 0 \tag{13}$$

Initially at rest in map coordinates? Then stays at rest in map coordinates.

In middle expression of (13), all quantities are fixed except for v_0. The only way that (13) can be satisfied is if $v_0 = 0$. *The test mass initially at rest does not change its map x-coordinate as the gravity wave passes over.*

Our result seems rather specialized in two senses: First, it treats only the vertical worldline traced out by a test mass at rest. Second, it deals only with a very short segment of the worldline, along which $\bar{h}$ is considered to be nearly constant. Concerning the second point, you can think of (13) as a tiny out-and-back "jog" *anywhere* on a much longer vertical worldline. Then our result implies that *any* jog in the vertical worldline does not lead to an increased value of the wristwatch time, even if h varies a lot over a longer stretch of the worldline.

The first specialization, the vertical worldline, is important: The gravity wave does not cause a kink in a *vertical* map worldline. The same is typically *not* true for a particle that is moving in map coordinates before the gravity wave arrives. (We say "typically" because the kink may not appear for some directions of motion of the test mass and for some polarization forms and directions of propagation of the gravity wave.) In this more general case, a kink in the worldline corresponds to a change of velocity. In other words, a passing gravity wave can change the map velocity of a moving particle just as if it were a velocity-dependent force. If the particle velocity is zero, then the force is zero: a particle at rest in map coordinates remains at rest.

Not at rest in map coordinates? Maybe kink in map worldline.

QUERY 4. Disproof of relativity? (optional)
"AHA!" declares Kristin Burgess. "Now I can disprove relativity once and for all. If the test mass *moves*, a passing gravity wave can cause a kink in the worldline of the test mass as observed in the local inertial Earth frame. No kink appears in its worldline if the test mass is at rest. But if a worldline has a kink in it as observed in one inertial frame, it will have a kink in it as observed in all overlapping relatively-moving inertial frames. An observer in any such frame can detect this kink. So the *absence* of a kink tells me *and every other inertial observer* that the test mass is 'at rest'? We have found a way to determine absolute rest using a local experiment. Goodbye relativity!" Is Kristin right? (A detailed answer is beyond the scope of this book, but you can use some relevant generalizations drawn from what we already know to think about this paradox. As an analogy from flat-spacetime electromagnetism, think of a charged particle at rest in a purely magnetic field: The particle experiences no magnetic force. In contrast, when the same charged particle moves in the same frame, it may experience a magnetic force for some directions of motion.)

In this book we make every measurement in a local inertial frame, not using differences in global map coordinates. So of what possible use is our result that a particle at rest in global coordinates does not move in those coordinates when a gravity wave passes over it? Answer: Just because something is at rest in map coordinates does not mean that it is at rest in local inertial Earth coordinates. In the following section we find that a gravity wave *does* move a test mass as observed in the Earth coordinates. LIGO—attached to the Earth—can detect gravity waves!

At rest in map coordinates? Still can move in Earth coordinates.

6 ■ DETECTION OF A GRAVITY WAVE BY LIGO

Make measurement in the local Earth frame.

Suppose that the gravity wave that satisfies metric (1) passes over the LIGO detector oriented as in Figure 5. We know how the test masses at the two ends of the legs of the detector respond to the gravity wave: they remain at rest in map coordinates (Section 5). We know how light propagates along both legs: as the gravity wave passes through, the map speed of light varies slightly from the value one, as given by equations (8) through (10) in Section 4.

Earth frame tied to LIGO slab

The trouble with map coordinates is that they are arbitrary and need not correspond to what an observer measures. Recall that we require all measurements to take place in a local inertial frame. So think of a local reference frame anchored to the concrete slab on which LIGO rests. As explained in the Introduction (Section 1), the gravity wave has essentially no effect on this slab. Call the coordinates in the resulting local coordinate system **Earth coordinates**. Earth coordinates are analogous to shell coordinates for the Schwarzschild black hole; useful only locally but yielding the numbers that predict results of measurements. The metric for the local inertial frame then has the form:

$$\Delta\tau^2 \approx \Delta t^2_{\rm Earth} - \Delta x^2_{\rm Earth} - \Delta y^2_{\rm Earth} - \Delta z^2_{\rm Earth} \tag{14}$$

Compare this with the approximate version of (1):

$$\Delta\tau^2 \approx \Delta t^2 - (1+h)\Delta x^2 - (1-h)\Delta y^2 - \Delta z^2 \qquad (h \ll 1) \tag{15}$$

Legalistically, in order to make the coefficients in (15) constants we should use the symbol $\bar{h}$, with a bar over the h, to indicate the average value of the gravity wave amplitude over the detector. However, in Query 1 you showed that for the frequencies at which LIGO is sensitive, the wavelength is very much greater than the dimensions of the detector, so the amplitude h of the gravity wave is effectively uniform across the LIGO detector. Therefore it is not necessary to take an average, and we use the symbol h without a superscript bar.

Earth frame coordinate differences

Comparing (14) with (15) yields:

$$\begin{aligned}
\Delta t_{\rm Earth} &= \Delta t \\
\Delta x_{\rm Earth} &= (1+h)^{1/2}\Delta x \approx (1+\frac{h}{2})\Delta x \qquad h \ll 1 \\
\Delta y_{\rm Earth} &= (1-h)^{1/2}\Delta y \approx (1-\frac{h}{2})\Delta y \qquad h \ll 1 \\
\Delta z_{\rm Earth} &= \Delta z
\end{aligned} \tag{16}$$

where we use approximation (7). Notice, first, that Earth time lapse $\Delta t_{\rm Earth}$ between two events is identical to their map time lapse Δt and the z component of their space separation in Earth coordinates, $\Delta z_{\rm Earth}$, is identical to the z component of their separation in map coordinates, Δz.

Now for the differences! Let Δx be the map x-coordinate separation between the pair of mirrors in the x-leg of the LIGO interferometer and Δy be the map separation between the corresponding pair of mirrors in the y-leg. As the z-directed wave passes through the LIGO detector, the test masses at rest at the ends of the legs stay at rest in map coordinates, as Section 5 showed.

Test masses move in Earth coordinates.

Therefore the value of Δx remains the same during this passage, as does the value of Δy. But the presence of the time-varying strain $h(t)$ in (16) tells us that these test masses move when observed in Earth coordinates. More: when the distance between test masses increases (say) along the Earth x-axis, it decreases along the perpendicular Earth y-axis; and vice versa. Perfect for detection of a gravity wave by an interferometer!

Light speed = 1 in Earth frame.

Earth metric (14) is that of an inertial frame in which the speed of light has the value one in whatever direction it moves. With light we have the opposite weirdness to that of the motion of test masses initially at rest: In map coordinates light moves at speeds different from one in the presence of this gravity wave—equations (8) through (10)—but in Earth coordinates light moves with speed one. This is reminiscent of the corresponding case near a Schwarzschild black hole: Light moves at speeds different from one in Schwarzschild map coordinates but at speed one in shell coordinates.

In summary the situation is this: As the gravity wave passes over the LIGO detector, the speed of light propagating down the two legs of the

Different Earth times along different legs

detector has the usual value one as measured by the Earth observer. However, for the Earth observer the separations between the test masses along the x-leg and the y-leg change: one increases while the other decreases, as given by equations (16). The result is a difference in the round-trip times of light along the two legs. It is this difference that LIGO is designed to measure and thereby to detect the gravity wave.

What will be the value of this difference in round-trip times between light propagation along the two legs? Let D be the length of each leg in the absence of the gravity wave. The round-trip time is twice this length divided by the speed of light, which has the value one in Earth coordinates. From equations (16) we find that the difference in round-trip times between light propagated along the two legs is

$$\Delta t_{\text{Earth}} = 2D\left(\frac{h}{2} + \frac{h}{2}\right) = 2Dh \qquad \text{(one round trip of light)} \tag{17}$$

Time difference after N round trips.

Using the latest interferometer techniques, LIGO reflects the light back and forth down each leg approximately $N = 140$ times. That is, light executes approximately 140 round trips, which multiplies the detected time shift, increasing the sensitivity of the detector by the same factor. Equation (17) becomes

$$\Delta t_{\text{Earth}} = 2NDh \qquad (N \text{ round trips of light}) \tag{18}$$

Quantities N and h have no units, so the unit of time in (18) is the same as the unit of D, for example meters.

QUERY 5. LIGO fast enough?
Do the 140 round trips of light take place in a time small compared with one period of the gravity wave being detected? (If it does not, then LIGO detection is not fast enough to track the change in gravity strain.)

QUERY 6. Application to LIGO.
Each leg of the LIGO interferometer is of length $D = 4$ kilometers. Assume that the laser emits light of wavelength 1000 nanometer $= 10^{-6}$ meter (infrared light from a NdYAG laser). Suppose that we want LIGO to reach a sensitivity of $h = 10^{-22}$. For $N = 140$, find the corresponding value of Δt_{Earth}. Express your answer as a decimal fraction of the period T of the laser light used in the experiment. (For background see `http://www.ligo.caltech.edu/LIGO_web/about/`)

QUERY 7. Faster derivation?
In this book we insist that global map coordinates are arbitrary human choices, so that we cannot depend on map coordinate differences to be directly measurable quantities. However, the value of h in (1) is so small that the metric differs only slightly from an inertial metric. This once, therefore, we treat map coordinates as directly measurable and ask you to redo the derivation of equations (17) and (18) using only map coordinates.

Remember that test masses initially at rest in map coordinates do not change their coordinates as the gravity wave passes over them (Section 4), but the gravity wave alters the map speeds of light, and differently in the x-direction, equation (8), than in the y-direction, equation (9). Assume that each leg of the interferometer has the length D_{map} in map coordinates.

A. Find an expression for the difference Δt in map time between the two legs for one round trip of the light.

B, How great do you expect the difference to be between times Δt and Δt_{Earth} and the difference between distances D (in Earth coordinates) and D_{map}? Taken together, will these differences be great enough so that the result of your prediction and that of equation (18) could be distinguished experimentally?

QUERY 8. Different directions of propagation of the gravity wave
Thus far we have assumed that the gravitational plane wave of the polarization described by equation (1) descends vertically onto the LIGO detector, as shown in Figure 5. Of course the observers cannot prearrange in what direction an incident gravity wave will move. Suppose that the wave described by (1) propagates along the direction of, say, the y-leg of the interferometer, while the x-direction lies along the other leg, as before. What is the equation that replaces (18) in this case?

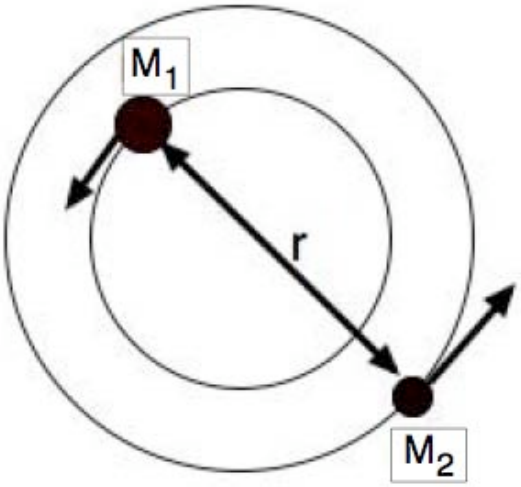

FIGURE 7 A binary system with each object in a circular path.

QUERY 9. LIGO fails to detect a gravity wave?
Think of various directions of propagation of the gravity wave pictured in Figure 3, together with different directions of x and y in equation (1) with respect to the LIGO detector. Give the name **orientation** to a given set of directions x and y—the transverse directions in (1)—plus z (the direction of propagation) in (1) relative to the LIGO detector. How many orientations are there for which LIGO will detect *no signal whatever*, even when its sensitivity is 10 times better than that needed to detect the wave arriving in the orientation shown in Figure 5? Are there zero such orientations? one? two? three? some other number less than 10? an infinite number?

7 ■ BINARY SYSTEM AS A SOURCE OF GRAVITY WAVES

Proof of the existence of gravity waves?

Unequal masses, each in circular orbit.

Now we consider in more detail gravity waves generated by a binary system consisting of two neutron stars, each in circular orbit around their center of mass. The binary system is the only known example of a stellar system for which we can explicitly calculate the emitted gravity waves. Suppose that the stars of the binary system have masses M_1 and M_2 and are assumed to orbit at a constant distance r apart, as shown in Figure 7.

Energy of the system.

The basic parameters of the orbit are adequately computed using Newtonian mechanics, according to which the energy of the system in conventional units is given by the expression:

$$E_{\rm conv} = -\frac{GM_{1,\rm kg}M_{2,\rm kg}}{2r} \qquad \text{(Newton)} \tag{19}$$

Rate of energy loss . . .

As these neutron stars orbit, they generate gravity waves. General relativity predicts the rate at which the orbital energy is lost to this radiation. In conventional units, this rate is:

$$\frac{dE_{\rm conv}}{dt_{\rm conv}} = -\frac{32G^4}{5c^5r^5}\left(M_{1,\rm kg}M_{2,\rm kg}\right)^2\left(M_{1,\rm kg}+M_{2,\rm kg}\right) \qquad \text{(Newtonian circular orbits)} \tag{20}$$

. . . derived from Einstein's equations.

Equation (20) assumes that the two stars are separated by much more than their Schwarzschild radii and that they are moving at nonrelativistic speeds. Deriving equation (20) involves a lengthy and difficult calculation starting from Einstein's field equations. The same is true of the derivation of the metric (1) for a gravity wave. These are two of only three equations in this chapter that we simply quote from a more advanced treatment of general relativity.

QUERY 10. Energy and rate of energy loss in geometric units

Convert equations (19) and (20) to geometric units to be consistent with our notation and to get rid of the constants G and c. Use the sloppy professional shortcut, "Let $G = c = 1$."

A. Show that (19) and (20) become:

$$E = -\frac{M_1M_2}{2r} \qquad \text{(Newton: geometric units, } E \text{ in units of length)} \tag{21}$$

$$\frac{dE}{dt} = -\frac{32}{5r^5}\left(M_1M_2\right)^2\left(M_1+M_2\right) \qquad \text{(geometric units, } E \text{ in units of length)} \tag{22}$$

B. Verify that in both of these equations E has the unit of length.

C. Suppose you are given the value of E in meters. Show how you would convert this value first to kilograms and then to joules.

QUERY 11. Rate of change of radius

Derive an expression for the rate at which the radius changes as a result of this energy loss. Show that the result is:

$$\frac{dr}{dt} = -\frac{64}{5r^3}M_1M_2\left(M_1+M_2\right) \qquad \text{(Newton: circular orbits)} \tag{23}$$

---

8 BINARY PULSAR PSR1913+16

Proof of gravity waves?

Hulse and Taylor discover binary.

On July 2, 1974 Russell A. Hulse was carrying out observations at the world's largest radio telescope at Arecibo, Puerto Rico. Hulse—a graduate student working under the direction of Joseph H. Taylor, then at the University of Massachusetts, Amherst—detected signals from a pulsar later named PSR1913+16. (PSR stands for "pulsar" and the numbers denote its celestial coordinates.) Here is an account of the discovery, excerpted from the Nobel Foundation website (which also has wonderful illustrations)
`http://www.nobel.se/physics/laureates/1993/illpres/discovery.html`
(Copyright ©2001 The Nobel Foundation)

> **THE DISCOVERY OF THE BINARY PULSAR**
> During 1974 Joseph Taylor and Russell Hulse were searching for new pulsars with the Arecibo telescope. They discovered 40, one of which was to be very important.
>
> When Hulse was observing the new pulsar, which has been named PSR1913+16, he found that the pulses arrived sometimes more often and sometimes less. The simplest interpretation was that the pulsar was orbiting another star very closely and at high velocity: Here one "pulsar year" is only about eight hours.
>
> By observing the shift in the pulses, Hulse and Taylor found that the stars were equally heavy, each weighing about 1.4 times as much as the Sun. Since they were not visible on any photographs either, it was concluded that the other body, somewhat unexpectedly, was also a neutron star. Seen from Earth, however, it does not show up as a pulsar.
> . . . .
>
> **MEASURING gravity waves**
> Since the two neutron stars in PSR1913+16 are moving so fast and close together they should, according to General Relativity, emit large amounts of gravity waves. This makes them lose energy: Their orbits will therefore shrink and their orbiting period will shorten.
>
> **Indirect evidence:** The binary pulsar has been observed continuously since its discovery, and the orbiting period has in fact decreased. Agreement with the prediction of General Relativity is better than 1/2%. This is considered to prove that gravity waves really exists. In turn, this result is currently one of our strongest supports for the validity of the General Theory of Relativity.

Data from binary pulsar

The signal from the pulsar constituted a very stable clock, stable to 10 significant figures. As a result, Hulse and Taylor were able to use general relativity to analyze the motion of the system in detail, verifying many general relativity predictions, some of which allowed them to determine the individual orbiting masses M_1 and M_2 (given below), which Newtonian mechanics does

not reveal. Their results show that the binary system PSR1913+16 has the following parameters:

$$
\begin{aligned}
M_1 &= (1.442 \pm 0.003) M_{\text{Sun}} && \text{(pulsar)} \\
M_2 &= (1.386 \pm 0.003) M_{\text{Sun}} && \text{(companion)} \\
a &= 2.3418 \pm 0.0001 \quad \text{light seconds} && \text{(Semi-major axis of both)} \\
e &= 0.617127 \pm 0.000003 && \text{(Eccentricity of both)}
\end{aligned}
\tag{24}
$$

Orbital period, ≈ 7.75 hours

Rate of advance of the periastron ≈ 4.2 degrees per Earth-year

Distance from Earth ≈ 7 kiloparsecs or about 20 000 light years. (This distance is quite uncertain.)

Each neutron star follows its own elliptical path about the center of mass. The semi-major axis of the elliptical orbit for a neutron star—label it a—is half of the major axis, the longest distance from one side of its orbit to the other. The semi-minor axis—label it b—is half of the minor axis. Then the eccentricity $e \equiv (a^2 - b^2)^{1/2}/a$. The word **periastron** refers to the point of closest approach of these "astron"omical objects (just as the word *perihelion* refers to the point of closest approach of an orbiting object to our Sun: Greek, "Helios"). Note how large the rate of this periastron advance is compared with 43 arcseconds of advance of the perihelion of the planet Mercury *per Earth-century*.

Meaning of *periastron*.

The non-zero eccentricity in equation (24) tells us that the neutron stars in PSR1913+16 are *not* in circular orbits. General relativity predicts that when a binary system has non-circular orbits it will radiate gravity waves at a greater rate than when the orbits are circular. Nevertheless, in the following QUERIES we assume for simplicity that the orbits are effectively circular, as in Figure 7. That is, we assume a binary system in which each companion is in a circular orbit with constant radial separation r equal to the major axis, twice the value of the semi-major axis given in (24). This is equivalent to setting to zero the eccentricity of each neutron star orbit.

We assume circular orbits.

QUERY 12. Shrinkage of r per orbit

For a single orbit, the separation r between the orbiting neutron stars (assumed to be in circular orbits) does not change much, but it does change a little. For one orbit, what is the approximate value of the change in this separation r? Express your answer in millimeters. (*Hint:* No integration is needed for an approximate calculation of this incremental change.)

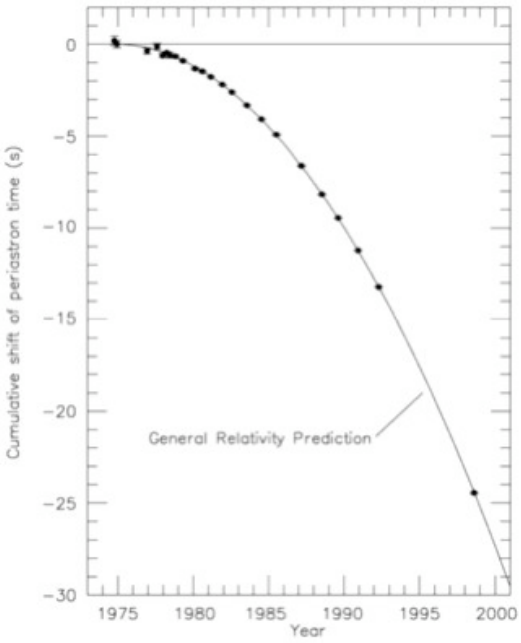

FIGURE 8 Decrease in the period in seconds (vertical axis) over the years 1975 to 1998 (horizontal axis) of binary system PSR1913+16. Agreement with the prediction of general relativity, assuming the change is due to emission of gravity waves, is now within 0.3 percent. This agreement appears to eliminate any other possible explanation for the change in orbits. From a paper (and Copyright ©2000) by J.H. Taylor and J. M. Weisberg.

QUERY 13. Energy radiated by idealized binary PSR1913+16

A. What is the power currently being radiated in gravity waves? Express your answer as a unitless measure (energy in meters divided by time in meters) and also in watts (joules per second).

B. Use equation (19) or (21) to calculate how much total energy in joules will be radiated in gravity waves from the present year to the future time when the two companions are separated by $r = 20$ kilometers (approximately the sum of their radii)? This total energy corresponds to how many kilograms of mass converted entirely to energy?

C. How long a time in years will it be before the two neutrons stars in PSR1913+16 are separated by only $r = 20$ kilometers, so that coalescence is imminent? (Only in the last millisecond or so before coalescence does the Newtonian description become completely useless.)

ADD QUERY ABOUT RADIATION RATE OF SUN-MERCURY BINARY SYSTEM AND LENGTH OF TIME TO COALESCE DUE TO GRAV RADIATION.

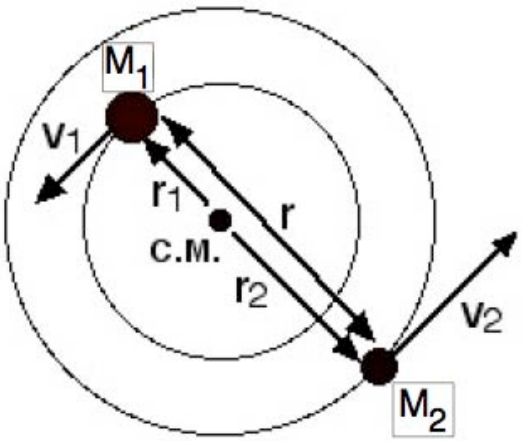

FIGURE 9 Figure 7 augmented to show the center of mass and orbit radii of individual components of PSR1913+16.

9 ■ GRAVITY WAVE AT EARTH DUE TO DISTANT BINARY SYSTEM

How far away from a binary system can we detect gravity waves?

Can LIGO on Earth's surface detect the gravity waves emitted by the distant binary system PSR1913+16 (idealized as one in which the neutron stars move in circular orbits as shown in Figure 7)? To answer this question we need to calculate the magnitude of h in the metric of equation (1).

Gravity waveform . . .

Here is the third and final result of general relativity quoted without proof in this chapter. The function $h(z,t)$ is given by the equation (in conventional units)

$$h(z,t) = -\frac{4G^2 M_1 M_2}{c^4 r z} \cos\left[\frac{2\pi f(z-ct)}{c}\right] \qquad \text{(conventional units)} \quad (25)$$

where f is the frequency of the binary orbit, r is the (constant!) distance between orbiters in Figures 7 and 9, and z is the distance from source to detector. Convert (25) to geometric units by setting $G = c = 1$. Note that $h(z,t)$ is a function of z and t.

Figure 10 schematically displays the notation of equation (25), along with relative orientations and relative magnitudes assumed in the equation. This equation makes the Newtonian assumptions that (a) the two stars are separated by a distance r much larger than their Schwarzschild radii and (b) they move at nonrelativistic speeds. Additional assumptions are:

(c) The distance z between the binary system and Earth is very much greater than a wavelength of the gravity wave. This assumption assures that the radiation at Earth constitutes the so-called "far radiation field" where it assumes the form of a plane wave given in equation (4).

(d) The binary stars are orbiting in the xy plane, so that from Earth the orbits would appear as circles if we could see them (which we cannot, because

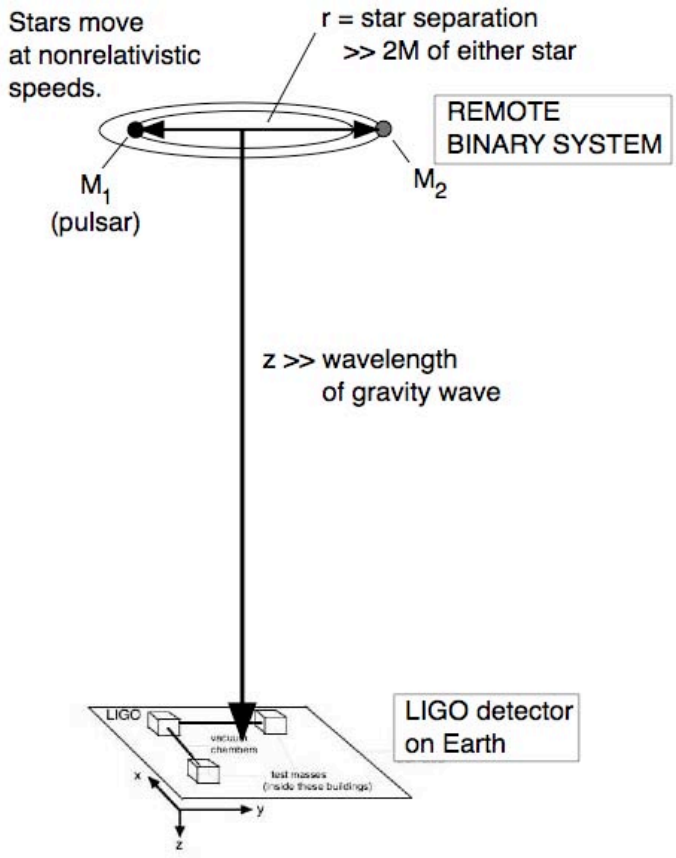

FIGURE 10 Schematic diagram, *not to scale*, showing notation and relative magnitudes for equation (25). The binary system and the LIGO detector lie in parallel planes.[Illustrator: See note in caption to Figure 5.]

they are too far away). Unfortunately this assumption is not true of the plane of the orbit of binary PSR1913+16, as we know from Doppler shifts of signals from the orbiting pulsar.

. . . for one case

Equation (25) describes only one linear polarization at Earth, the one generated by metric (1) and shown in Figure 3. The orthogonal polarization shown in Figure 4 is also transverse and equally strong, with components proportional to $(1 \pm h)$. The formula for the magnitude of h in that orthogonally polarized wave is identical to (25) with a sine function replacing the cosine function. We have not displayed the metric for that orthogonal polarization.

Detection requirements

In order for LIGO to detect a gravity wave, two conditions must be met: (a) the amplitude h of the gravity wave must be sufficiently large, and (b) the frequency of the wave must be in the range in which LIGO is most sensitive

(100 to 400 hertz). QUERY 13 deals with the amplitude of the wave. The frequency of gravity waves, discussed in QUERY 14, contains a surprise.

QUERY 14. Amplitude of gravity wave from PSR1913+16 at Earth

A. Use (25) to calculate the maximum amplitude of h at Earth due to the radiation from the "idealized circular-orbit" binary system PSR1913+16. Consider this amplitude to be positive.

B. Can either Initial LIGO or Advanced LIGO detect the gravity waves whose amplitude is given in part A?

C. What is the maximum amplitude of h at Earth just before coalescence of PSR1913+16, when the neutron stars are separated by a distance $r = 20$ kilometers (but with orbits still described approximately by Newtonian mechanics)?

QUERY 15. Frequency of gravity waves emitted from PSR1913+16

A. In order for either Initial LIGO or Advanced LIGO to detect the gravity waves whose amplitude is given in Query 13, the frequency of the gravity wave must be in the range 100 to 400 hertz. In Figure 9 the point C. M. is the stationary center of mass of the pulsar system. Using the symbols in Figure 9, fill in the steps to complete the following derivation.

$$\frac{v_1^2}{r_1} = \frac{GM_1}{r_1^2} \qquad \text{(for } M_1\text{, Newton, conventional units)} \tag{26}$$

$$\frac{v_2^2}{r_1} = \frac{GM_2}{r_2^2} \qquad \text{(for } M_2\text{, Newton, conventional units)} \tag{27}$$

$$M_1 r_1 = M_2 r_2 \qquad \text{(center-of-mass condition)} \tag{28}$$

$$f_{\text{orbit}} \equiv \frac{1}{T_{\text{orbit}}} = \frac{v_1}{2\pi r_1} = \frac{v_2}{2\pi r_2} \qquad \text{(common orbital frequency)} \tag{29}$$

where f_{orbit} and T_{orbit} are the frequency and period of the orbit, respectively. From these equations, show that for $r \equiv r_1 + r_2$ the frequency of the orbit is

$$f_{\text{orbit}} = \frac{1}{2\pi}\left[\frac{G\left(M_1 + M_2\right)}{r^3}\right]^{1/2} \tag{30}$$

B. Here is a surprise: The frequency f of the gravity wave generated by this binary pair and appearing in (25) is twice the orbital frequency.

$$f_{\text{gravity wave}} = 2 f_{\text{orbit}} \tag{31}$$

Why this doubling? Essentially it is because gravity waves are waves of tides. Just as there are two high tides and two low tides per day caused by the moon's gravity acting on the Earth, there are two peaks and two troughs of gravity waves generated per binary orbit.

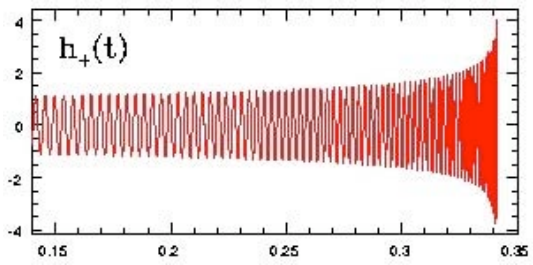

FIGURE 11
The "chirp" of one polarization of gravity wave as the two components of a binary system coalesce. (The plot for the other polarization is indistinguishable from this one.)

C. Approximate the average of the component masses in (24) by the value $M = 1.4M_{\rm Sun}$. Find the distance r between the binary stars when the orbital frequency is 75 hertz, so that the frequency of the gravity wave is 150 hertz. [ANS: Approximately 100 km.]

D. Using results quoted earlier in this chapter, estimate the time for the binary system to decay from the current radial separation to the radial separation calculated in part C.
ANS: $t_2 - t_1 = 5(r_2^4 - r_1^4)/(256M^3)$, everything in unit meter.

"Chirp" at coalescence

Newtonian mechanics predicts the motion of the binary system surprisingly accurately until the two components touch, a few milliseconds before they coalescence. As this happens, the gravity wave sweeps upward in both frequency and amplitude in what is called a **chirp**. Figure 11 is a predicted wave form for such a chirp.

To hear an audio simulation of the chirp, visit one of the following websites:
`http://www.lsc-group.phys.uwm.edu/~patrick/work/talks/itp/chirp.002.au`
`http://www.lsc-group.phys.uwm.edu/~patrick/work/talks/itp/chirp.002.wav`

Detection of such a waveform sweeping through the frequencies for which LIGO is sensitive would be a "smoking gun" for the coalescence of a binary source. Although LIGO cannot detect emission from PSR1913+16, we expect that many other binary systems are close to provide a detectable signal for Advanced LIGO.

It took Engineer and Scientist Maurice Cotterell just 6-weeks to discover how electricity and magnetism work together to produce the force of Gravity, and 3 years to find a way of explaining it. Gravity, along with 11 other 'great mysteries of Physics', is explained in his book *FUTURESCIENCE—forbidden science of the 21st-century*. The third Hardback edition is now available, exclusively, from www.MauriceCotterell.com

How Gravity Works

Abstract

How Gravity Works-a Unified field theory

This *explanation of the gravitational mechanism* provides a causal mechanism that reconciles physical phenomena with Newton's equation for the force of Gravity. It shows how electricity and magnetism work together to produce the force of Gravity and in so doing represents the first Unified Field Theory. It explains the reason why the gravitational force is proportional to the masses of the attracting bodies and why the force decreases in accordance with a square law scale. The Gravitational Constant is defined. The reason why objects accelerate to Earth in accordance with a square law scale is explained. The architecture of the atom is explained—the reason why electrons orbit the atom in up to 8 shells/sub-shells; why the shells contain the number of electrons that they do; and why the shells are offset by at least 45°, are all explained.

Conclusion; The hydrogen atom [and helium atom] generate *helically polarised electromagnetic radiation* (gravity radiation) from polar regions that bombards neighbouring atoms drawing them towards the source of the radiation. Gravity radiation then causes the nucleus of the neighbouring atom to spin axially (the 'motor effect') and, at the same time, synchronises the spin of the electrons in both atoms. The neighbouring atom then, in turn, generates helically polarised electromagnetic energy (the 'generator effect'). Both atoms spin axially in the same direction. Hence, the gravitational forces from both atoms pull in the same direction and the forces are additive. The gravitational Constant G is shown to be the instantaneous alternating magnetic force between any two electron-magnets in neighbouring atoms and, hence, the gravitational force F is proportional to G x m1 x M2 (where m1 and M2 represent the electron count of neighbouring atoms).

electricity gravity and magnetism

three sides of the same coin

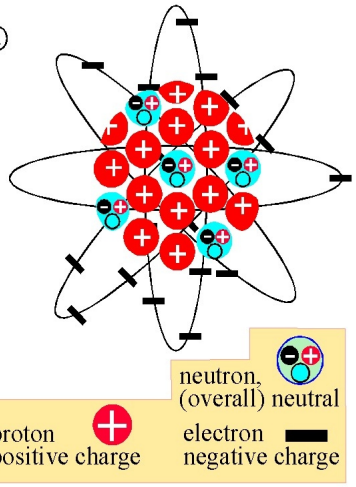
How Gravity Works

Orthodox Science does not understand the force that causes atoms to attract each other—because they do not understand the nature of the force, or the nature of the atom.

The accepted Model of the Atom

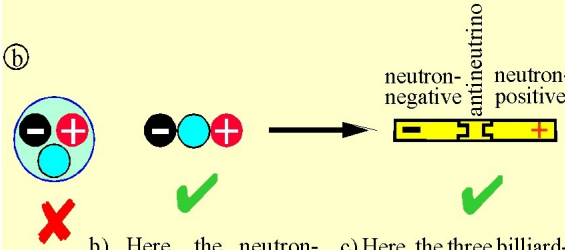
The accepted model of the atom (*right*) recognises that complex atoms are made of electric positive charges, protons (shown in red), electric negative charges (black), and neutrons (blue). The neutrons have no overall electrical charge but are known to be made of ½ of a proton, ½ of an electron and a neutral particle named the antineutrino. But this model *cannot* be correct because it raises three crucial questions; 1. Why—given that positive repels positive—do the positive charges simply not just spring apart? 2. Given that positive attracts negative, what stops the orbiting negative charges from being sucked-in to the positive charges in the nucleus? and, 3. What stops the ½ proton and the ½ electron inside the neutron from being drawn together and annihilating each other?

ⓐ



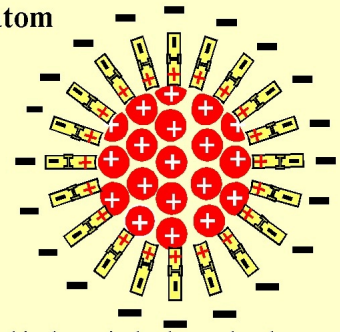
So what makes the complex atom stable (!)?—the new atom

ⓑ



b) Here, the neutron-negative particle is shown separated from the neutron-positive particle by the neutron-neutral particle (the antineutrino) using the billiard-ball-style convention.

c) Here, the three billiard-ball-style particles have been replaced with a tiny positive battery-like symbol and a tiny negative battery-like symbol that are kept apart by the neutral anti-neutrino. This new representation will from now on, herein, be referred to as the 'spiked-neutron'.



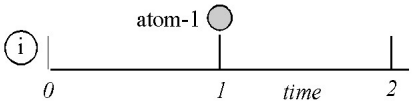
d) In this theoretical scheme the electrons and protons are kept apart by the spiked-neutrons. The positive pole of each spiked-neutron is embedded in the mass of protons contained in the nucleus. The neutron-positive poles push against the positive protons preventing them from springing apart. The neutron-negative poles repel the electrons preventing them from getting closer to the nucleus. The spiked-neutrons act like springs, forcing-out the electrons and forcing-in the protons.

Supporting evidence: Researchers, at the Hahn-Meitner Institute, Berlin, announced that 'neutrons behave like compass needles' (Science Daily, 31.3.2008)

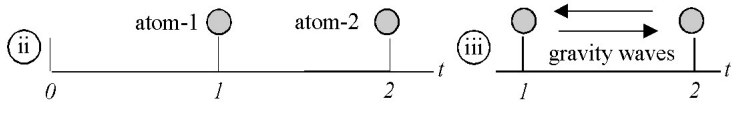
What's the nature of the force?

Isaac Newton defined Gravity as 'the force between 2 bodies' [atoms]—although he never understood what caused it, how it worked, or where it came from. c) However, when we recognise that the Universe began with just 1 atom, it becomes clear that *the force of gravity must travel*. This means that each atom must give-off some form of energy. The only energy known to travel through space is electromagnetic energy, radio waves.

ⓒ Before the creation of the Universe, at time zero, no physical atoms existed. Then, a moment later, at time interval *1*, the first atom, atom number 1, must have appeared.



i) At *time-1* gravity could not exist because only 1 atom exists, and Newtonian gravity is the force between 'two' atoms.



ii) At *time-2* atom-2 appears and gravity exists. Thus, a gravitational force must *travel* from atom-1 to atom-2, and from atom-2 to atom-1, between time intervals *1* and *2*. iii) This means that gravity must *travel* to establish itself between the atoms.

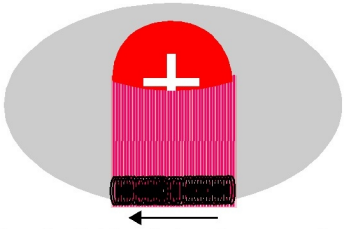
figure 1.

But how could an atom give off radio waves?

In 1831, Michael Faraday demonstrated that when a coil is swiped through a magnetic field, an electric field [a voltage] is produced across the coil. The corollary is also true; whenever a coil is swiped through an electric field [a voltage] a magnetic field is produced [induced] into the coil. In order to make the atom stable, it was firstly necessary to change the shape of the neutron. In order to enable a gravitational mechanism, we must now change the shape of the electron—into a coil-shape.

ⓐ

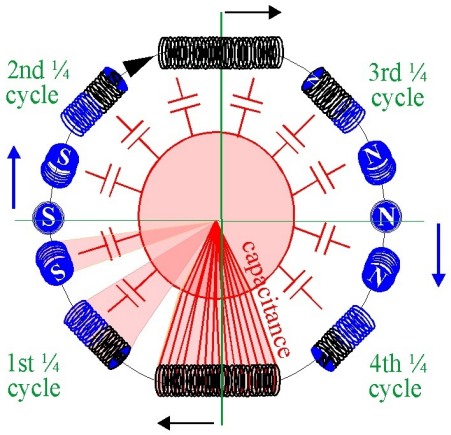
here, hydrogen, the simplest of atoms, is used to explain the principles involved



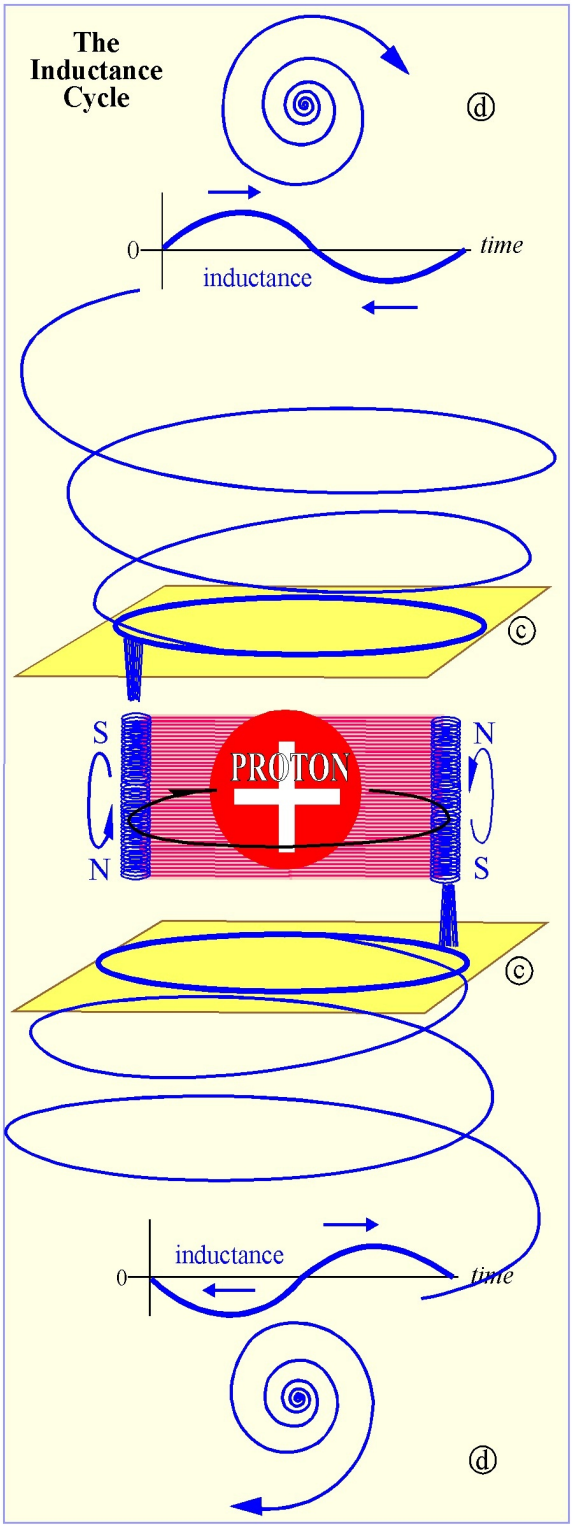
hydrogen atom

a) An electric field subsists between the orbiting negative electron and the positive proton. The amount of electric field contained in the space between the particles is known as its 'Capacitance'.

ⓑ



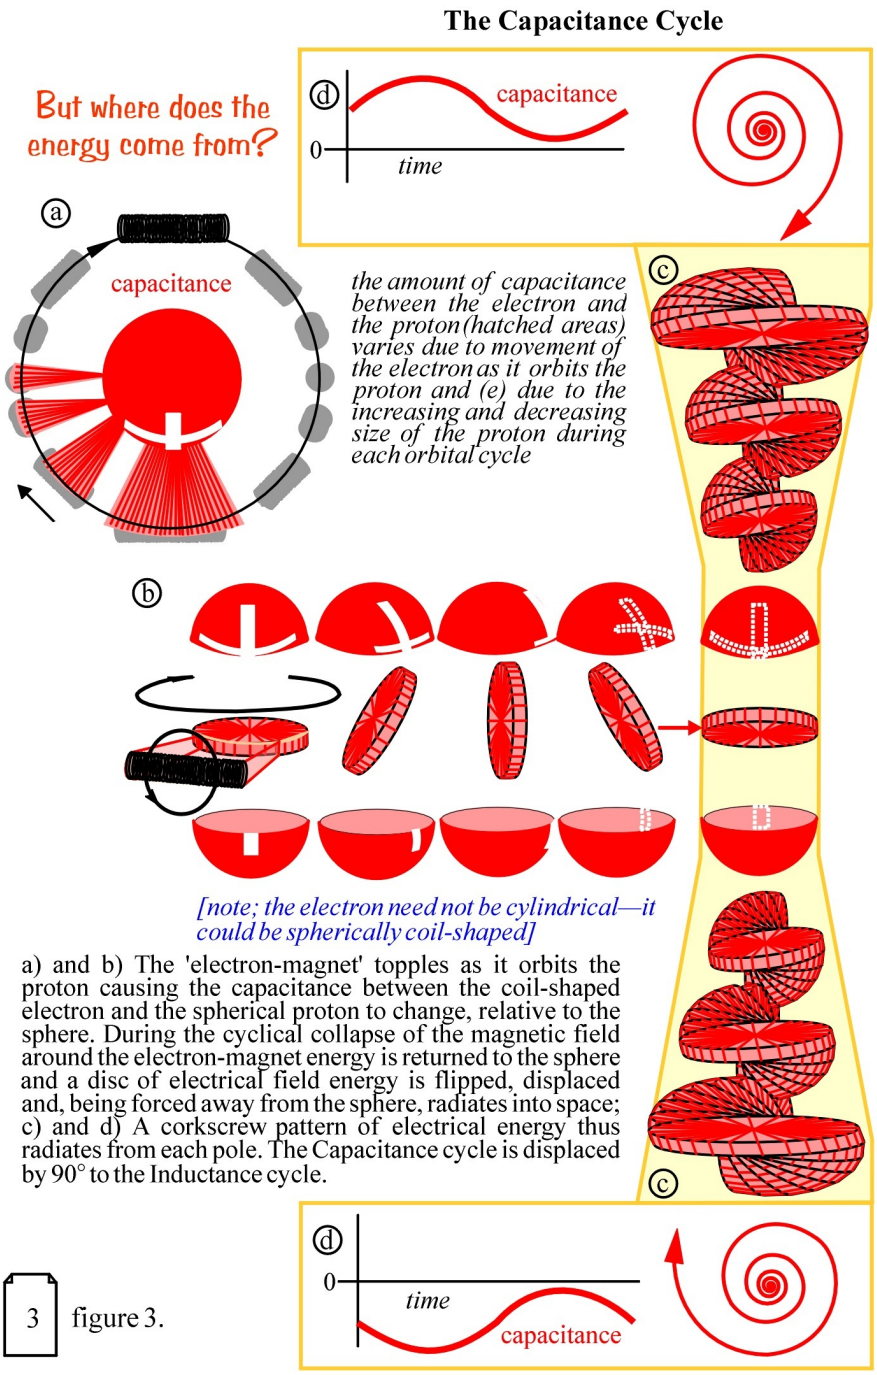
b) As the electron slices through the electric field, a magnetic field is induced into the electron. Because an electric field and an associated magnetic field are always displaced by 90°, the induced magnetic field parries against the associated electric field causing the elevation of the electron to twist to a more vertical position. Once the electron becomes vertical the coils of the electron no longer slice through the electric field. But the electron continues to spin through its own inertia and as it twists to a more horizontal elevation it once again begins to slice through the electric field. More magnetism is again induced into the electron during the second quarter cycle—at the same time as the magnetic field uploaded during the first quarter cycle begins to collapse. The magnetic field around the electron [although it should now be referred to as an 'electron-magnet'] is thus pushed-out into space; it 'radiates' into space. The electron-magnet changes direction as it slices through the electric field during quadrants 3 and 4, thus the associated magnetic field around the electron-magnet reverses, relative to the first and second quarter cycles.



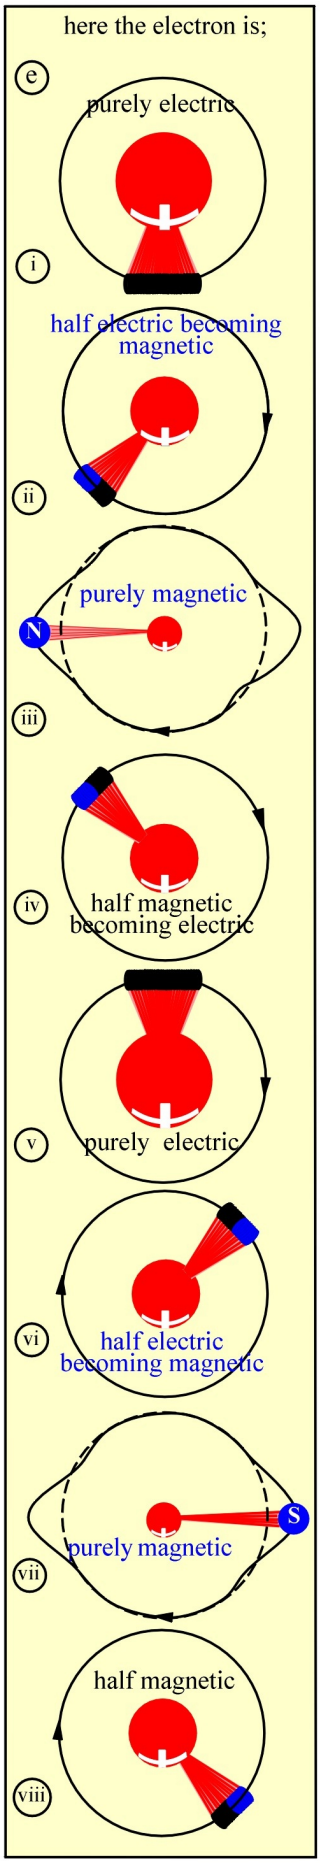
The electromagnetic interaction between the particles causes the electron-magnet to spin once [through 360°] like the opposing blades of a windmill, during each orbit of the proton. c) and d) It can be seen that the electron-magnet radiates helically polarised (corkscrew-style) magnetic energy from the equatorial region to the polar regions. c) Radiation from the northern sector is displaced by 180° from radiation from the southern sector.

figure 2.

The Capacitance Cycle



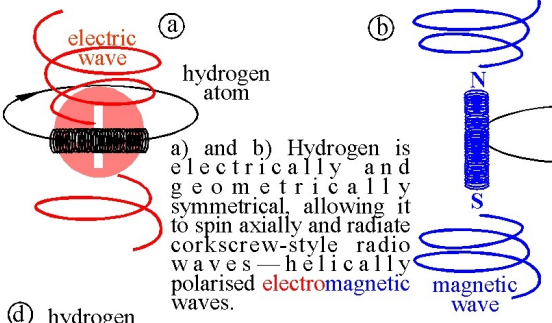
3 figure 3.



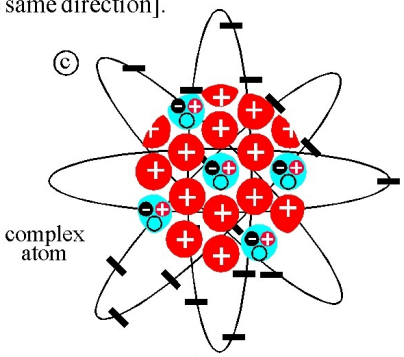
e) As the electron-magnet sucks-in energy from the proton the proton rapidly compresses (shrinks) and cools, as the induced magnetism rises in the electron-magnet. When the electron-magnet becomes vertical and stops sucking-in energy, the proton stops compressing. As soon as that happens the super-cold miniature proton sucks-in ambient heat (above –273.15° C) causing the proton to heat-up and expand rapidly. The surface area of the proton thus gets larger and smaller as the electron-magnet orbits the proton, so the amount of electric field (capacitance) between the particles must vary in a cyclical way [because Capacitance is proportional to the surface area between the particles]. Below –273.15° C the electron cannot access sources of heat to sustain electromagnetic oscillation and the electron, starved of input energy, ceases to orbit the proton. Oscillations cease. The atom ceases radiating corkscrew-style electromagnetic energy and the atom ceases to attract other atoms. e(i) to e(viii). Whenever the electron absorbs energy, it drains the electric field of some energy and the tension between the two particles diminishes, allowing the electron to increase the size of its orbit. Whenever energy is returned, the renewed stronger field pulls the electron back to a position inside the original orbit, momentarily, before returning to its original orbit, e(iii) and e(vii).

How do corkscrew-style electromagnetic radio-waves affect other atoms?

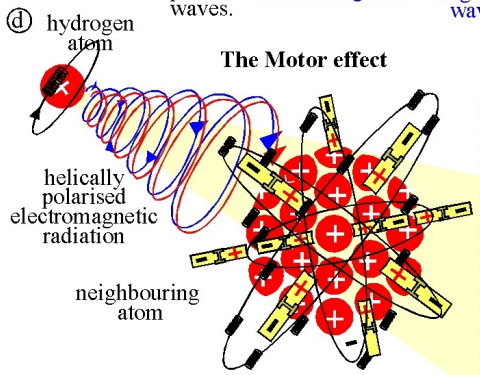
Gravity requires that every atom attracts every other atom in every different direction—and 93% of atoms in the Universe are hydrogen atoms. Hence, for a gravitational mechanism to be enabled by corkscrew-style radiating waves three conditions must be met: 1. All hydrogen atoms throughout the Universe must be randomly orientated. 2. Corkscrew-style radio-waves from a hydrogen atom must *not* interfere with corkscrew-style radio-waves from other hydrogen atoms, and 3. If corkscrew-style radio-waves from the hydrogen atom are the prime-mover in the gravitational mechanism then other [non-hydrogen] atoms *must* be affected [in some way *switched-on*] by the corkscrew-style radio waves from the hydrogen atom [in order to satisfy Newton's observations that bodies in alignment, like the Sun and Moon pull in the same direction].



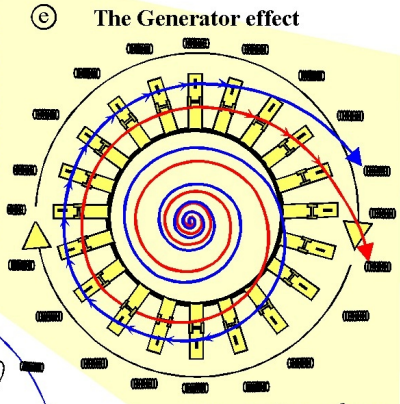
a) and b) Hydrogen is electrically and geometrically symmetrical, allowing it to spin axially and radiate corkscrew-style radio waves—helically polarised electromagnetic waves.



c) More complex atoms are not electrically-geometrically-symmetrical—electrons orbit in shells off-set by at least 45°. Electrons thus bunch together as they orbit the atom. The mass distribution of the atom therefore changes, causing the atom to 'tumble', not to spin autonomously. More complex atoms therefore do not *normally* spin or radiate radio waves.

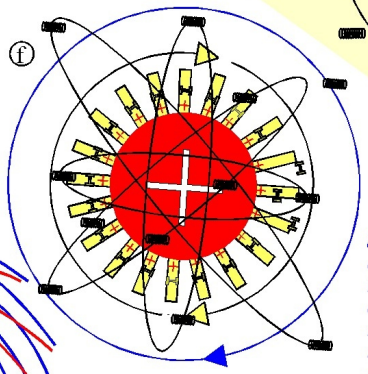


d) and e) However, when helically polarised electromagnetic radiation from the hydrogen atom bombards more complex atoms it acts on the negative charges of the neighbouring atom causing the nucleus and the electron-cage to spin axially. The mass of the electron is twice that of the neutron-negative charge, hence the torque on the electron-cage is twice that on the neutron-negative charges in the nucleus. Thus, the electron-cage spins faster than the nucleus.

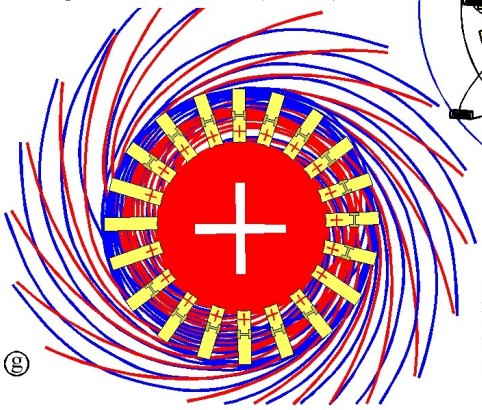


cross-section of new model with spiked-neutrons

f) Orbiting electron-magnets, in axially spinning atoms, generate helically polarised electromagnetic energy that radiates from the atom. The power output of the atomic generator is proportional to the differential speed between the nucleus and electron cage and also proportional to the number of orbiting electrons (atomic mass). Elements with more mass thus generate more electromagnetic energy which pulls them towards the Earth with more force, making them more difficult (heavier) to lift.



Supporting evidence: 'when electrons are bombarded by helically polarised radiation they align themselves—like compass needles—and follow the corkscrew spin of the waves' [Nature, 2009; 458 (7238):610DOI:10.1038.07871 (persistent spin helix)].

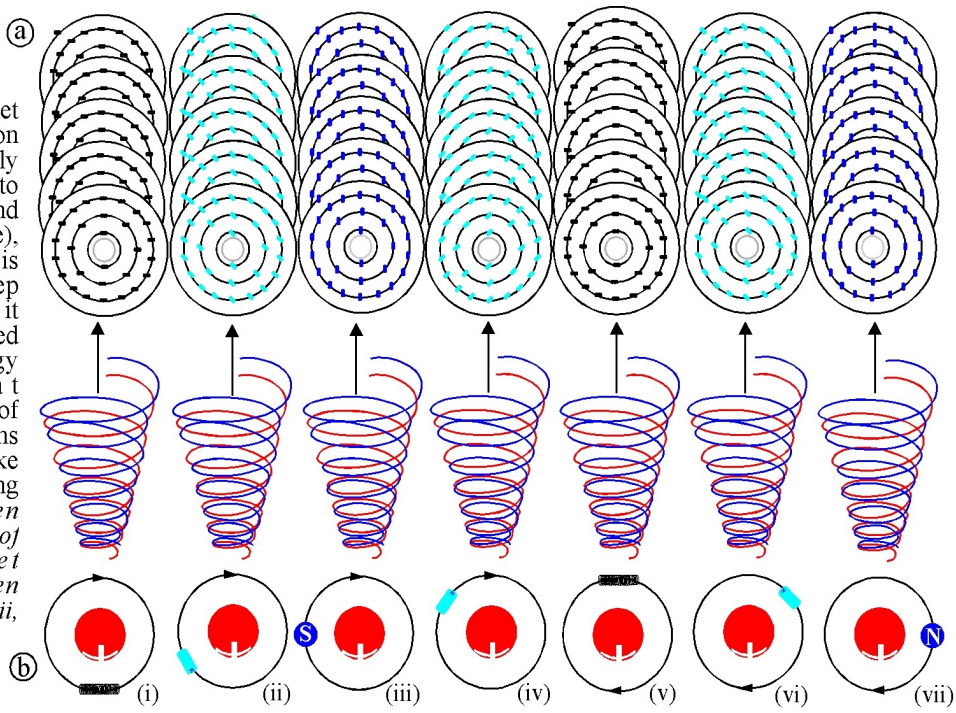


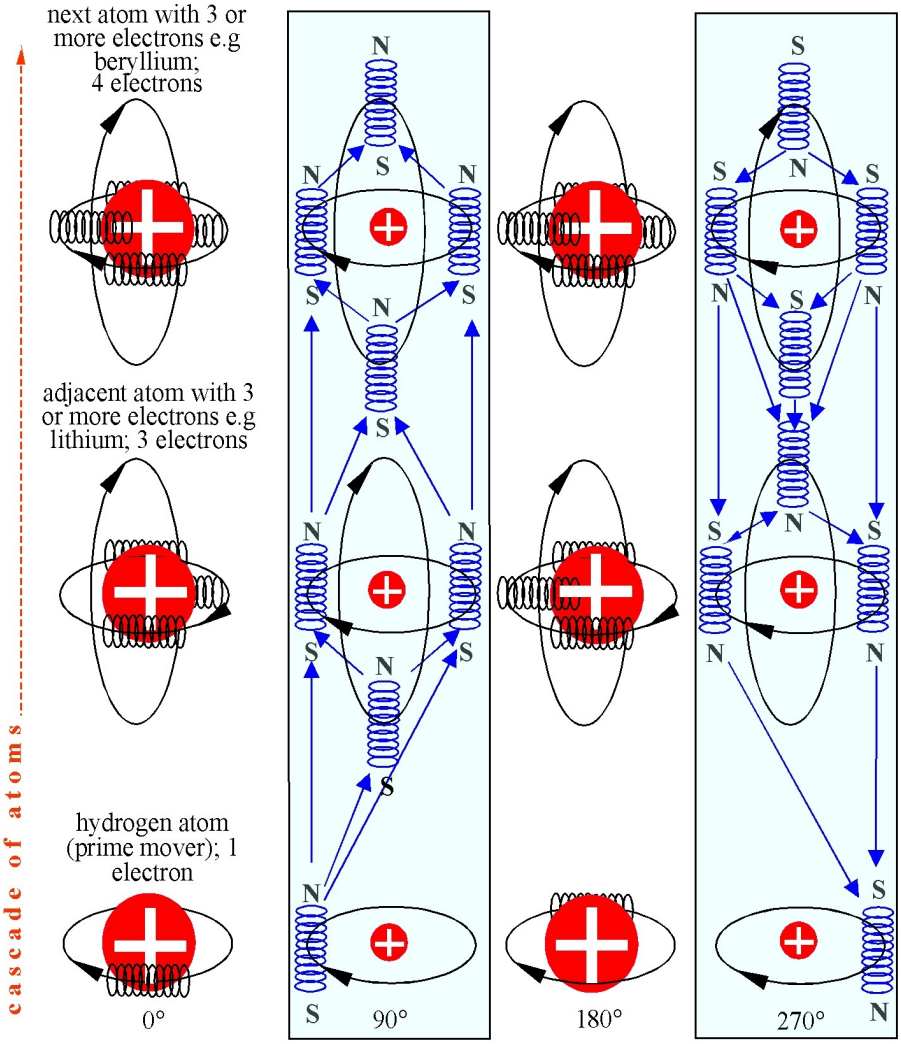
g) The neighbouring atom now radiates helically polarised electromagnetic radiation that bombards other neighbouring atoms in alignment.

figure 4.

Hydrogen synchro-spin

b) As the electron-magnet orbits the hydrogen proton it changes from a purely electric particle (black) to one that is half electric and half magnetic (light blue), and then to one that is purely magnetic (deep blue). At the same time it radiates helically polarised electromagnetic energy into space that synchronises the spin of electrons in nearby atoms causing them to spin—like windscreen wipers rotating through 360°. [*Seven consecutive snapshots of the electron-magnet orbiting the hydrogen proton are shown; time i, ii, iii, iv, v, vi and vii*].





no gravity when electron-magnets are at 0°

electron-magnetic force (gravity) when electron-magnets are at 90° (vertical)

no gravity when electron-magnets are at 180° (horizontal)

electron-magnetic force (gravity) when electron-magnets are at 270° (vertical)

How gravity works

c) A vertical cascade of atoms; helically polarised electromagnetic energy (not shown here) from the hydrogen atom bombards the lithium atom synchronising the spin of its electron-magnets with that of the hydrogen electron-magnet. The lithium electron-magnets then spin axially and radiate helically polarised electromagnetic radiation that bombards the beryllium atom, synchronising the spin of its electron-magnets with that of the hydrogen atom. The beryllium electron-magnets then spin axially and the beryllium electron-magnets radiate helically polarised electromagnetic energy etc. It can be seen that, in a cascade of atoms, helically polarised electromagnetic radiation from the hydrogen atom synchronises the spin of all electrons in atoms in alignment with the hydrogen atom. As a result the magnetic moments of orbiting electron-magnets in a cascade of atoms attract each other. This is the force of gravity. The electron-magnetic moments alternate during each orbital cycle of the hydrogen electron-magnet, hence gravity cannot be measured.

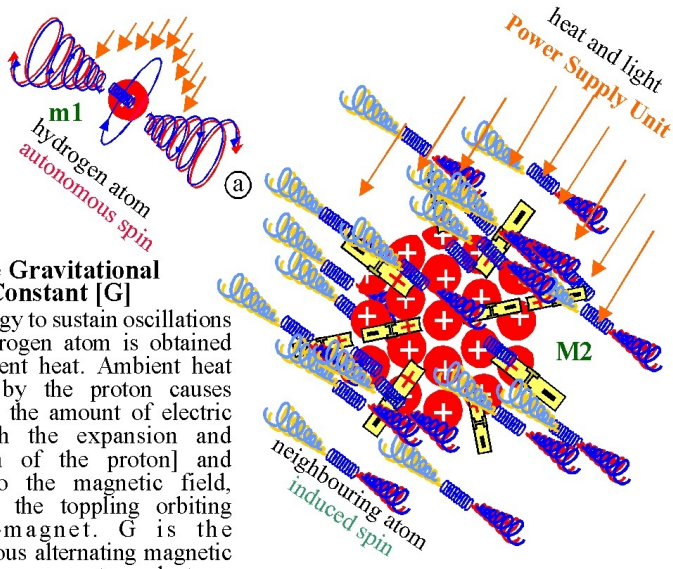
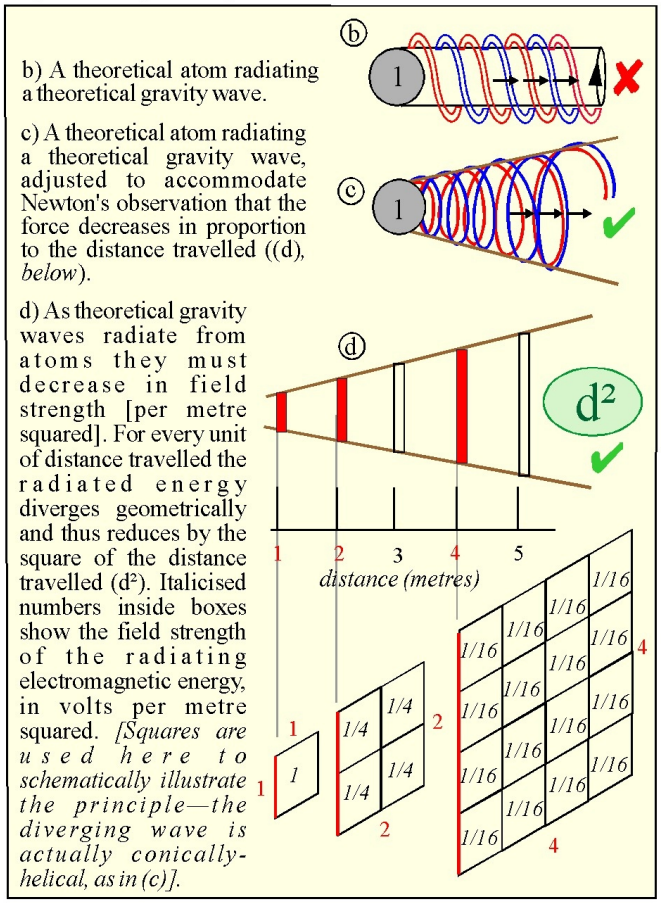
figure 5.



The Gravitational Constant [G]

a) The energy to sustain oscillations in the hydrogen atom is obtained from ambient heat. Ambient heat sucked-in by the proton causes changes in the amount of electric field [with the expansion and contraction of the proton] and changes to the magnetic field, caused by the toppling orbiting electron-magnet. G is the 'instantaneous alternating magnetic force between any two electron-magnets in neighbouring atoms'.



b) A theoretical atom radiating a theoretical gravity wave.

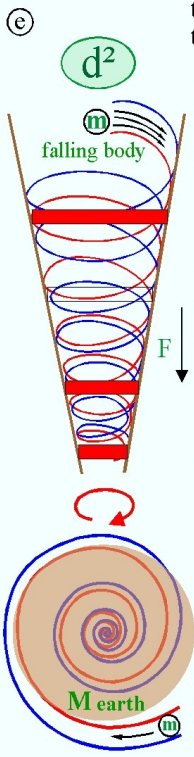
c) A theoretical atom radiating a theoretical gravity wave, adjusted to accommodate Newton's observation that the force decreases in proportion to the distance travelled ((d), *below*).

d) As theoretical gravity waves radiate from atoms they must decrease in field strength [per metre squared]. For every unit of distance travelled the radiated energy diverges geometrically and thus reduces by the square of the distance travelled (d^2). Italicised numbers inside boxes show the field strength of the radiating electromagnetic energy, in volts per metre squared. *[Squares are used here to schematically illustrate the principle—the diverging wave is actually conically-helical, as in (c)].*

Derivation of Newton's equation

The magnetic force between any two magnets is proportional to the magnetic force of one magnet multiplied by the magnetic force of the second magnet. The magnetic force between two atoms can therefore be calculated by multiplying the electron-magnetic force of one electron-magnet [G, the gravitational Constant] by the number of electron-magnets in atom 1 (a proportion of the mass of atom 1, m1) multiplied by the number of electron-magnets in atom 2 (a proportion of the mass of atom 2, M2); or as Newton said, the force (F) can be calculated by multiplying G [the magnetic force of 1 electron-magnet] multiplied by m1 x M2. (b) – (d) explain why the result must be divided by the distance (between the two atoms) squared.

Why objects accelerate to Earth in proportion to d^2



e) The frequency of the helically polarised EM radiation from the Earth remains constant. However, as m approaches M the spiraling EM radiation accelerates the differential rotation between each atomic nucleus and electron cage of which m is made. As a result the 'relative' atomic frequency increases and hence the output of the 'atomic generator' increases, increasing uniformly the attracting EM Force between m and M in accordance with a square-law scale as m proceeds along the EM spiral. M thus attracts m with square-law [d^2] uniform acceleration.

[m is shown spiralling towards M with the EM wave stationary but, in actuality, m approaches M in a straight line as the wave spirals across m]

Hence Isaac Newton's equation for the force of gravity; where the force is proportional to the masses (**m** & **M**) of the two attracting bodies and the strength of the force decreases inversely with the square of the distance between them (d^2).

$$F = GmM/d^2$$

G is Newton's gravitational Constant

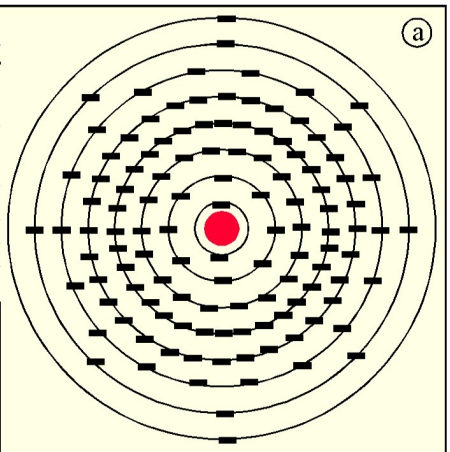
—the instantaneous alternating magnetic force between any two electron-magnets in neighbouring atoms

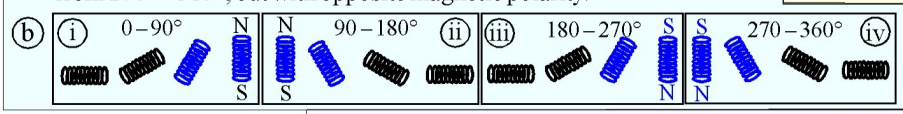
figure 6.

Proof that the electron is a coil-shaped electron-magnet—and electron-shell architecture explained

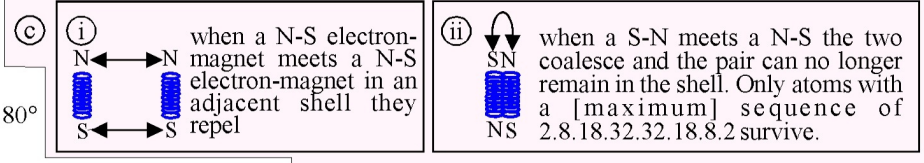
a) Schematic showing the theoretical maximum numbers of electrons filling the maximum number of available shells in an atom. The maximum number of electrons in the shell closest to the nucleus is 2. The maximum number of electrons in the next outermost shell/subshell is 8, followed by shells/subshells containing a maximum of 18, 32, 32, 18, 8, 2. It can be seen that, theoretically, the heaviest atom (illustrated) contains 120 electrons. The number of electrons orbiting an atom is usually balanced [but there are exceptions] with the same number of protons in the centre and (in our 'new atom') the same number of spiked-neutrons protruding from the centre (not shown). This also means that there are a maximum of only 120 different fundamental materials (elements). The heavier ones are more '*mass*ive' and hence said to contain more *mass* (electrons, protons and neutrons).

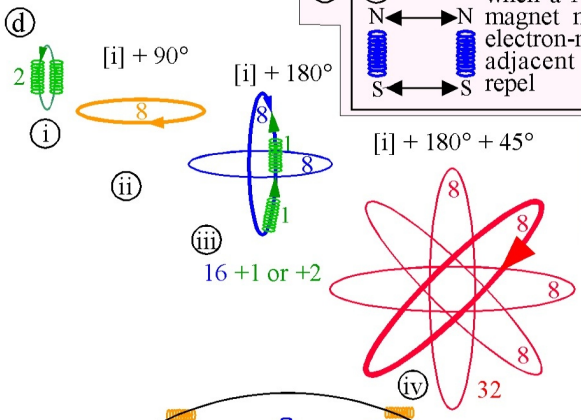


b(i – iv) illustrate the electric – magnetic tipping point of the orbiting electron-magnet [EM] at 45° interval: bi) From 45° – 90° (1/8 of the time) the magnetic field of the EM rises [and it is more magnetic than electric]. bii) From 90° – 135° it falls [but is still more magnetic than electric]. b(iii – iv) The same thing happens between 225°– 270°, and from 270° – 315°, but with opposite magnetic polarity.

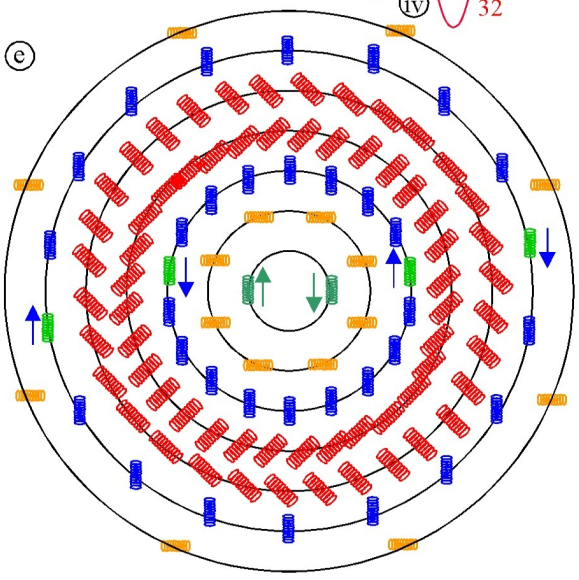


orthodox Science does not understand why the atom is structured the way it is—the reasons are given, below





c(i – ii) when a northsouth [N-S] EM meets a northsouth [N-S] EM the two repel each other, and when a northsouth [N-S] meets a southnorth [S-N] the two attract, stick together, and exit the host shell. Hence, as subatomic particles accrete into atoms, EMs inside shells/sub-shells must be separated by at least 45° to avoid annihilation and EMs in one shell must be separated by at least 45° from those in adjacent shells. Hence the constraint of up to 8 EMs per shell/sub-shell [8 x 45° = 360] and the requirement for different shell/sub-shell planar orientations.



schematic only—EMs are actually synchronised by gravity waves and [instead] the inclination of each shell/sub-shell is offset as shown in d(i – iv)

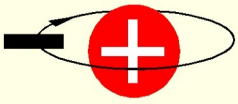
d) and e) As a general rule orbital shells [or sub-shells of equidistant radii] cannot sustain more then 8 EMs because of considerations set down in b(i – iv) and, to avoid magnetic conflict *between* shells/subshells, the plane of successive shells/subshells must be progressively offset by at least 45°. However, shells 3 and 6 can sustain up to 2 more EMs in the scheme proposed in (d) and (e) because the magnetic moments from the 2 EMs in shell 1 (being equal and opposite to 2 EMs in shell 3) cancel, and magnetic moments from 2 EMs in shell 3 cancel those of 2 EMs in shell 6, allowing those shells/sub-shells to sustain up to 18, rather than 16, EMs.

here, to further illustrate the relationship between magnetic moments, EMs in successive shells are shown reorientated; in shell 2 by 90°, in shell 3 by a further 90°, in shell 4, by a further 45°, in shell 5 by a further 90°, in shell 6 by a further 45° and in shell 7 by a further 90°. It can be seen that no magnetic conflicts occur in such a scheme and that the 2 EMs in shell 1 (green) influence the magnetic moments of those in shells 3 and 6, so that those shells can sustain up to 2 more EMs (green) than generally possible. This defined structure confirms that the electron must be coil-shaped and that it behaves as an electromagnetic particle

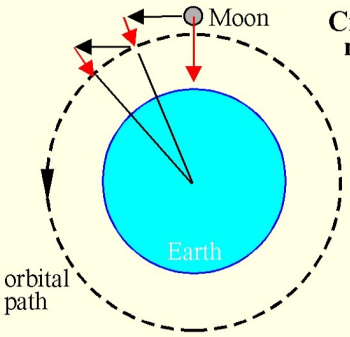
figure 7.

What makes the atom stable (II)?

ⓐ



a) Hydrogen, the simplest of atoms, contains only 1 proton that is orbited by 1 electron. The electron is attracted to the positive proton but does not crash into the atom—for the same reason that the Moon does not crash into the Earth (*right*)



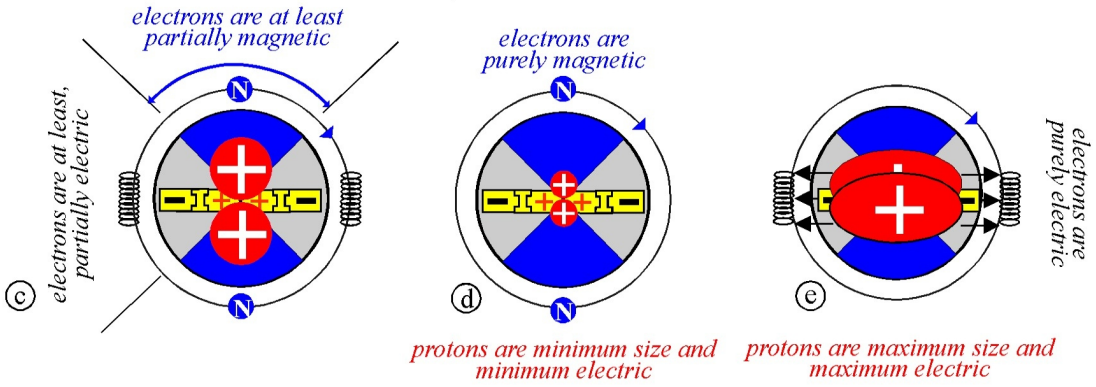
Circular orbital motion of the Moon

Newton reasoned that the Moon is continually falling towards the Earth with the same force and acceleration as a falling apple. At the same time, it is moving away from the Earth in its journey through space. The resulting motion captures the Moon in Earth's orbit (shown by the broken circular line).

Why atoms with spiked-neutrons are stable

note; helium, like hydrogen, is electrically and geometrically symmetrical and hence spins axially and autonomously and radiates helically polarised electromagnetic energy, however, helium is subordinate to hydrogen because hydrogen has no spiked-neutrons and is therefore unaffected by any radiation from helium

ⓑ



plan view of a helium atom with 2 electrons, two protons and 2 spiked-neutrons. The electron-magnets alternately possess an increasing and decreasing magnetic field that alternates with an increase and decrease of atomic capacitance. The two forces unite in self-sustained oscillation. The spiked-neutrons prevent the electric-electrons from crashing into the atom

Figure 3e) showed how the electron behaves as a permanent magnet at 90° and 270° from its starting position and how it does not possess a magnetic field at 0° and 180°.The electron is magnetic therefore during only half of the time it orbits the nucleus. We note further that, because a purely magnetic field and a purely electric field are displaced by 90°, a particle cannot be both purely electric and purely magnetic simultaneously, the two are mutually exclusive. It follows that if an electrically negative electron possesses magnetic qualities for half of the time it cannot be simultaneously electrical during that same part of the cycle. The electron, therefore, can only be considered as having electrical properties for half of the time. c) Shows the electric and magnetic possibilities, in plan view, of two electrons as they orbit the nucleus of a helium atom. d) When the electrons are each purely magnetic they cannot be attracted to an electric particle (the proton). Hence the magnetic electron is not attracted towards the nucleus during the quadrants shaded in blue. e) 90° later, the electron is maximum electric, but the charge on the nearby neutron-negative prevents them moving closer to the nucleus. Thus, the electrons cannot be sucked-into the nucleus. b) We also note that during the blue quadrants the protons, drained of energy, physically shrink, compress rapidly, release heat and cool. Hence the capacitance between electrons and protons reduces during the blue quadrants [because capacitance varies with distance between particles and the surface area of each particle]. In regard to the proton; during the blue quadrants, when the electron is maximum-magnetic, the positive electrical charge of each proton (and the force of repulsion between protons) is minimal, hence the protons have little propensity to move apart during the blue quadrants. e) As the electrons move into the grey quadrants the protons begin to suck-in ambient heat and rapidly expand. As the protons expand the distance between them and the electrons reduces and their surface area increases, increasing the amount of capacitance between them. It can thus be seen that when the electric particle is maximum-electric, the proton is also maximum-electric and attraction between the electrons and protons is maximum. The protons are thus stretched between the pair of electrons and have no propensity to spring apart; which explains why the maximum, and minimum, number of electrons in the first orbital shells of atoms containing spiked-neutrons must always be 2.

Guidelines to Antigravity*

ROBERT L. FORWARD
Hughes Research Laboratories, Malibu, California
(Received 12 September 1962)

This paper emphasizes certain little known aspects of Einstein's general theory of relativity. Although these features are of minor theoretical importance, their understanding and use can lead to the generation and control of gravitational forces. Three distinctly different non-Newtonian gravitational forces are described. The research areas which might lead to methods for the control of gravitation are pointed out and guidelines for initial investigation into these areas are given.

INTRODUCTION

EINSTEIN'S general theory of relativity provides a number of ways to generate non-Newtonian gravitational forces. Theoretically, all of these forces could be used to counteract the gravitational field of the earth, thus acting as a form of antigravity. The three outlined here were probably known by Einstein before he published his paper on the principle of general relativity in 1916.[1] They were first specifically derived by Thirring[2] in 1918, and since then have been contained in nearly every text on general relativity.[3–5]

Although non-Newtonian forces are well known to the theorists in general relativity, they are little known to those outside the field, and it was for this reason that it was felt that a simplified discussion of these unusual gravitational effects would be of interest to the nonspecialist.

The equations of general relativity not only predict the usual radial Newtonian gravitational force behavior of a stationary mass on a stationary test body, but they also predict that a moving mass can create forces on a test body which are similar to the usual centrifugal and Coriolis forces, although much smaller. In addition, when the general relativity field equations are linearized, they result in a set of dynamic gravitational field relations similar to the Maxwell relations. Thus one can use intuitive pictures from electromagnetic theory to design theoretical models. Whether the effects predicted by the linearized theory really exist, will, of course, have to be checked by repeating the calculations with the nonlinearized field equations.

The essential point is that all of these unusual forces create accelerations which are independent of the mass of the test body and the forces are, therefore, indistinguishable from the usual Newtonian gravitational force.

NON-NEWTONIAN GRAVITATIONAL FORCES

Effect of Rotating Masses on Stationary Bodies

By using Einstein's general theory of relativity for a rotating system of masses, it can be shown that in addition to the usual Newtonian term, the gravitational scalar potential contains terms which arise from the rotation of the body. One of the shapes which has been rigorously investigated is the rotating massive ring.[3]

For a massive ring rotating in the x-y plane, the non-Newtonian acceleration on a stationary test body near the origin is approximately

$$\ddot{x} = (MG\omega^2/2c^2R)x,$$
$$\ddot{y} = (MG\omega^2/2c^2R)y, \qquad (1)$$

and

$$\ddot{z} = -(MG\omega^2/c^2R)z.$$

Where M and R are the mass and radius of the ring, ω is the angular velocity, $G = 6.67 \times 10^{-11}$ m³/kg-sec² is the Newtonian gravitational constant, c is the speed of light, and x, y, z are the coordinates of the test body with respect to the origin of the rotating mass. From these equations it is evident that the rotating mass not only

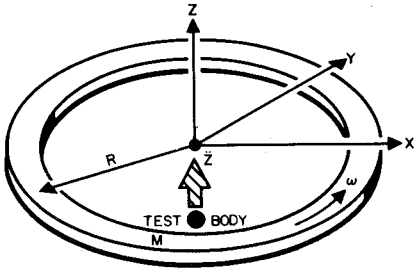

FIG. 1. Non-Newtonian component of acceleration on a test body below the center of a rotating massive ring.

forces the test body away from the axis in an imitation of centrifugal force, but also pulls it upward into the plane of rotation as shown in Fig. 1.

Effect of Rotating Masses on Moving Bodies

It has been pointed out that a rotating mass will exert a force similar to centrifugal force on a stationary test body; also, if the test body is moving at some constant velocity **v**, it will experience an additional force which is proportional to the cross product of the angular velocity of the rotating mass and the linear velocity of the test body. The additional force can be compared with two others: mechanically, it acts like a very weak Coriolis force; electrically,[4,6] it acts like the gravitational equivalent of the Lorentz force on a charged particle moving through a magnetic field.

One of the shapes which has been investigated is the rotating massive spherical shell. The acceleration on a test body moving with a velocity **v** inside the shell is approximately[4]

$$\ddot{x} = (GM/3c^2R)[\tfrac{4}{5}\omega^2 x - 8\omega v_y],$$
$$\ddot{y} = (GM/3c^2R)[\tfrac{4}{5}\omega^2 y + 8\omega v_x], \qquad (2)$$

and

$$\ddot{z} = -(8GM\omega^2 z/15c^3R),$$

where v_x and v_y are the x and y components of the velocity of the test body and M and R are the mass and radius of the spherical shell. The first term in each expression is the centrifugal-type force on a stationary test body described in the previous section. The second term in the x and y components of the acceleration depends upon the velocity of the test body as shown in Fig. 2.

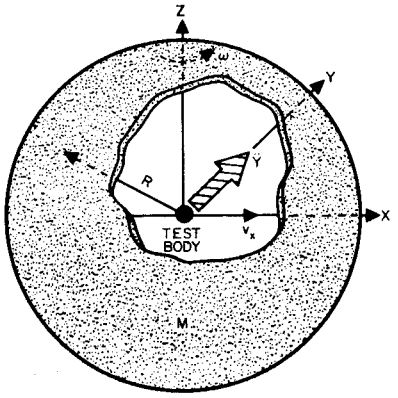

FIG. 2. Non-Newtonian component of acceleration on a test body with a velocity v_x at the center of a rotating massive sphere.

Effect of Accelerated Masses on Stationary Bodies

In employing Einstein's Theory to investigate the effect of a large accelerated mass on a small test body, it is found that the accelerated body drags the test body along with it. The exact equations are[4]

$$\ddot{\mathbf{r}} = \nabla(GM/R) + (4GM/c^2R)\mathbf{a} + (4GM/c^3)(\mathbf{a}\cdot\mathbf{R}/R^2)\mathbf{v}, \qquad (3)$$
$$= F_1/m + F_2/m + F_3/m,$$

where M, **a**, and **v** are the mass, acceleration, and velocity of the large body, respectively, and **R** is the distance from the small body to the large body. In addition to the usual Newtonian attraction, the test body experiences forces in the direction of the acceleration and the velocity of the large body as shown in Fig. 3.

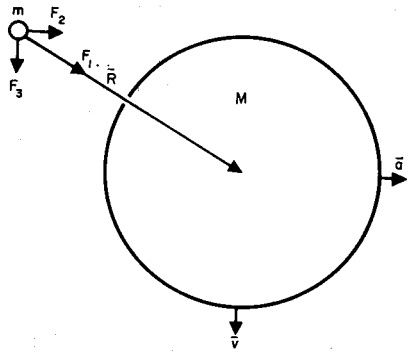

FIG. 3. Forces on a test body near a massive, accelerating, moving body.

[6] Robert L. Forward, Proc. IRE 49, 892 (1961).

CREATING NON-NEWTONIAN GRAVITATIONAL FORCES

Devices Using Moving Masses

The equations in the previous section contain two common factors. One is the Newtonian gravitational field,

$$GM/r^2 \approx (4\pi/3)G\rho r, \tag{4}$$

and the other is the ratio of the characteristic system velocity to the velocity of light such as

$$v^2/c^2 \quad \text{or} \quad ar/c^2. \tag{5}$$

In order to obtain measurable amounts of gravitational force, these quantities must be as large as possible. To obtain a high gravitational field, either a large mass or a high density is required. The greater the density, the less total mass necessary to achieve the same gravitational field.

To obtain high rotational velocities, we cannot use the mechanical strength of materials since this limits the obtainable equatorial velocities to approximately the speed of sound.[7] Because of this, it will be necessary to use fields to hold the systems together under inertial stresses. One example would be the high gravitational fields obtainable with dense matter. However, any practical device which might be constructed would probably use electric or magnetic fields. By using electromagnetic forces to contain rotating systems, it would be possible for the masses to reach relativistic velocities; thus a comparatively small amount of matter, if dense enough and moving fast enough, could produce usable gravitational effects.

An example of a system held together by gravitational fields is a contact binary dwarf star system. The force equation describing the mutual rotation of the stars is

$$-(GMM/(2r)^2) = -M\omega^2 r = -(Mv^2/r). \tag{6}$$

A particle coming near the system will experience not only a radial acceleration[4]

$$\ddot{x}_r = -GM\left[\frac{1}{(b-r)^2}+\frac{1}{(b+r)^2}\right] - \frac{4GMa}{c^2}\left[\frac{1}{b-r}-\frac{1}{b+r}\right], \tag{7}$$

but also a tangential acceleration

$$\ddot{x}_t = \frac{4GMva}{c^3}\left[\frac{1}{b-r}+\frac{1}{b+r}\right] \approx \frac{1}{c^3 b}\left(\frac{GM}{r}\right)^{\frac{5}{2}}, \tag{8}$$

where b is the distance of the particle from the center of the system.

In applying these equations to a test object (such as a space vehicle) passing by this star system, it is evident that, in general, the radial acceleration will not introduce any net change in velocity, but that the tangential acceleration will transfer energy and momentum to the vehicle. For a neutron binary star, this acceleration can be greater than one million g's; although these accelerations seem very high, there are no stresses on the human body because the forces are gravitational. Such systems could be used to accelerate space vehicles to nearly the speed of light.

Devices Based on Analogies between Electromagnetic and Gravitational Fields

There are other types of devices for obtaining non-Newtonian gravitational forces which follow from the known electromagnetic analogies based on Einstein's general theory of relativity; however, these devices have not been analyzed using the complete field equations. For instance, two rotating gyroscopes should repel each other if oriented properly, and two pipes with massive liquid flowing through them should exhibit a pinch effect.

Although the rotating gyroscopes and flowing masses should exhibit non-Newtonian forces, the linearized theory does not predict an interaction with a stationary test body. A device which electromagnetic analogies predict might be able to create a non-Newtonian gravitational force that will accelerate a nonrotating, nonmoving body is one that contains accelerated masses whose mass flow is like the current flow in a wire wound torus.[8] If we look at the electromagnetic model, a current **I** through the wire causes a magnetic field in the torus. If the current constantly increases, then the magnetic field also increases with time. This time-varying magnetic field then creates a dipole electric field. (Fig. 4.)

[7] J. W. Beams, Sci. Am. 204, No. 4, 134 (1961).

[8] Robert L. Forward, Proc. IRE 44, 1402 (1961).

The value of the electric field at the center of the torus is

$$E=-\dot{B}=+(d/dt)(\mu NIr^2/4\pi R^2), \qquad (9)$$

where R is radius of the torus, r is the radius of one of the loops of wire wound around it, and N is the total number of turns.

If we replace the wires with pipes carrying a massive liquid, then the known analogy between the electromagnetic and gravitational fields can now be used.[6] All the electromagnetic quantities are transformed to their equivalent gravitational quantities to obtain

$$G=-\dot{K}=-\frac{d}{dt}\left(\frac{\eta NTr^2}{4\pi R^2}\right), \qquad (10)$$

where G is the gravitational field generated by the total mass current NT, and $\eta=3.73\times10^{-26}$ m/kg is the gravitational equivalent to the magnetic permeability.[6] (See Fig. 5.)

It is important to notice in the above equation that the time derivative operates on the entire quantity in the brackets. One would normally say that all quantities are independent of time except the mass flow T. If the amount of mass flow increases with time, then $\dot{T}>0$, and thus a gravitational field G can be generated. However, in electromagnetism, the permeability of some materials such as iron is nonlinear, which allows the construction of highly efficient electromagnetic field generators. A material with a highly nonlinear η would also be useful in the construction of efficient gravitational field generators.

RESEARCH AREAS

Dense Materials

It has been emphasized that in order to achieve measurable gravitational effects with moderate amounts of mass, dense matter is required. Thus, the study of degenerate matter could lead to the generation and control of gravitation. Methods must be found to manufacture, contain, and control matter with densities from 10^8 to 10^{15} g/cm^3. The best starting point appears to be an investigation of the neutron–neutron interaction. By using extremely low temperatures and strong magnetic fields, one should be able to cool the thermal neutrons from a pile and concentrate them into a small region through the interaction of the magnetic field with the magnetic moment of the neutron.[9] The Fermi energy will limit the density to about 10^{-6} g/cm^3, but the formation of tetraneutrons (n^4) or the existence of a superconductive-type phase space condensation will create bosons which do not have this limitation. The results of a more comprehensive study of the properties of a cold neutron gas and the methods for containment will be given in a future paper.

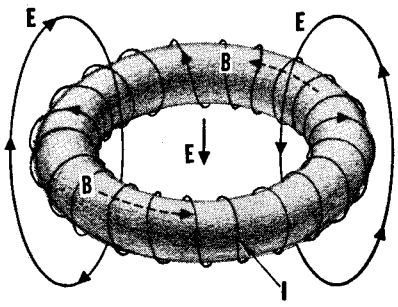

FIG. 4. Generator of a dipole electric field.

Gravitational Properties of Matter

In studying analogies between electromagnetism and gravitation, it can be seen that one analogous quantity has not been investigated. This is the gravitational equivalent to the magnetic permeability. Electrical power distribution systems depend upon the anomalously large and nonlinear permeability of iron and other magnetic materials. Since all atoms have spin, all materials will have a gravitational permeability which is different from that of free space. Rough calculations show that this difference is very small, but experimental investigation may

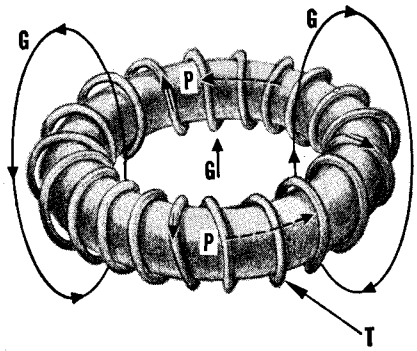

FIG. 5. Generator of a dipole gravitational field.

[9] V. V. Vladimirskii, Soviet Phys.—JETP 12, 740 (1961).

find materials with anomalously large or nonlinear properties that can be used to enhance time-varying gravitational fields. Also, since the magnetic moment and the inertial moment are combined in an atom, it may be possible to use this property to convert time-varying electromagnetic fields into time-varying gravitational fields. At present, the only way to search for such materials is to intersperse wedges of material between gravitational wave generators and detectors, such as those described by J. Weber,[10] and look for a change in amplitude or direction of propagation. The first efforts in this direction[11] have been carried out by the Russian workers Braginsky, Rudenko, and Rukman with negative results.

It is obvious that research in the field of gravitation will be very difficult since even the most optimistic calculations indicate that very large devices will be required to create usable gravitational forces. Antigravity, like space travel, will probably have no direct effect on the daily life of the average person. Future progress in the control of gravitation, like all modern sciences, will require special projects involving large sums of money, men, and energy.

Part I

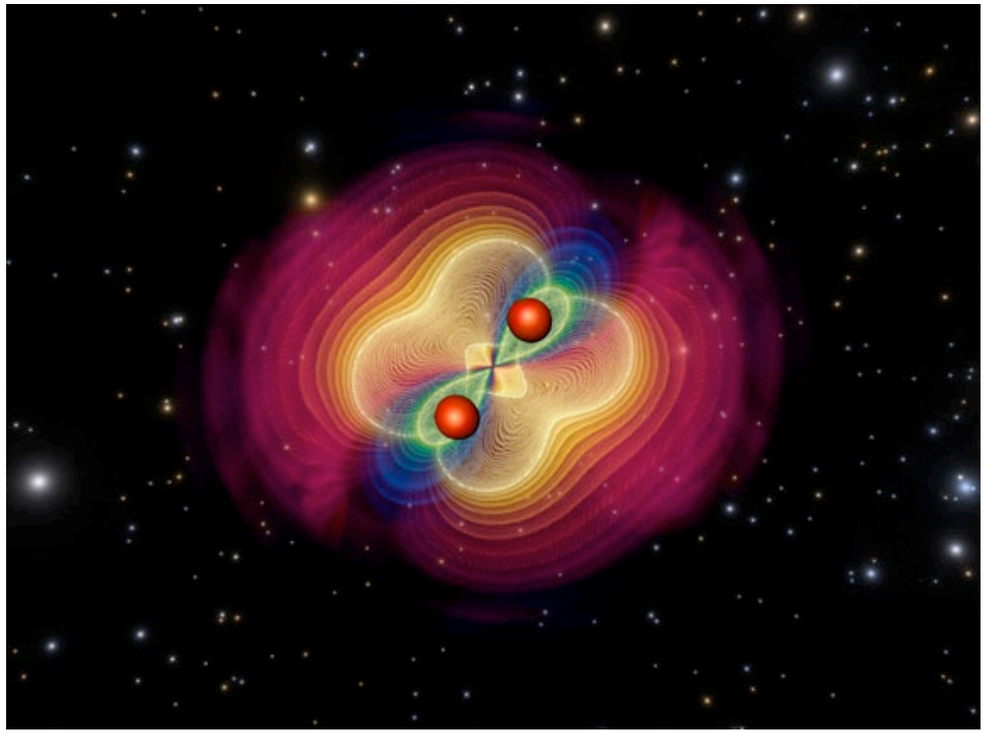
GW theory

Newtonian vs General Relativistic gravity

Newtonian field equations	**GR field equations**
$\nabla^2\Phi = 4\,\pi G\rho$	$G^{ab} = \dfrac{8\pi G}{c^4} T^{ab}$
Source: mass density Gravitational field: scalar Φ	Source: energy-momentum tensor (includes mass densities/currents) Gravitational field: metric tensor g_{ab}

GWs: origins

- Electromagnetism: accelerating charges produce EM radiation.



- Gravitation: accelerating masses produce gravitational radiation. (another hint: gravity has finite speed.)

GWs in linear gravity

- We consider weak gravitational fields:

$$g_{\mu\nu} \approx \eta_{\mu\nu} + h_{\mu\nu} + \mathcal{O}(h_{\mu\nu}^2)$$

↑

flat Minkowski metric

- The GR field equations in vacuum reduce to the standard wave equation:

$$\left(\frac{\partial^2}{\partial t^2} - \nabla^2 \right) h^{\mu\nu} = \Box h^{\mu\nu} = 0$$

- Comment: GR gravity like electromagnetism has a "gauge" freedom associated with the choice of coordinate system. The above equation applies in the so-called "transverse-traceless (TT)" gauge where

$$h_{0\mu} = 0, \qquad h^{\mu}_{\mu} = 0$$

Wave solutions

- Solving the previous wave equation in weak gravity is easy. The solutions represent “plane waves”:

$$h_{\mu\nu} = A_{\mu\nu} e^{i k_a x^a}$$

wave-vector

- Basic properties: $A_{\mu\nu} k^\mu = 0, \qquad k_a k^a = 0$

transverse waves

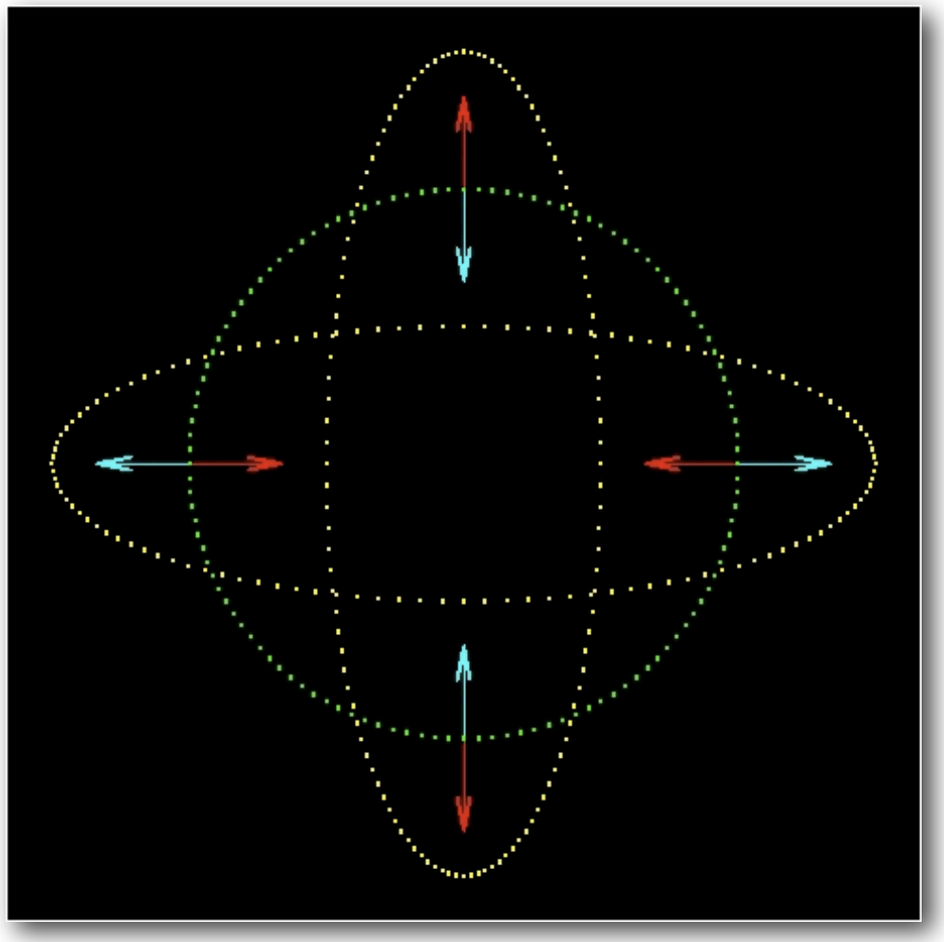
null vector = propagation along light rays

- Amplitude: $A^{\mu\nu} = h_+ e_+^{\mu\nu} + h_{\rm x} e_{\rm x}^{\mu\nu}$

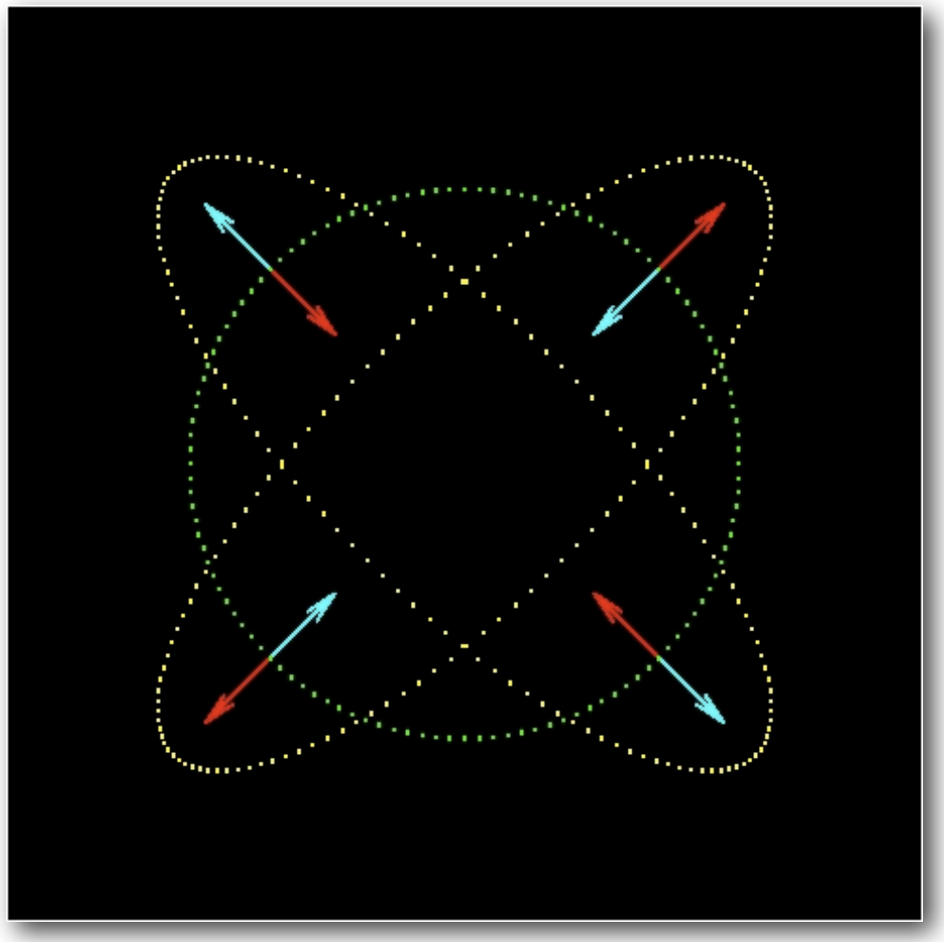
two polarizations

GWs: polarization

- GWs come in two polarizations:



"+" polarization



"x" polarization

GWs: more properties

- EM waves: at lowest order the radiation can be emitted by a dipole source (l=1). Monopolar radiation is forbidden as a result of charge conservation.

- GWs: the lowest allowed multipole is the quadrupole (l=2). The monopole is forbidden as a result of mass conservation. Similarly, dipole radiation is absent as a result of momentum conservation.

- GWs represents propagating “ripples in spacetime” or, more accurately, a propagating curvature perturbation. The perturbed curvature (Riemann tensor) is given by (in the TT gauge):

$$R^{\rm TT}_{j0k0} = -\frac{1}{2}\,\partial_t^2 h^{\rm TT}_{jk}\,, \qquad\qquad j,k = 1,2,3$$

GWs and curvature

- As we mentioned, GWs represent a fluctuating curvature field.
- Their effect on test particles is of tidal nature.
- Equation of geodetic deviation (in weak gravity):

$$\frac{d^2\xi^k}{dt^2} = -R^{k\ \mathrm{TT}}_{0j0}\,\xi^j$$

distance between geodesics (test particles)

- Newtonian limit: $R^{\mathrm{TT}}_{k0j0} \approx \dfrac{\partial^2\Phi}{\partial x^k \partial x^j}$

Newtonian grav. potential

GWs vs EM waves

- Similarities:

✓ Propagation with the speed of light.

✓ Amplitude decreases as ~ 1/r.

✓ Frequency redshift (Doppler, gravitational, cosmological).

- Differences:

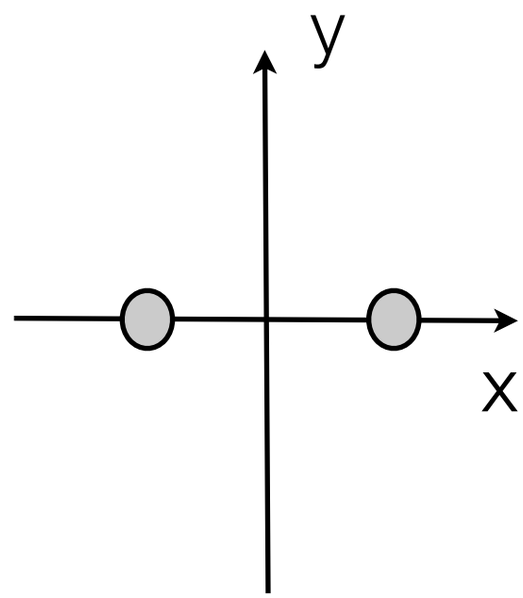
✓ GWs propagate through matter with little interaction. Hard to detect, but they carry uncontaminated information about their sources.

✓ Strong GWs are generated by bulk (coherent) motion. They require strong gravity/high velocities (compact objects like black holes and neutron star).

✓ EM waves originate from small-scale, incoherent motion of charged particles. They are subject to “environmental” contamination (interstellar absorption etc.).

Effect on test particles (I)

- We consider a pair of test particles on the cartesian axis Ox at distances $\pm x_0$ from the origin and we assume a GW traveling in the z-direction.



- Their distance will be given by the relation:

$$dl^2 = g_{\mu\nu} dx^\mu dx^\nu = \ldots = -g_{11} dx^2 =$$

$$= (1 - h_{11})(2x_0)^2 = [1 - h_+ \cos(\omega t)]\,(2x_0)^2$$

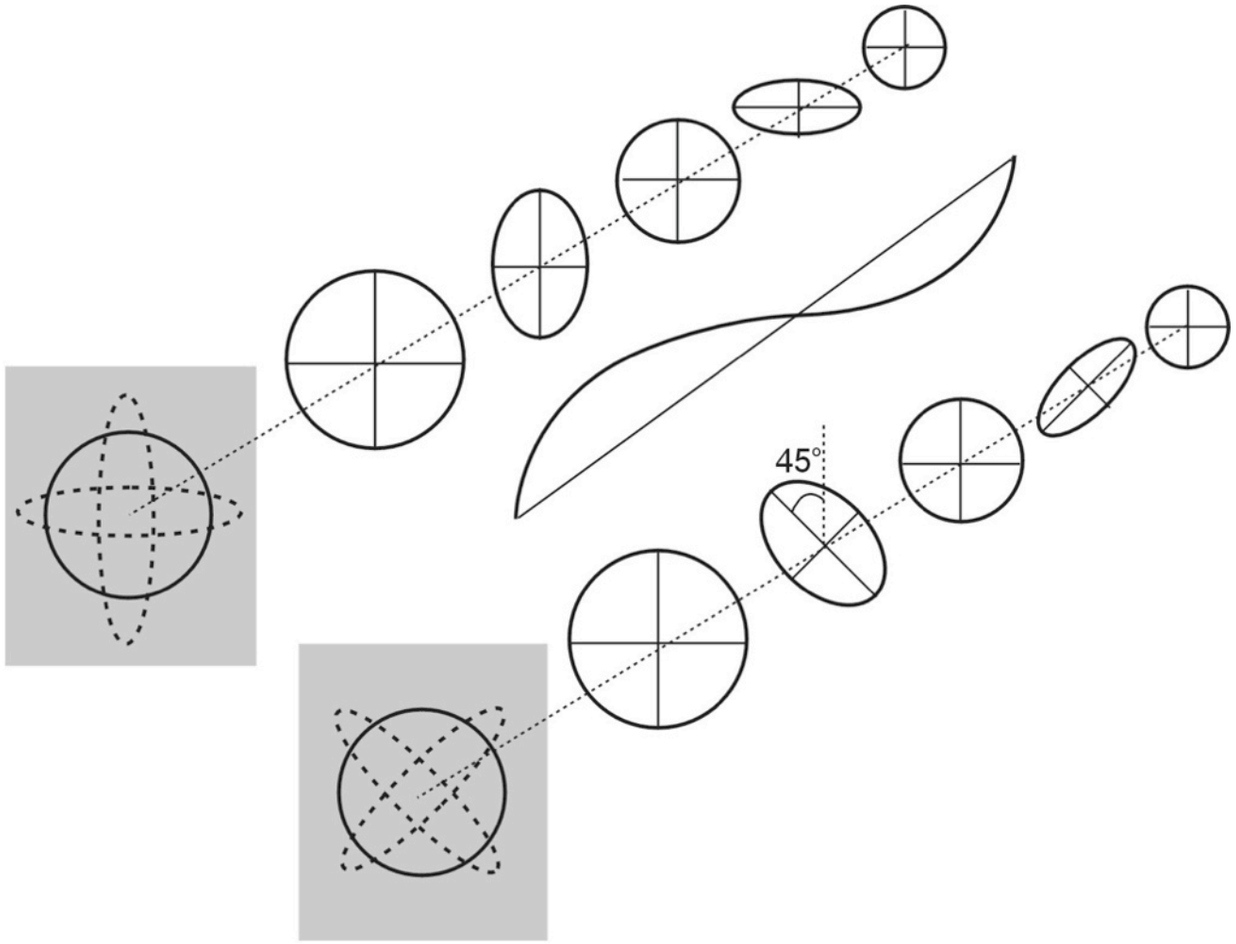
$$dl \approx \left[1 - \frac{1}{2} h_+ \cos(\omega t)\right](2x_0)$$

Effect on test particles (II)

- Similarly for a pair of particles placed on the y-axis:

- Comment: the same result can be derived using the geodetic deviation equation.

$$dl \approx \left[1 + \frac{1}{2} h_+ \cos(\omega t)\right] (2y_0)$$



The quadrupole formula

- Einstein (1918) derived the quadrupole formula for gravitational radiation by solving the linearized field equations with a source term:

$$\Box h^{\mu\nu}(t,\vec{x}) = -\kappa T^{\mu\nu}(t,\vec{x}) \quad \longrightarrow \quad h^{\mu\nu} = -\frac{\kappa}{4\pi}\int_V d^3x' \frac{T^{\mu\nu}(t-|\vec{x}-\vec{x}'|,\vec{x}')}{|\vec{x}-\vec{x}'|}$$

- This solution suggests that the wave amplitude is proportional to the second time derivative of the quadrupole moment of the source:

$$h^{\mu\nu} = \frac{2}{r}\frac{G}{c^4}\ddot{Q}^{\mu\nu}_{\rm TT}(t-r/c) \qquad\qquad Q^{\mu\nu}_{\rm TT} = \int d^3x\,\rho\left(x^\mu x^\nu - \frac{1}{3}\delta^{\mu\nu}r^2\right)$$

(quadrupole moment in the “TT gauge” and at the retarded time t-r/c)

- This result is quite accurate for all sources, as long as the wavelength is much longer than the source size R.

GW luminosity

- GWs carry energy. The stress-energy carried by GWs cannot be localized within a wavelength. Instead, one can say that a certain amount of stress-energy is contained in a region of the space which extends over several wavelengths. The stress-energy tensor can be written as:

$$T^{\rm GW}_{\mu\nu} = \frac{c^4}{32\pi G}\langle \partial_\mu h^{\rm TT}_{ij} \partial_\nu h^{ij}_{\rm TT}\rangle$$

- Using the previous quadrupole formula we obtain the GW luminosity:

$$L_{\rm GW} = \frac{dE_{\rm GW}}{dt} = \int dA\, T^{\rm GW}_{0j}\hat{n}^j \quad \longrightarrow \quad L_{\rm GW} = \frac{1}{5}\frac{G}{c^5}\langle \dddot{Q}^{\rm TT}_{\mu\nu}\, \dddot{Q}^{\mu\nu}_{\rm TT}\rangle$$

Basic estimates (I)

- The quadrupole moment of a system is approximately equal to the mass M of the part of the system that moves, times the square of the size R of the system. This means that the 3rd-order time derivative of the quadrupole moment is:

$$\dddot{Q} \sim \frac{MR^2}{T^3} \sim \frac{Mv^2}{T} \sim \frac{E_{\rm ns}}{T}$$

v = mean velocity of source's non-spherical motion,

E_{ns} = kinetic energy of non-spherical motion

T = timescale for a mass to move from one side of the system to the other.

- For a self gravitating system: $T \sim \sqrt{R^3/GM}$

- This relation provides a rough estimate of the characteristic frequency of the system $f \sim 2\pi/T$.

Basic estimates (II)

- The luminosity of GWs from a given source is approximately:

$$L_{\rm GW} \sim \frac{G^4}{c^5}\left(\frac{M}{R}\right)^5 \sim \frac{G}{c^5}\left(\frac{M}{R}\right)^2 v^6 \sim \frac{c^5}{G}\left(\frac{R_{\rm Sch}}{R}\right)^2 \left(\frac{v}{c}\right)^6$$

where $R_{\rm Sch} = 2GM/c^2$ is the Schwarzschild radius of the source. It is obvious that the maximum GW luminosity can be achieved if $R \sim R_{\rm Sch}$ and v ~ c.
That is, the source needs to be compact and relativistic.

- Using the above order-of-magnitude estimates, we can get a rough estimate of the amplitude of GWs at a distance r from the source:

$$h \sim \frac{G}{c^4}\frac{E_{\rm ns}}{r} \sim \frac{G}{c^4}\frac{\epsilon E_{\rm kin}}{r}$$

$\epsilon =$ the kinetic energy fraction that is able to produce GWs.

Basic estimates (III)

- Another estimate for the GW amplitude can be derived from the flux formula

$$F_{\rm GW} = \frac{L_{\rm GW}}{4\pi r^2} = \frac{c^3}{16\pi G}|\partial_t h|^2$$

- We obtain:

$$h \approx 10^{-22}\left(\frac{E_{\rm GW}}{10^{-4}\,M_\odot}\right)^{1/2}\left(\frac{1\,\mathrm{kHz}}{f_{\rm GW}}\right)\left(\frac{\tau}{1\,\mathrm{ms}}\right)^{-1/2}\left(\frac{15\,\mathrm{Mpc}}{r}\right)$$

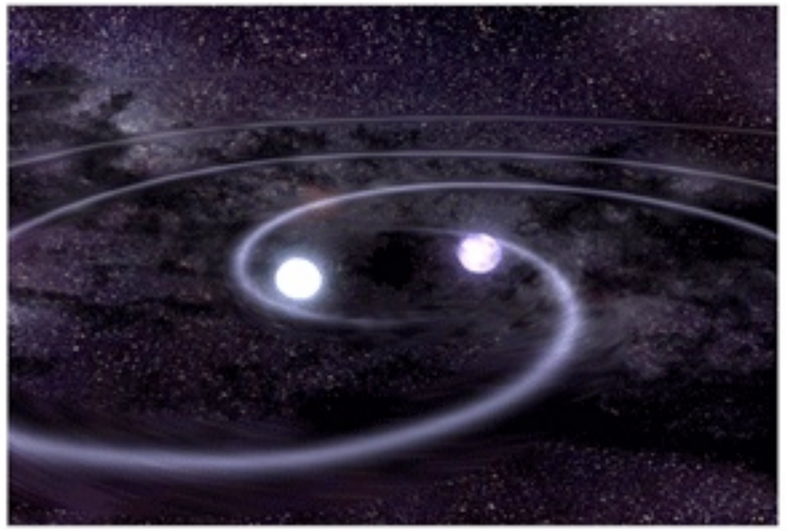
for example, this formula could describe the GW strain from a supernova explosion at the Virgo cluster during which the energy $E_{\rm GW}$ is released in GWs at a frequency of 1 kHz, and with signal duration of the order of 1 ms.

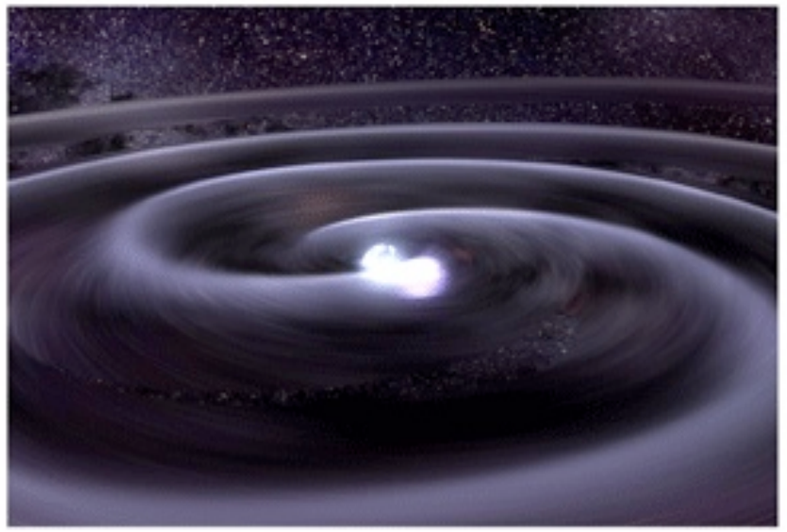
- This is why GWs are hard to detect: for a GW detector with arm length of $l = 4\,\mathrm{km}$ we are looking for changes in the arm-length of the order of

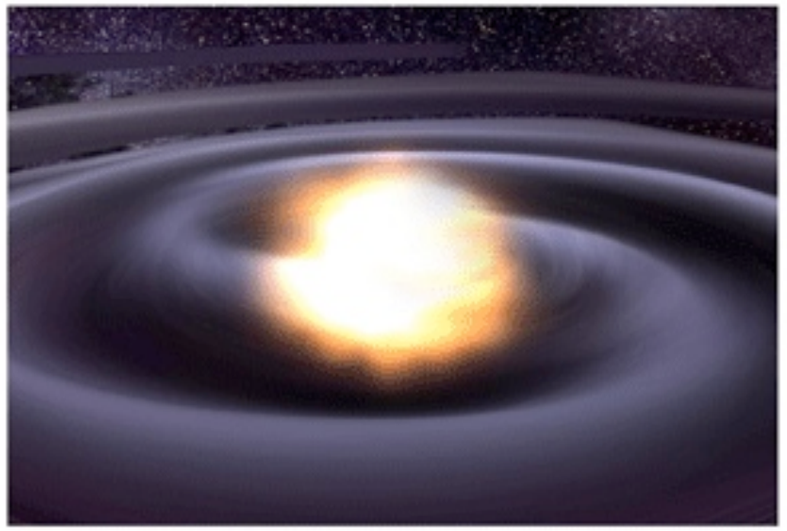
$$\Delta l = hl = 4\times 10^{-17}\,\mathrm{cm} \quad !!$$

Part II

GW sources

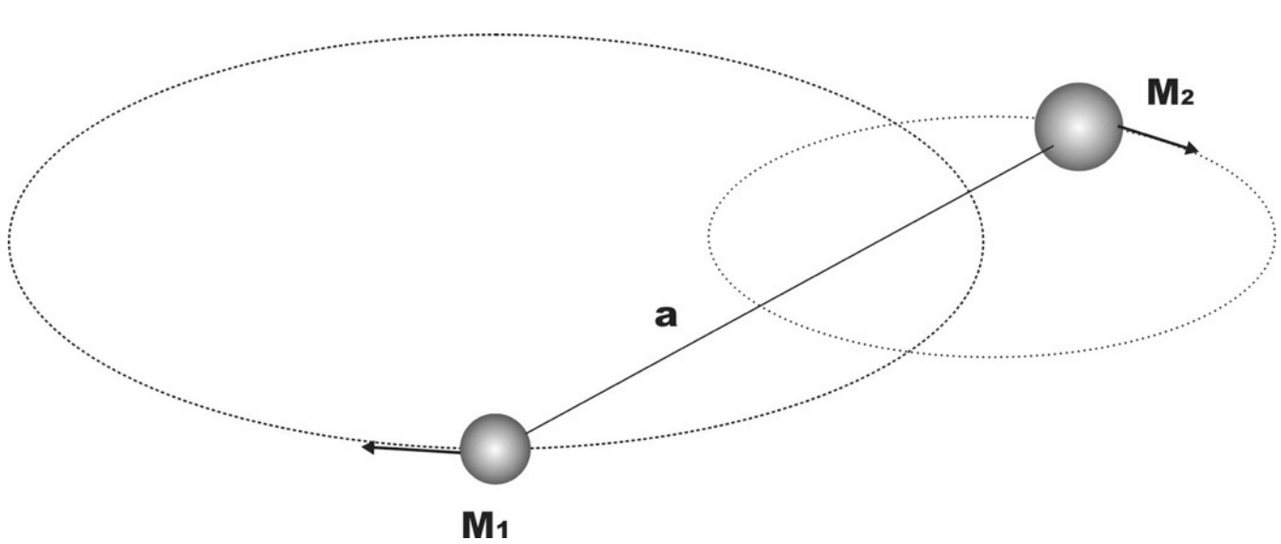






GW emission from a binary system (I)

- The binary consists of the two bodies M1 and M2 at distances a_1 and a_2 from the center of mass. The orbits are circular and lie on the x-y plane. The orbital angular frequency is Ω.



- We also define: $a = a_1 + a_2, \qquad \mu = M_1 M_2 / M, \qquad M = M_1 + M_2$

GW emission from a binary system (II)

- The only non-vanishing components of the quadrupole tensor are :

$$Q_{xx} = -Q_{yy} = (a_1^2 M_1 + a_2^2 M_2)\cos^2(\Omega t) = \frac{1}{2}\mu a^2 \cos(2\Omega t)$$

$$Q_{xy} = Q_{yx} = \frac{1}{2}\mu a^2 \sin(2\Omega t)$$

(GW frequency = 2Ω)

- And the GW luminosity of the system is (we use Kepler's 3rd law $\Omega^2 = GM/a^3$)

$$L_{\rm GW} = -\frac{dE}{dt} = \frac{G}{5c^5}(\mu\Omega a^2)^2 \langle\, 2\sin^2(2\Omega t) + 2\cos^2(2\Omega t)\,\rangle$$

$$= \frac{32}{5}\frac{G}{c^5}\mu^2 a^4 \Omega^6 = \frac{32}{5}\frac{G^4}{c^5}\frac{M^3\mu^2}{a^5}$$

GW emission from a binary system (III)

- The total energy of the binary system can be written as :

$$E = \frac{1}{2}\Omega^2 \left(M_1 a_1^2 + M_2 a_2^2\right) - \frac{G M_1 M_2}{a} = -\frac{1}{2}\frac{G\mu M}{a}$$

- As the gravitating system loses energy by emitting radiation, the distance between the two bodies shrinks at a rate:

$$\frac{dE}{dt} = \frac{G\mu M}{2a^2}\frac{da}{dt} \quad \rightarrow \quad \frac{da}{dt} = -\frac{64}{5}\frac{G^3}{c^5}\frac{\mu M}{a^3}$$

- The orbital frequency increases accordingly $\dot{T}/T = (3/2)\dot{a}/a$.

- The system will coalesce after a time: $\tau = \frac{5}{256}\frac{c^5}{G^3}\frac{a_0^4}{\mu M^4}$ (initial separation)

GW emission from a binary system (IV)

- In this analysis we have assumed circular orbits. In general the orbits can be elliptical, but it has been shown that GW emission circularizes them faster than the coalescence timescale.

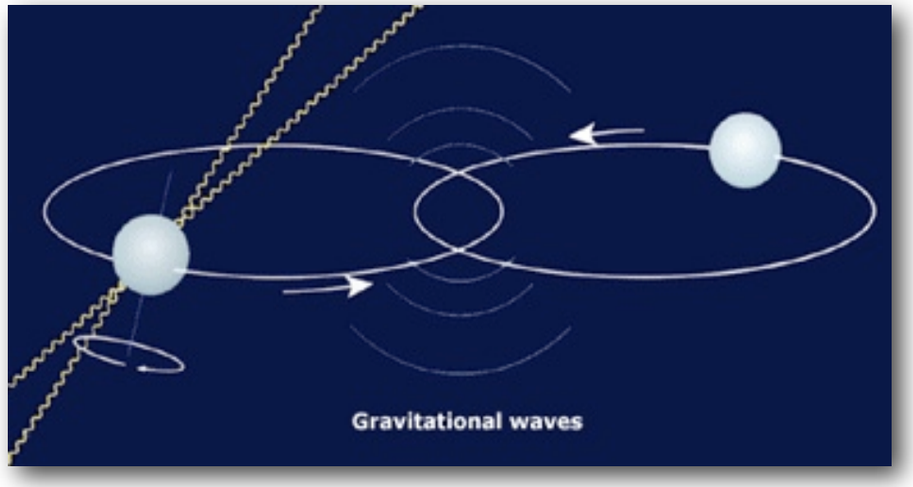
- The GW amplitude is (ignoring geometrical factors):

$$h \approx 5 \times 10^{-22} \left(\frac{M}{2.8 M_\odot}\right)^{2/3} \left(\frac{\mu}{0.7 M_\odot}\right) \left(\frac{f}{100\,\mathrm{Hz}}\right)^{2/3} \left(\frac{15\,\mathrm{Mpc}}{r}\right)$$

(set distance to the Virgo cluster, why?)

PSR 1913+16: a Nobel-prize GW source

- The now famous Hulse & Taylor binary neutron star system provided the first astrophysical evidence of the existence of GWs !



- The system's parameters: $r = 5\,\mathrm{Kpc}, \quad M_1 \approx M_2 \approx 1.4\,M_\odot, \quad T = 7\,\mathrm{h}\ 45\,\mathrm{min}$

- Using the previous equations we can predict:

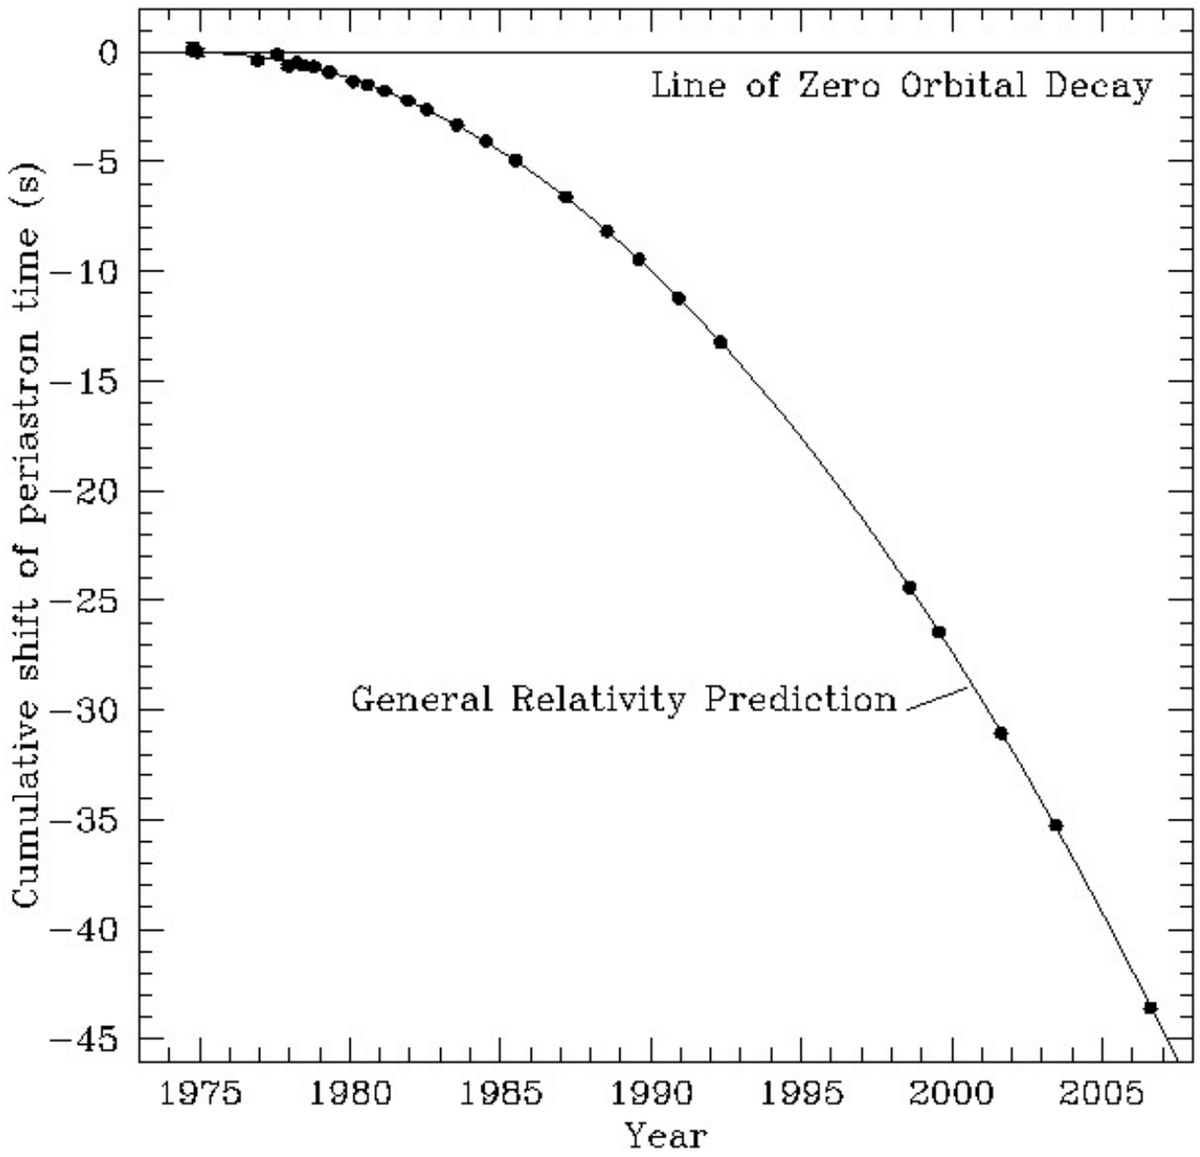
$$\dot{T} = -2.4 \times 10^{-12}\,\mathrm{sec/sec}, \qquad f_{\mathrm{GW}} = 7 \times 10^{-5}\,\mathrm{Hz}, \qquad h \sim 10^{-23}, \quad \tau \approx 3.5 \times 10^{8}\,\mathrm{yr}$$

Theory vs observations

- How can the orbital parameters be measured with such high precision?

- One of the neutron stars is a pulsar, emitting extremely stable periodic radio pulses. The emission is modulated by the orbital motion.

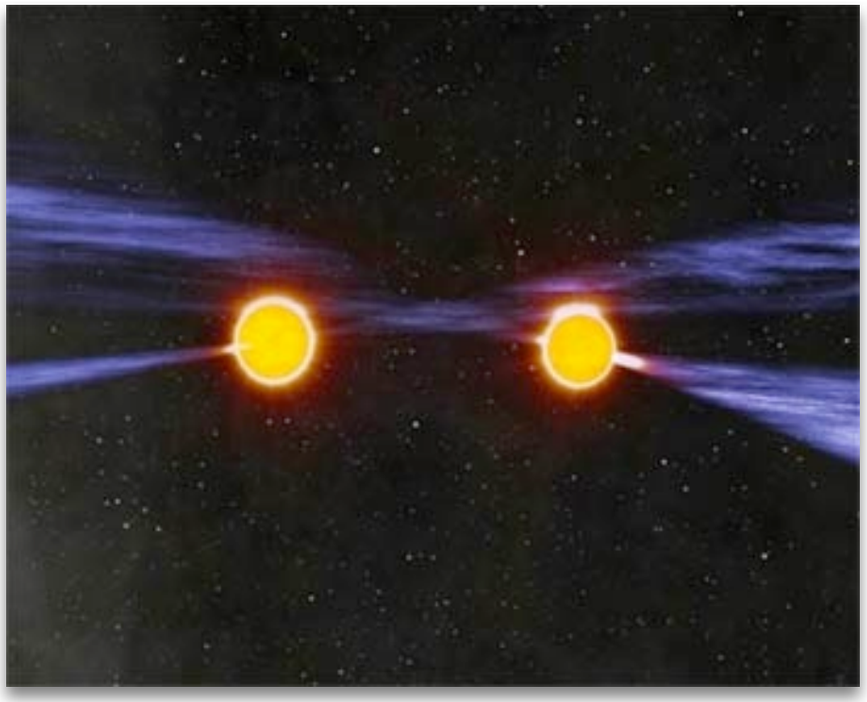
- Since the discovery of the H-T system in 1974 more such binaries were found by astronomers.

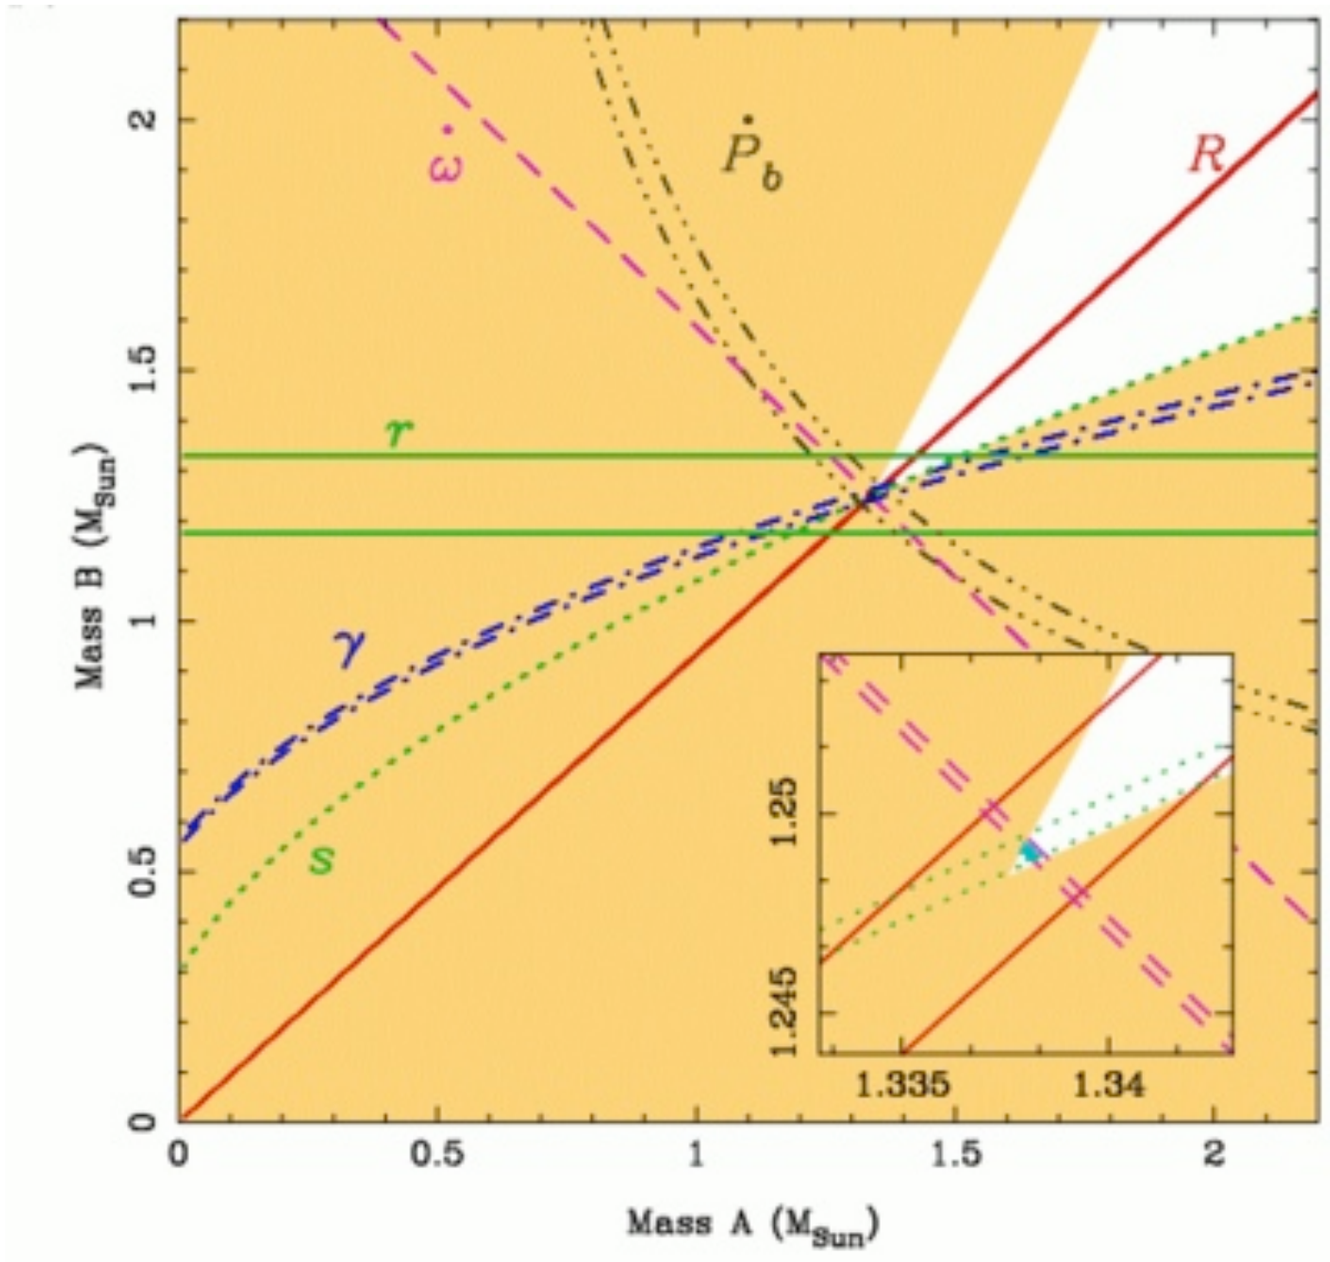


The double pulsar system

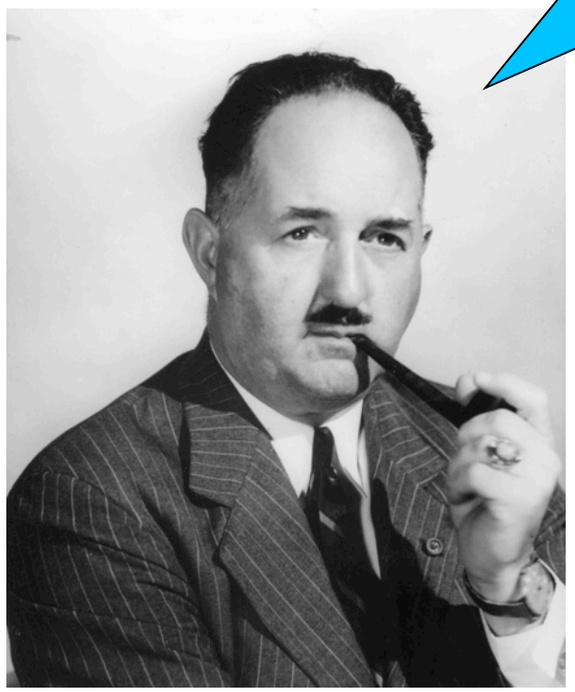
- Discovered in 2003, this binary system consists of two pulsars: PSR J0737–3039A & B.

- This rare system allows for high- precision tests of GR.



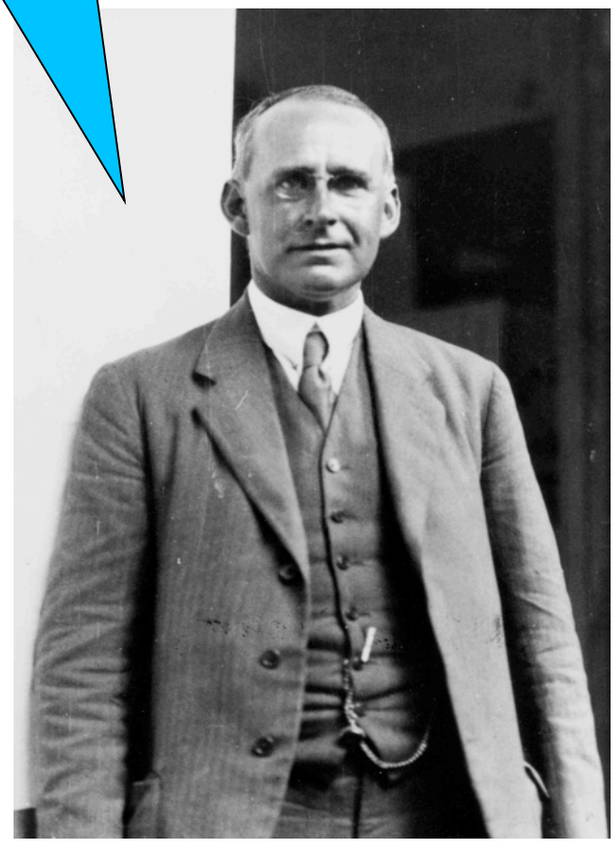


Do GWs exist? a historical footnote



They do Exist

Howard P. Robertson

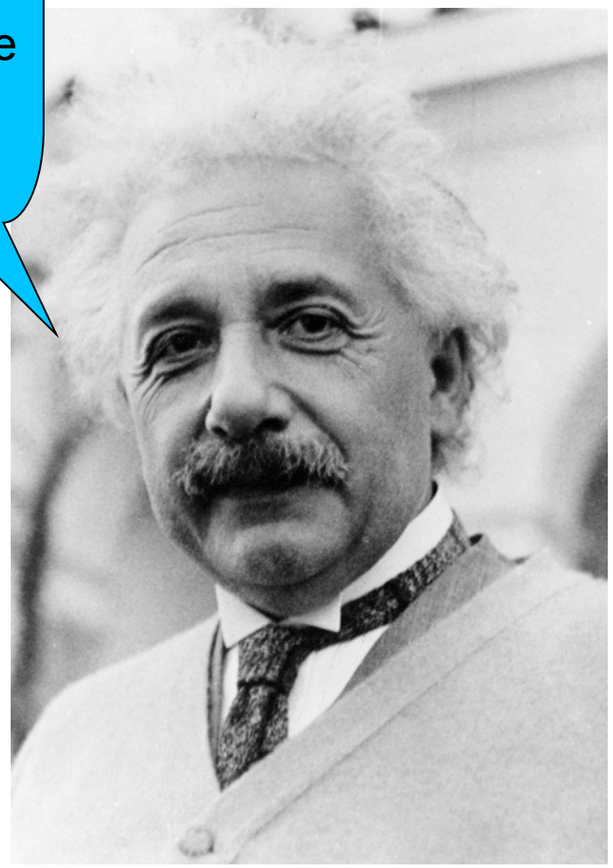


I'm skeptical

Arthur S. Eddington

They don't … They do!

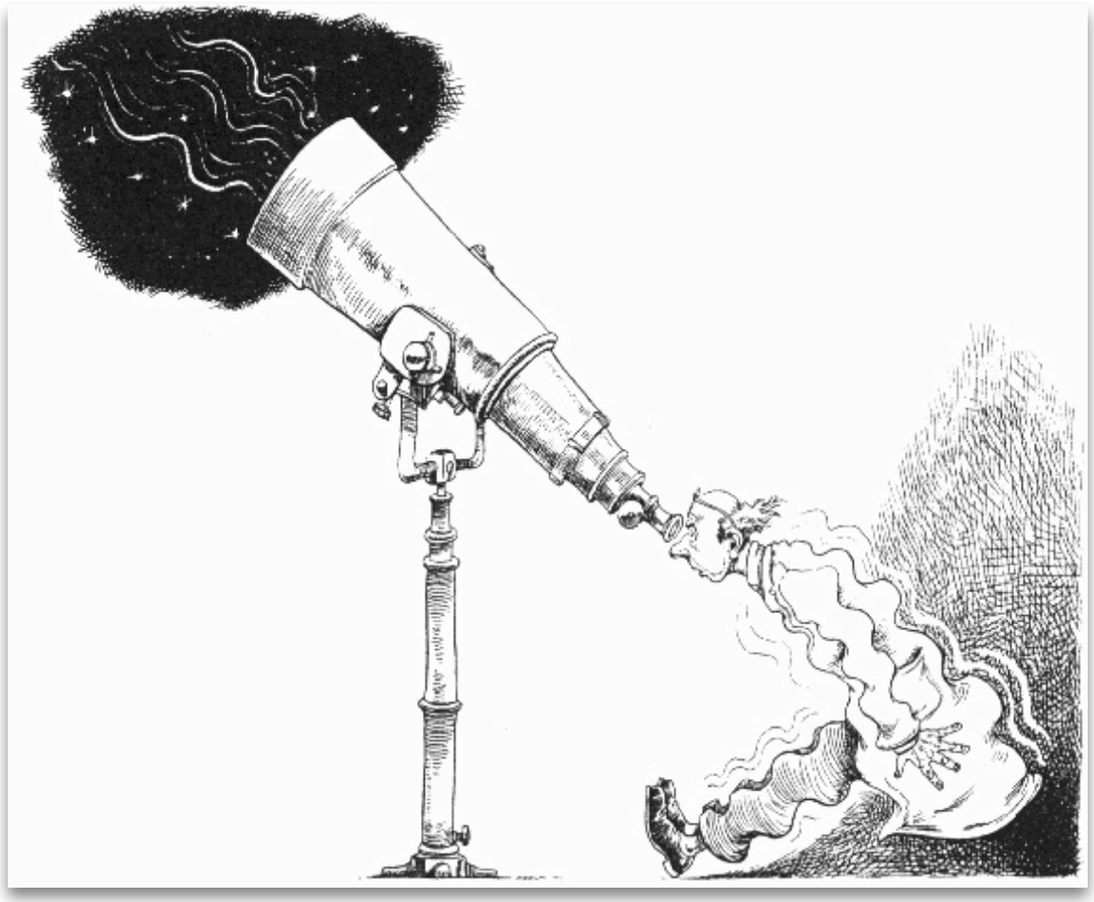
No, wait, they don't … or maybe they do



Albert Einstein

Part III

Detection of GWs



GW detectors: prehistory

- For decades after the formulation of Einstein's GR the notion of GWs was a topic for speculations and remote from real astrophysics.

- Joe Weber pioneered the construction of the first "primitive" bar detector. However, his claims of a GW detection were never verified ...

- Theoretical work in the 1970s-1990s (and the discovery of the Hulse-Taylor pulsar) advanced the popularity of GWs.

- GW astronomy is expected to become reality in the present decade.

A toy model GW detector

- Consider a GW propagating along the z-axis (with a "+" polarization and frequency ω), impinging on an idealized detector consisting of two masses joined by a spring (of length L) along the x-axis

- The resulting motion is that of a forced oscillator (with friction τ, natural frequency ω_0):

$$\ddot{\xi} + \dot{\xi}/\tau + \omega_0^2 \xi = -\frac{1}{2}\omega^2 L h_+ e^{i\omega t}$$

- The solution is:

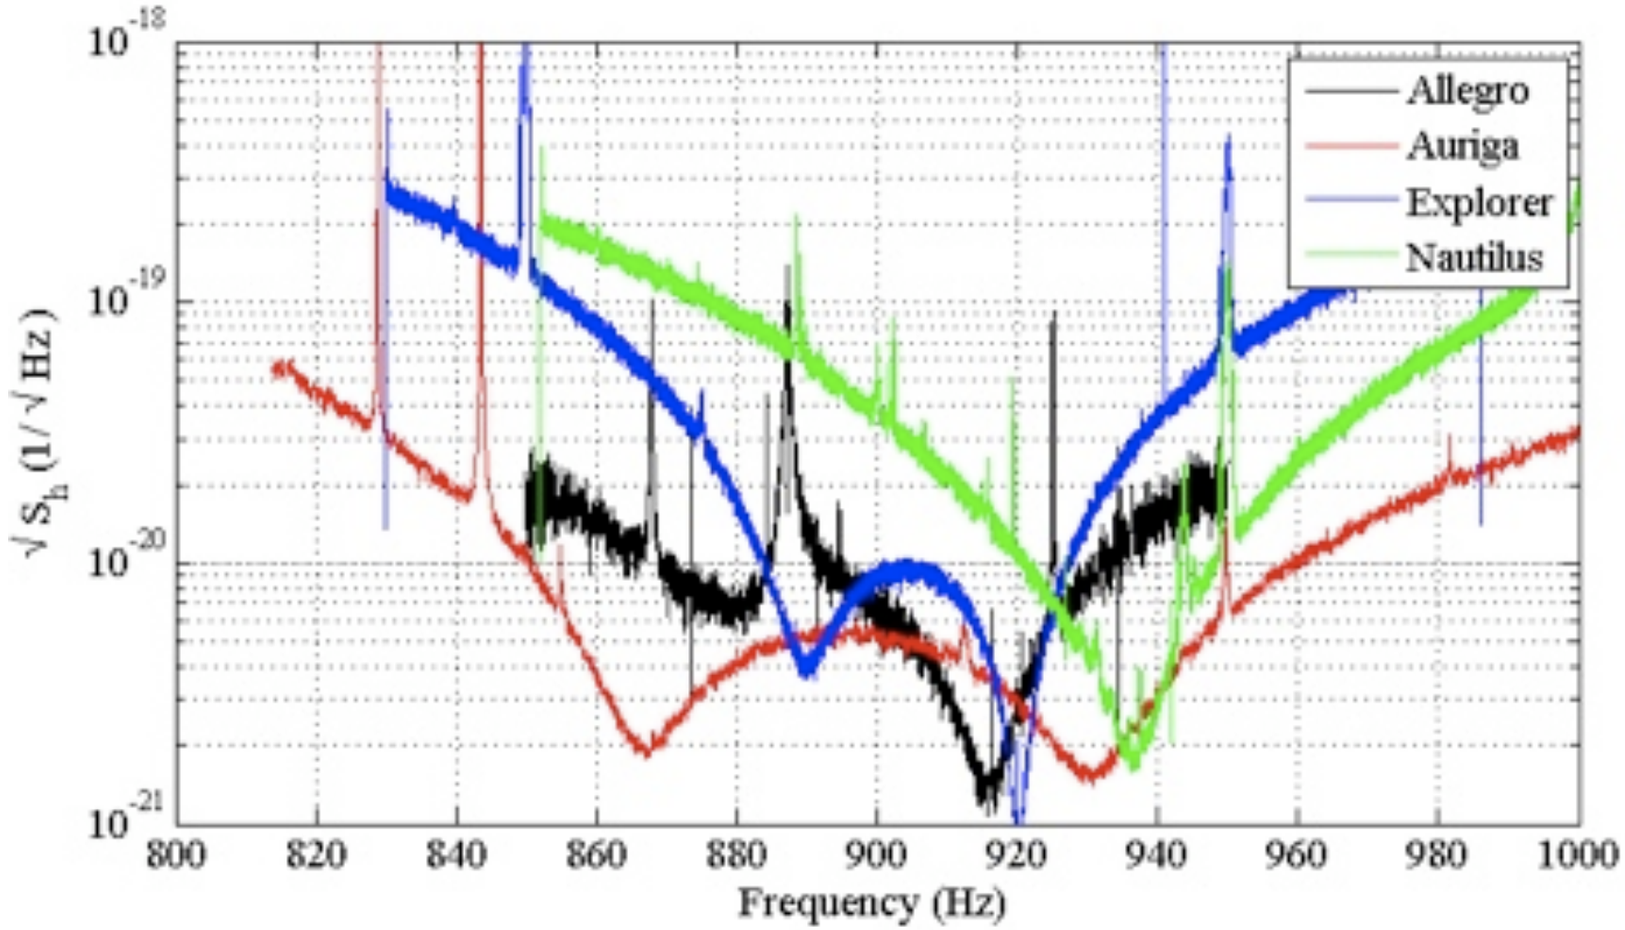
$$\xi = \frac{\omega^2 L h_+}{2(\omega_0^2 - \omega^2 + i\omega/\tau)} e^{i\omega t}$$

- The maximum amplitude is achieved at $\omega \approx \omega_0$ and has a size: $\xi_{\max} = \frac{1}{2}\omega_0 \tau L h_+$

- The detector can be optimized by increasing $\omega_0 \tau L$.

Bar detectors

- Bar detectors are narrow bandwidth instruments (like the previous toy-model)

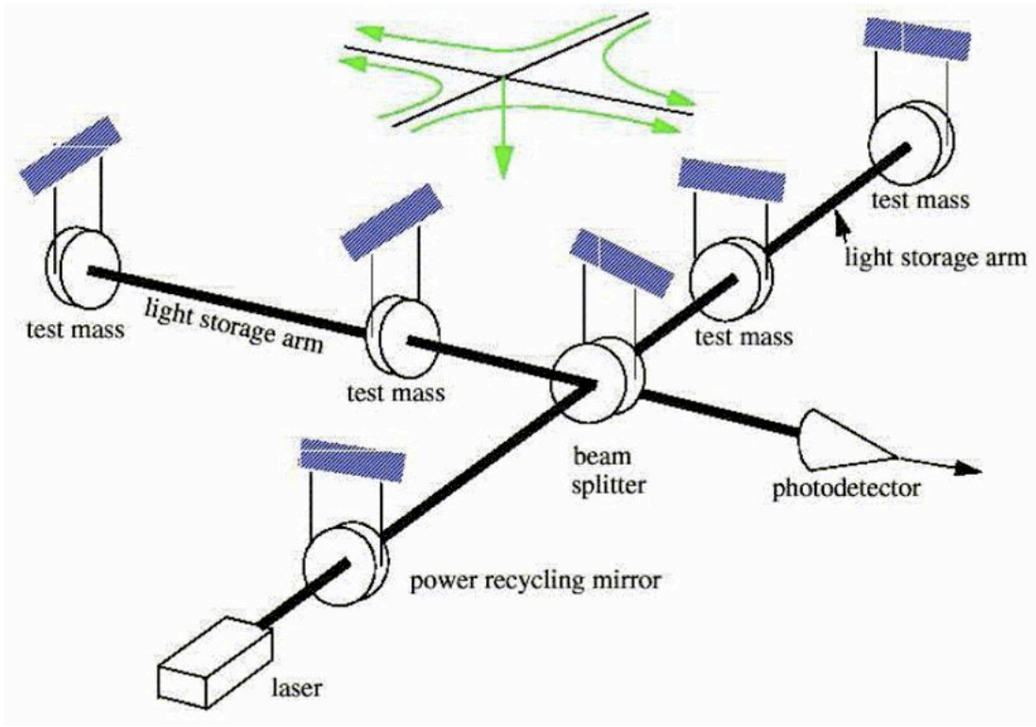


Sensitivity curves of various bar detectors

Detectors: laser interferometry

- A laser interferometer is an alternative choice for GW detection, offering a combination of very high sensitivities over a broad frequency band.

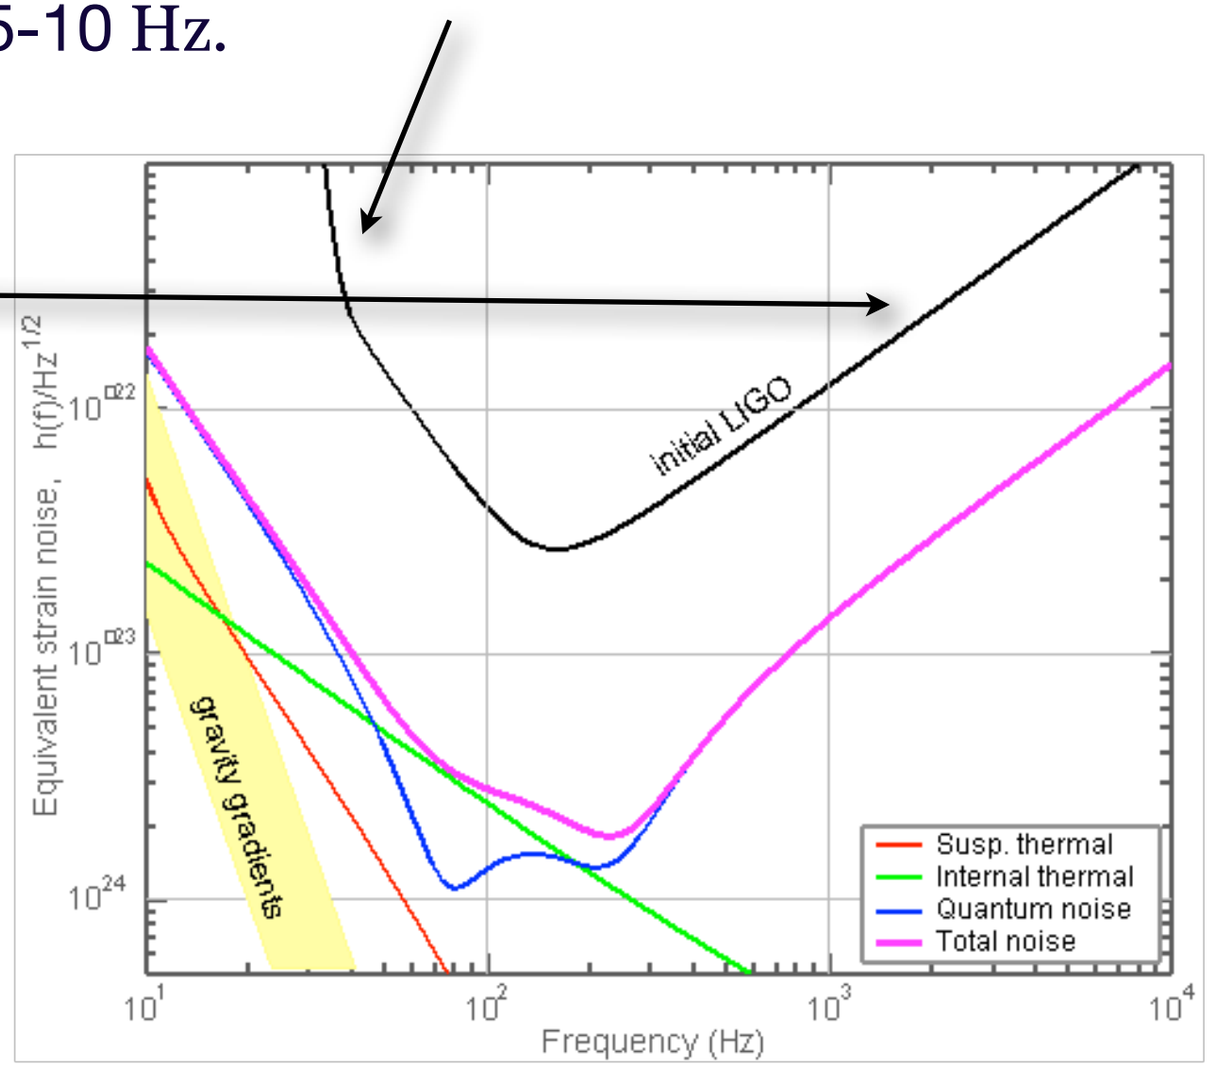
- Suspended mirrors play the role of “test-particles”, placed in perpendicular directions. The light is reflected on the mirrors and returns back to the beam splitter and then to a photodetector where the fringe pattern is monitored.



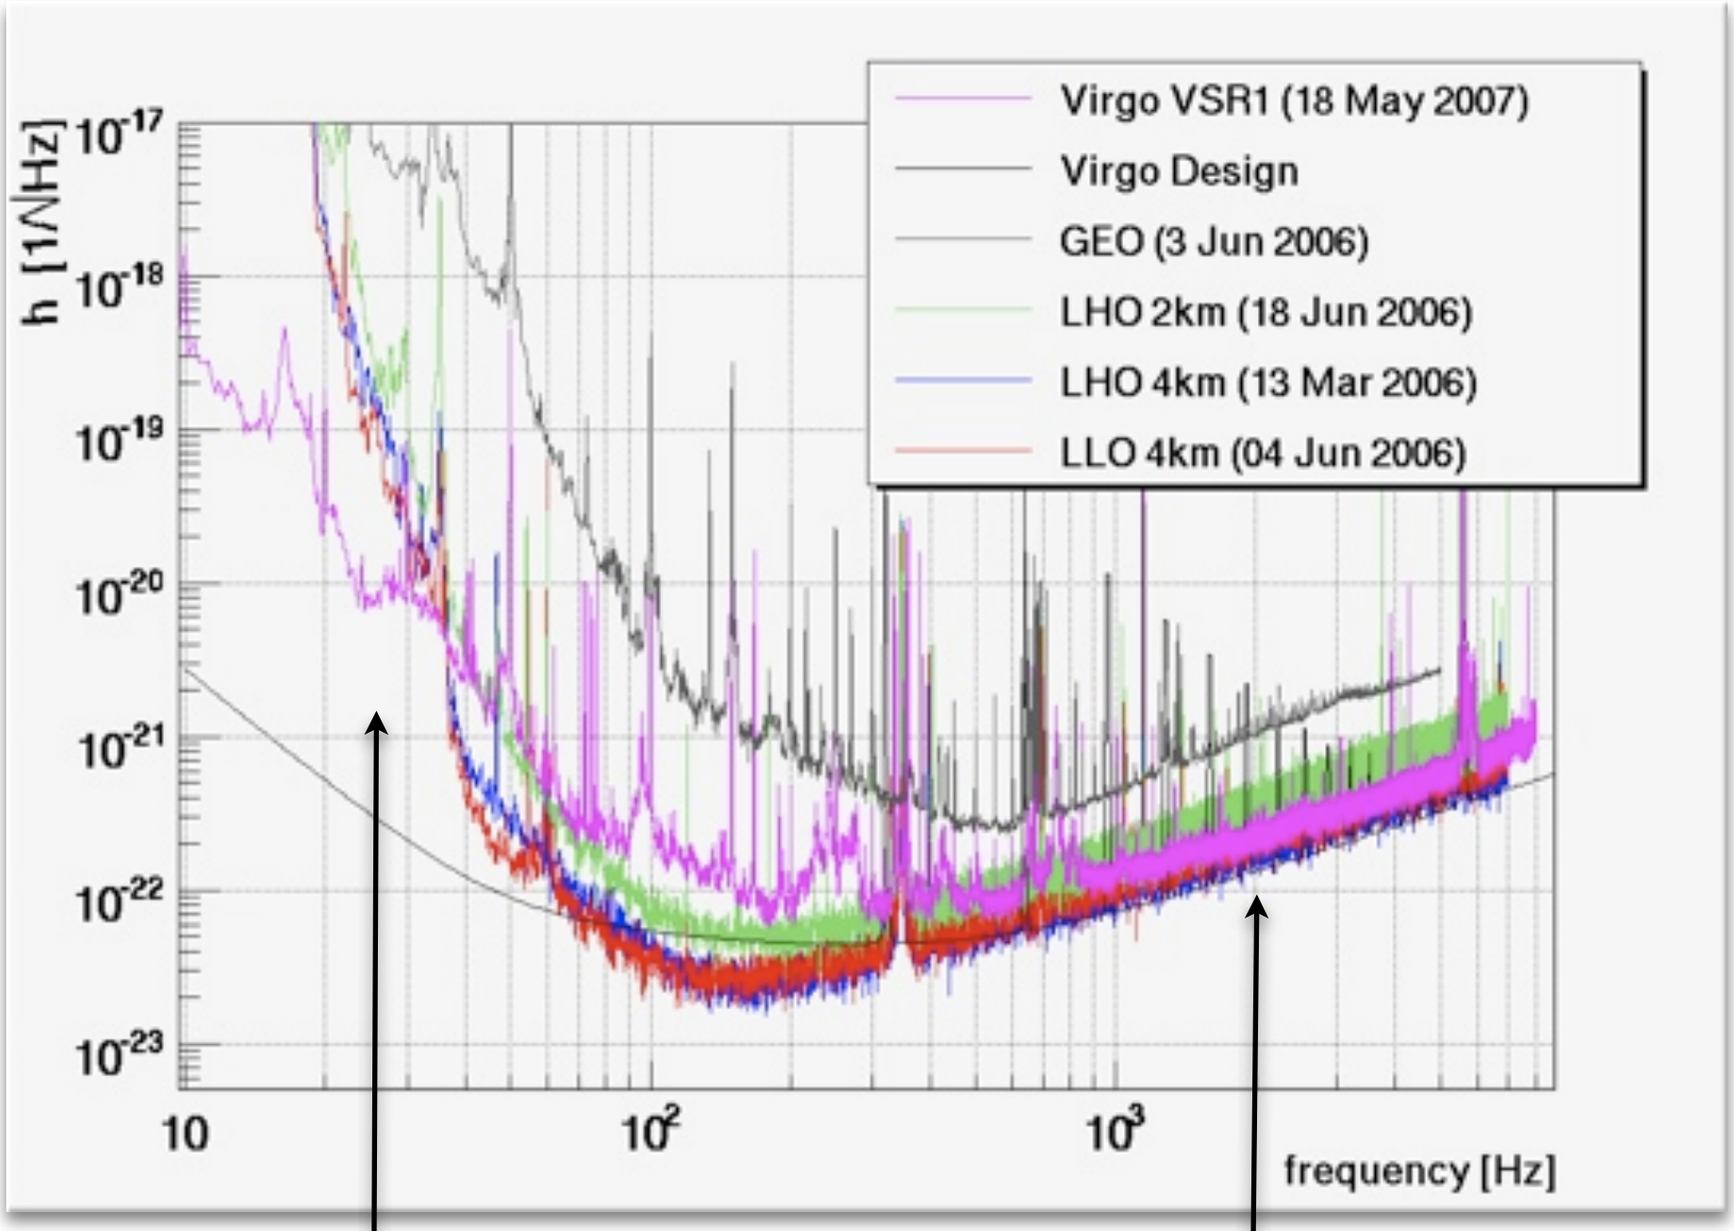
Noise in interferometric detectors

- Seismic noise (low frequencies). At frequencies below 60 Hz, the noise in the interferometers is dominated by seismic noise. The vibrations of the ground couple to the mirrors via the wire suspensions which support them. This effect is strongly suppressed by properly designed suspension systems. Still, seismic noise is very difficult to eliminate at frequencies below 5-10 Hz.

- Photon shot noise (high frequencies). The precision of the measurements is restricted by fluctuations in the fringe pattern due to fluctuations in the number of detected photons. The number of detected photons is proportional to the intensity of the laser beam. Statistical fluctuations in the number of detected photons imply an uncertainty in the measurement of the arm length.



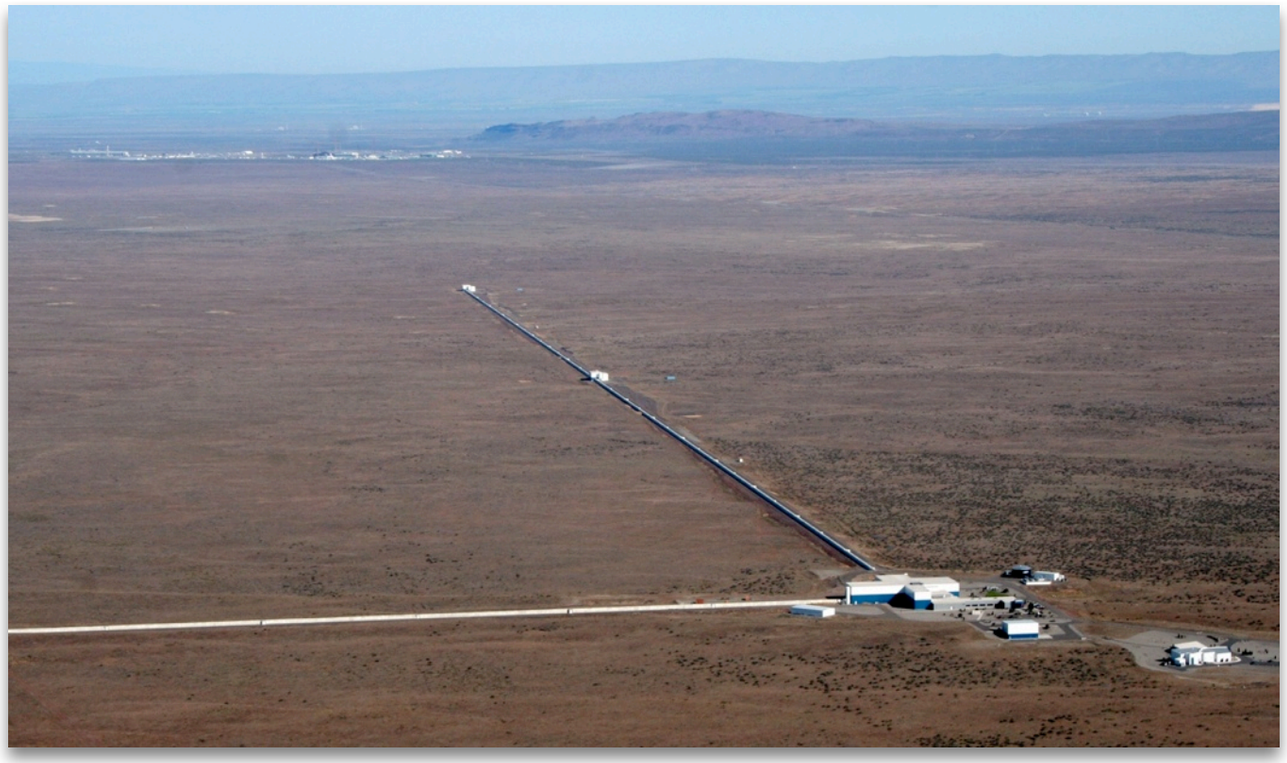
Detectors: real-life sensitivity



Seismic noise

laser photon noise

Detectors: the present (I)



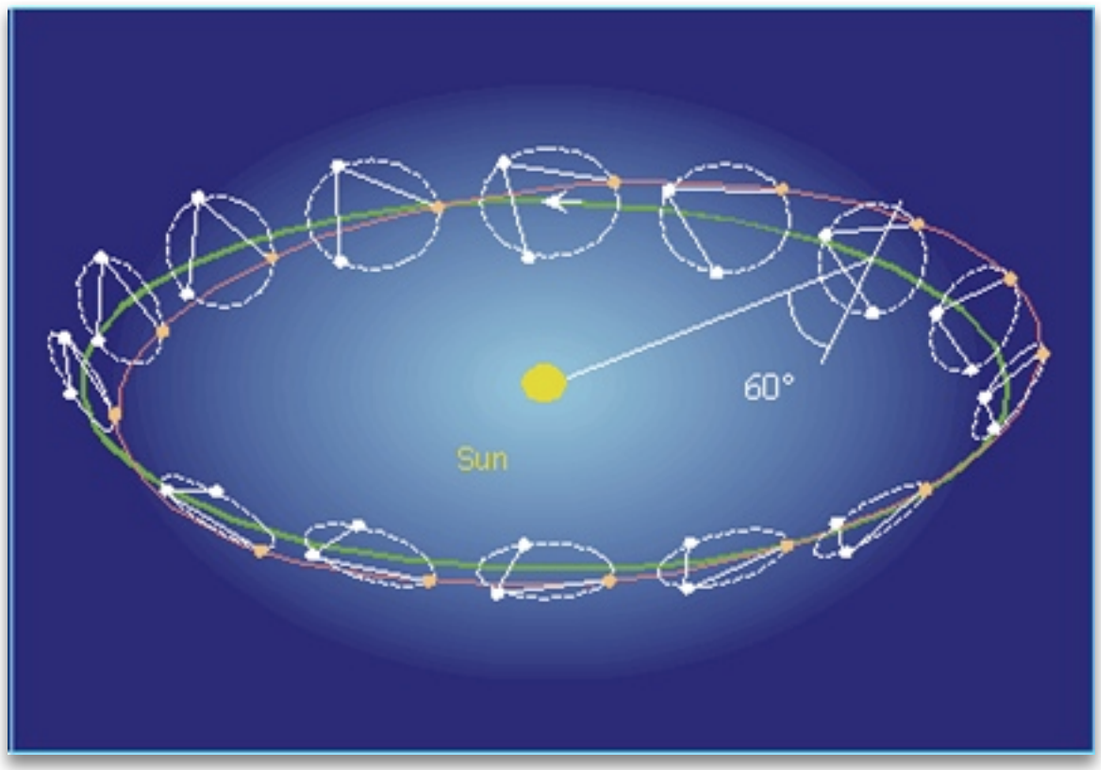
The twin LIGO detectors (L = 4 km) at Livingston Louisiana and Hanford Washington (US).

Detectors: the present (II)

The VIRGO detector (L= 3 km) near Pisa, Italy

Going to space: the LISA detector

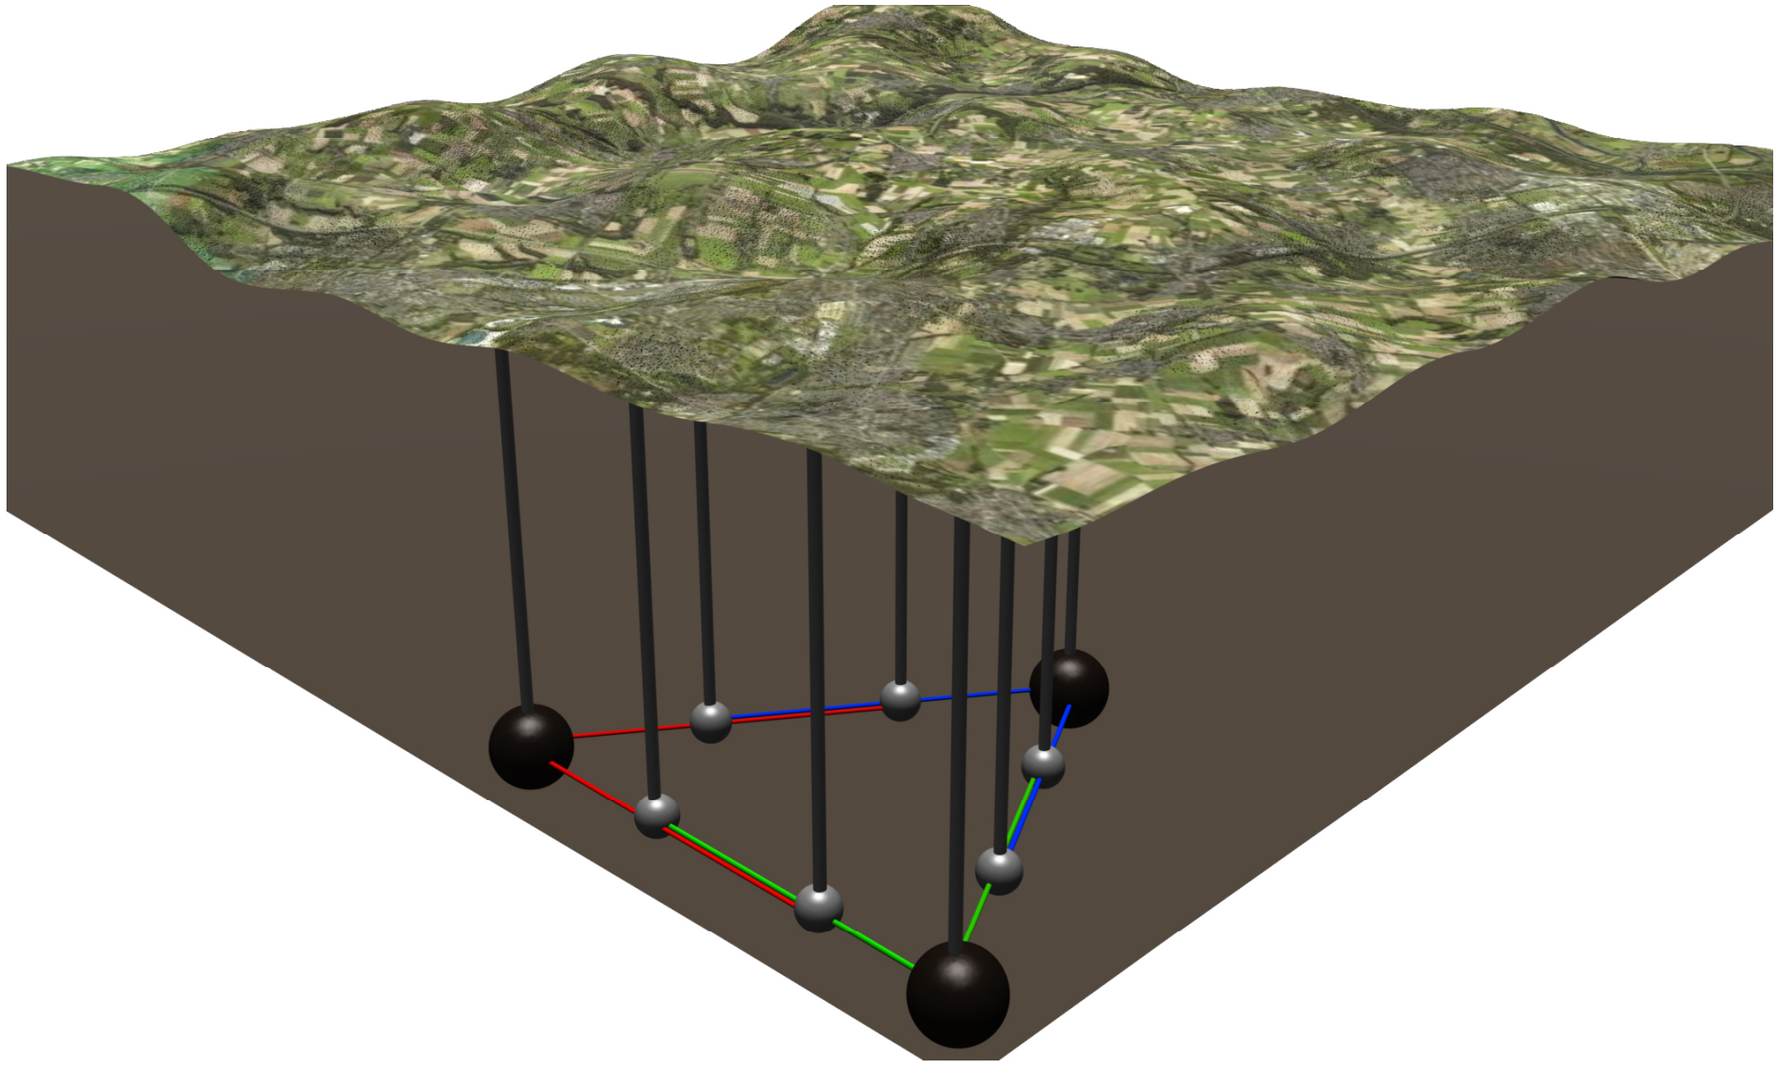
- Space-based detectors: “noise-free” environment, abundance of space!
- Long-arm baseline, low frequency sensitivity
- LISA: Up until recently a joint NASA/ESA mission, now an ESA mission only. To be launched around 2020.



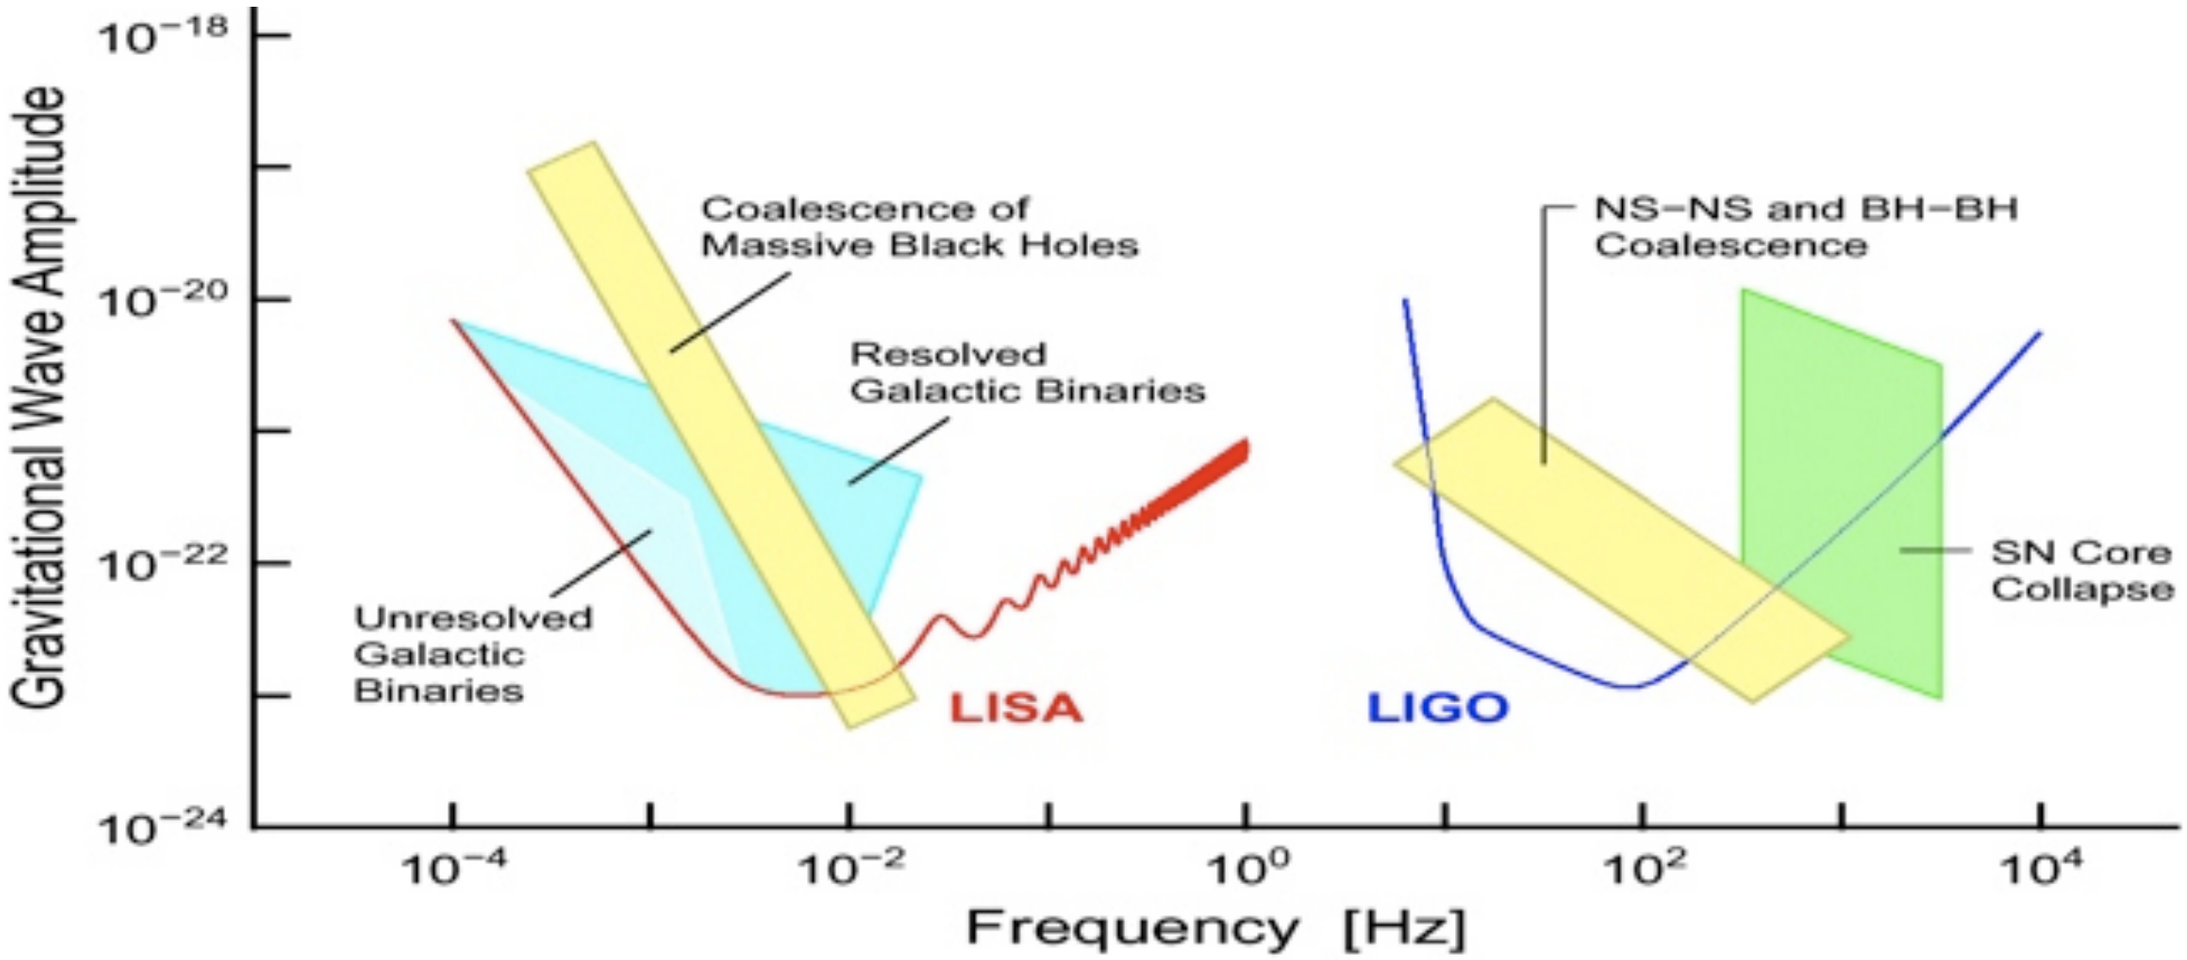
LISA (NASA-ESA)

Going underground: the ET

- The Einstein Telescope will be the next generation underground detector.



GWs detectors: ground and space



GW-related research in Spain

- Barcelona: binary BH systems, GW data analysis.

- Valencia: numerical GR/hydrodynamics, neutron star physics.

- Palma de Mallorca: GW data analysis, binary BHs.

GRAVITATIONAL WAVE PHYSICS

Kostas D. Kokkotas *

Department of Physics, Aristotle University of Thessaloniki
Thessaloniki 54124, Greece.

Abstract: Gravitational waves are propagating fluctuations of gravitational fields, that is, "ripples" in spacetime, generated mainly by moving massive bodies. These distortions of spacetime travel with the speed of light. Every body in the path of such a wave feels a tidal gravitational force that acts perpendicular to the waves direction of propagation; these forces change the distance between points, and the size of the changes is proportional to the distance between the points. Gravitational waves can be detected by devices which measure the induced length changes. The frequencies and the amplitudes of the waves are related to the motion of the masses involved. Thus, the analysis of gravitational waveforms allows us to learn about their source and, if there are more than two detectors involved in observation, to estimate the distance and position of their source on the sky.

1. INTRODUCTION

Einstein first postulated the existence of gravitational waves in 1916 as a consequence of his theory of General Relativity, but no direct detection of such waves has been made yet. The best evidence thus far for their existence is due to the work of 1993 Nobel laureates Joseph Taylor and Russell Hulse. They observed, in 1974, two neutron stars orbiting faster and faster around each other, exactly what would be expected if the binary neutron star was losing energy in the form of emitted gravitational waves. The predicted rate of orbital acceleration caused by gravitational

radiation emission according to general relativity was verified observationally, with high precision.

Cosmic gravitational waves, upon arriving on earth, are much weaker than the corresponding electromagnetic waves. The reason is that strong gravitational waves are emitted by *very* massive compact sources undergoing *very* violent dynamics. These kinds of sources are not very common and so the corresponding gravitational waves come from large astronomical distances. On the other hand, the waves thus produced propagate essentially unscathed through space, without being scattered or absorbed from intervening matter.

1.1 Why are gravitational waves interesting?

Detection of gravitational waves is important for two reasons: First, their detection is expected to open up a new window for observational astronomy since the information carried by gravitational waves is very different from that carried by electromagnetic waves. This new window onto universe will complement our view of the cosmos and will help us unveil the fabric of spacetime around black-holes, observe directly the formation of black holes or the merging of binary systems consisting of black holes or neutron stars, search for rapidly spinning neutron stars, dig deep into the very early moments of the origin of the universe, and look at the very center of the galaxies where supermassive black holes weighting millions of solar masses are hidden. These are only a few of the great scientific discoveries that scientists will witness during the first decade of the 21st century. Second, detecting gravitational waves is important for our understanding of the fundamental laws of physics; the proof that gravitational waves exist will verify a fundamental 85-year-old prediction of general relativity. Also, by comparing the arrival times of light and gravitational waves, from, e.g., supernovae, Einstein's prediction that light and gravitational waves travel at the same speed could be checked. Finally, we could verify that they have the polarization predicted by general relativity.

1.2 How we will detect them?

Up to now, the only indication of the existence of gravitational waves is the indirect evidence that the orbital energy in the Hulse-Taylor binary pulsar is drained away at a rate consistent with the prediction of general relativity. The gravitational wave is a signal, the shape of which depends upon the changes in the gravitational field of its source. As it has been mentioned earlier, any body in the path of the wave will feel an oscillating tidal gravitational force that acts in a plane perpendicular to the waves direction of propagation. This means that a group of freely moving masses, placed on a plane perpendicular to the direction of propagation of the wave, will oscillate as long as the wave passes through them, and the distance between them will vary as a function of time as in Figure 1. Thus, the detection of gravitational waves can be accomplished by monitoring the tiny changes in the distance between

freely moving test masses. These changes are extremely small; for example, when the Hulse-Taylor binary system finally merges, the strong gravitational wave signal that will be emitted will induce changes in the distance of two particles on earth, that are 1 km apart much smaller than the diameter of the atomic nucleus! To measure such motions of macroscopic objects is a tremendous challenge for experimentalists. As early as the mid-1960s, Joseph Weber designed and constructed heavy metal bars, seismically isolated, to which a set of piezoelectric strain transducers were bonded in such a way that they could detect vibrations of the bar if it had been excited by a gravitational wave. Today, there are a number of such apparatuses operating around the world which have achieved unprecedented sensitivities, but they still are not sensitive enough to detect gravitational waves. Another form of gravitational wave detector that is more promising uses laser beams to measure the distance between two well-separated masses. Such devices are basically kilometer sized laser interferometers consisting of three masses placed in an L-shaped configuration. The laser beams are reflected back and forth between the mirrors attached to the three masses, the mirrors lying several kilometers away from each other. A gravitational wave passing by will cause the lengths of the two arms to oscillate with time. When one arm contracts, the other expands, and this pattern alternates. The result is that the interference pattern of the two laser beams changes with time. With this technique, higher sensitivities could be achieved than are possible with the bar detectors. It is expected that laser interferometric detectors are the ones that will provide us with the first direct detection of gravitational waves.

2. THEORY OF GRAVITATIONAL WAVES

Newton's theory of gravity has enjoyed great success in describing many aspects of our every-day life and additionally explains most of the motions of celestial bodies in the universe. General relativity corrected Newton's theory and is recognized as one of the most ingenious creations of the human mind. The laws of general relativity, though, in the case of slowly moving bodies and weak gravitational fields reduce to the standard laws of Newtonian theory. Nevertheless, general relativity is conceptually different from Newton's theory as it introduces the notion of spacetime and its geometry. One of the basic differences of the two theories concerns the speed of propagation of any change in a gravitational field. As the apple falls from the tree, we have a rearrangement of the distribution of mass of the earth, the gravitational field changes, and a distant observer with a high-precision instrument will detect this change. According to Newton, the changes of the field are instantaneous, i.e., they propagate with infinite speed; if this were true, however the principle of causality would break down. No information can travel faster than the speed of light. In Einstein's theory there is no such ambiguity; the information of the varying gravitational field propagates with finite speed, the speed of light, as a ripple in the

Figure 1: The effects of a gravitational wave travelling perpendicular the plane of a circular ring of particles, is sketched as a series of snapshots. The deformations due the two polarizations are shown.

fabric of spacetime. These are the gravitational waves. The existence of gravitational waves is an immediate consequence of any relativistic theory of gravity. However, the strength and the form of the waves depend on the details of the gravitational theory. This means that the detection of gravitational waves will also serve as a test of basic gravitational theory.

The fundamental geometrical framework of relativistic metric theories of gravity is spacetime, which mathematically can be described as a four-dimensional manifold whose points are called *events*. Every event is labeled by four coordinates x^μ ($\mu = 0, 1, 2, 3$); the three coordinates x^i ($i = 1, 2, 3$) give the spatial position of the event, while x^0 is related to the coordinate time t ($x^0 = ct$, where c is the speed of light, which unless otherwise stated will be set equal to 1). The choice of the coordinate system is quite arbitrary and coordinate transformations of the form $\tilde{x}^\mu = f^\mu(x^\lambda)$ are allowed. The motion of a test particle is described by a curve in spacetime. The distance ds between two neighboring events, one with coordinates x^μ and the other with coordinates $x^\mu + dx^\mu$, can be expressed as a function of the coordinates via a symmetric tensor $g_{\mu\nu}(x^\lambda) = g_{\nu\mu}(x^\lambda)$, i.e.,

$$ds^2 = g_{\mu\nu} dx^\mu dx^\nu \tag{2.1}$$

This is a generalization of the standard measure of distance between two points in Euclidian space. For the Minkowski spacetime (the spacetime of special relativity),

$g_{\mu\nu} \equiv \eta_{\mu\nu} = \text{diag}(-1, 1, 1, 1)$. The symmetric tensor is called the *metric tensor* or simply the metric of the spacetime. In general relativity the gravitational field is described by the metric tensor alone, but in many other theories one or more supplementary fields may be needed as well. In what follows, we will consider only the general relativistic description of gravitational fields, since most of the alternative theories fail to pass the experimental tests.

The information about the degree of curvature (i.e., the deviation from flatness) of a spacetime is encoded in the metric of the spacetime. According to general relativity, any distribution of mass bends the spacetime fabric and the Riemann tensor $R_{\kappa\lambda\mu\nu}$ (that is a function of the metric tensor $g_{\mu\nu}$ and of its first and second derivatives) is a measure of the spacetime curvature. The Riemann tensor has 20 independent components. When it vanishes the corresponding spacetime is flat.

In the following presentation, we will consider mass distributions, which we will describe by the stress-energy tensor $T^{\mu\nu}(x^\lambda)$. For a perfect fluid (a fluid or gas with isotropic pressure but without viscosity or shear stresses) the stress-energy tensor is given by the following expression

$$T^{\mu\nu}(x^\lambda) = (\rho + p)u^\mu u^\nu + pg^{\mu\nu}, \tag{2.2}$$

where $p(x^\lambda)$ is the local pressure, $\rho(x^\lambda)$ is the local energy density and $u^\mu(x^\lambda)$ is the four velocity of the infinitesimal fluid element characterized by the event x^λ.

Einstein's gravitational field equations connect the curvature tensor (see below) and the stress-energy tensor through the fundamental relation

$$G_{\mu\nu} \equiv R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R = kT_{\mu\nu} \tag{2.3}$$

This means that the gravitational field, which is directly connected to the geometry of spacetime, is related to the distribution of matter and radiation in the universe. By solving the field equations, both the gravitational field (the $g_{\mu\nu}$) and the motion of matter is determined. $R_{\mu\nu}$ is the so- called Ricci tensor and comes from a contraction of the Riemann tensor ($R_{\mu\nu} = g^{\alpha\sigma}R_{\sigma\mu\rho\nu}$), R is the scalar curvature ($R = g^{\rho\sigma}R_{\rho\sigma}$), while $G_{\mu\nu}$ is the so-called Einstein tensor, $k = 8\pi G/c^4$ is the coupling constant of the theory and is the gravitational constant, which, unless otherwise stated will be considered equal to 1. The vanishing of the Ricci tensor corresponds to a spacetime free of any matter distribution. However, this does not imply that the Riemann tensor is zero. As a consequence, in the empty space far from any matter distribution, the Ricci tensor will vanish while the Riemann tensor can be nonzero; this means that the effects of a propagating gravitational wave in an empty spacetime will be described via the Riemann tensor.

2.1 Linearized theory

Now lets assume that an observer is far away from a given static matter distribution, and the spacetime in which he or she lives is described by a metric $g_{\mu\nu}$. Any change

in the matter distribution, i.e., in $T_{\mu\nu}$, will induce a change in the gravitational field, which will be recorded as a change in metric. The new metric will be

$$\tilde{g}_{\mu\nu} = g_{\mu\nu} + h_{\mu\nu} \tag{2.4}$$

where $h_{\mu\nu}$ is a tensor describing the variations induced in the spacetime metric. As we will describe analytically later, this new tensor describes the propagation of ripples in spacetime curvature, i.e., *the gravitational waves*. In order to calculate the new tensor we have to solve Einsteins equations for the varying matter distribution. This is not an easy task in general. However, there is a convenient, yet powerful, way to proceed, namely to assume that $h_{\mu\nu}$ is small ($|h_{\mu\nu}| \ll 1$), so that we need only keep terms linear in $h_{\mu\nu}$ in our calculations. In making this approximation we are effectively assuming that the disturbances produced in spacetime are not huge. This *linearization approach* has proved extremely useful for calculations, and for weak fields at least, gives accurate results for the generation of the waves and for their propagation.

The first attempt to prove that in general relativity gravitational perturbations propagate as waves with the speed of light is due to Einstein himself. Shortly after the formulation of his theory - the year after - he proved that by assuming linearized perturbations around a flat metric, i.e., $g_{\mu\nu} = \eta_{\mu\nu}$, then the tensor

$$\tilde{h}_{\mu\nu} \equiv h_{\mu\nu} - \frac{1}{2}\eta_{\mu\nu}h^{\alpha}_{\alpha} \tag{2.5}$$

is governed by a wave equation, which admits plane wave solutions similar to the ones of electromagnetism; here $h_{\mu\nu}$ is the metric perturbation and $\tilde{h}_{\mu\nu}$ is the gravitational field (or the trace reverse of $h_{\mu\nu}$). Then the linear field equations in vacuum have the form

$$\left(-\frac{\partial^2}{\partial t^2} + \nabla^2\right)\tilde{h}^{\mu\nu} \equiv \partial_\lambda \partial^\lambda \tilde{h}^{\mu\nu} = 0 \tag{2.6}$$

($\partial_\mu k^\alpha \equiv \partial k^\alpha / \partial x^\mu$), which is the three-dimensional wave equation. To obtain the above simplified form, the condition $\partial_\mu \tilde{h}^{\mu\nu} = 0$, known as *Hilbert's gauge condition* (equivalent to the Lorentz gauge condition of electromagnetism), has been assumed. A gauge transformation is a suitable change of coordinates defined by

$$x'^{\mu} \equiv x^{\mu} + \xi^{\mu} \tag{2.7}$$

which induces a redefinition of the gravitational field tensor

$$\tilde{h}'_{\mu\nu} \equiv \tilde{h}_{\mu\nu} - \partial_\mu \xi_\nu - \partial_\nu \xi_\mu + \eta_{\mu\nu}\partial_\lambda \xi^\lambda. \tag{2.8}$$

It can be easily proved that ξ^μ must satisfy the condition

$$\partial_\nu \partial^\nu \xi^\mu = 0, \tag{2.9}$$

so that the new gravitational field is in agreement with the Hilberts gauge condition. The solution of equation (2.9) defines the four components of ξ^μ so that the new tensor $\tilde{h}'_{\mu\nu}$ is also a solution of the wave equation (2.6), and thus, have the same physical meaning as $\tilde{h}_{\mu\nu}$. In general, gauge transformations correspond to symmetries of the field equations, which means that the field equations are invariant under such transformations. This implies that the field equations do not determine the field uniquely; however, this ambiguity in determining the field is devoid of any physical meaning.

The simplest solution to the wave equation (2.6) is a plane wave solution of the form

$$\tilde{h}^{\mu\nu} = A^{\mu\nu} e^{ik_\alpha x^\alpha}, \tag{2.10}$$

where $A^{\mu\nu}$ is a constant symmetric tensor, the *polarization tensor*, in which information about the amplitude and the polarization of the waves is encoded, while k_α is a constant vector, the *wave vector*, that determines the propagation direction of the wave and its frequency. In physical applications we will use only the real part of the above wave solution. By applying the Hilbert gauge condition on the plane wave solution we obtain the relation $A^{\mu\nu}k_\mu = 0$, the geometrical meaning of which is that $A^{\mu\nu}$ and k_μ are orthogonal. This relation can be written as four equations that impose four conditions on $A^{\mu\nu}$, and this is the first step in reducing the number of its independent components. As a consequence, $A^{\mu\nu}$, instead of having 10 independent components (as has every symmetric second rank tensor in a four dimensional space), has only 6 independent ones. Further substitution of the plane wave solution in the wave equation leads to the important equation $k_\mu k^\mu = k_0^2 - (k_x^2 + k_y^2 + k_z^2) = 0$, which means that k_μ is a *lightlike* or *null vector*, i.e., the wave propagates on the light-cone. This means that the speed of the wave is 1, i.e., equal to the speed of light. The frequency of the wave is $\omega = k^0$.

Up to this point it has been proven that $A^{\mu\nu}$ has six arbitrary components, but due to the gauge freedom, i.e., the freedom in choosing the four components of the vector ξ^μ, the actual number of its independent components can be reduced to **two**, in a suitable chosen gauge. The *transverse–traceless* or *TT gauge* is an example of such a gauge. In this gauge, only the spatial components of $\tilde{h}_{\mu\nu}$ are non-zero (hence $\tilde{h}_{\mu 0} = 0$), which means that the wave is *transverse* to its own direction of propagation, and, additionally, the sum of the diagonal components is zero ($\tilde{h}^\mu_\mu = h^0_0 + h^1_1 + h^2_2 + h^3_3 \equiv \tilde{h} = h = 0$) (*traceless*). Due to this last property and equation (5), in this gauge there is no difference between $h_{\mu\nu}$(the perturbation of the metric) and $\tilde{h}_{\mu\nu}$ (the gravitational field). It is customary to write the gravitational wave solution in the TT gauge as $h^{TT}_{\mu\nu}$. That $A_{\mu\nu}$ has only two independent components means that a gravitational wave is completely described by two dimensionless amplitudes, h_+ and $h_\times$, say. If, for example, we assume a wave propagating along the z-direction,

then the amplitude $A^{\mu\nu}$ can be written as

$$A^{\mu\nu} = h_+ \epsilon_+^{\mu\nu} + h_\times \epsilon_\times^{\mu\nu} \tag{2.11}$$

where $\epsilon_+^{\mu\nu}$ and $\epsilon_\times^{\mu\nu}$ are the so-called *unit polarization tensors* defined by

$$\epsilon_+^{\mu\nu} \equiv \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \qquad \epsilon_\times^{\mu\nu} \equiv \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \tag{2.12}$$

As mentioned earlier, the Riemann tensor is a measure of the curvature of spacetime. A gravitational wave, propagating in a flat spacetime, generates periodic distortions, which can be described in terms of the Riemann tensor. In linearized theory the Riemann tensor takes the following gauge-independent form:

$$R_{\kappa\lambda\mu\nu} = \frac{1}{2}\left(\partial_{\nu\kappa} h_{\lambda\mu} + \partial_{\lambda\mu} h_{\kappa\nu} - \partial_{\kappa\mu} h_{\lambda\nu} - \partial_{\lambda\nu} h_{\kappa\mu}\right), \tag{2.13}$$

which is considerably simplified by choosing the TT gauge:

$$R^{TT}_{j0k0} = -\frac{1}{2}\frac{\partial^2}{\partial t^2} h^{TT}_{jk}, \quad j,k = 1,2,3. \tag{2.14}$$

Furthermore, in the Newtonian limit

$$R^{TT}_{j0k0} \approx \frac{\partial^2 \Phi}{\partial x^j \partial x^k}, \tag{2.15}$$

where Φ describes the gravitational potential in Newtonian theory. Earlier we defined the Riemann tensor as a geometrical object, but this tensor has a simple physical interpretation: it is the tidal force field and describes the relative acceleration between two particles in free fall. If we assume two particles moving freely along geodesics of a curved spacetime with coordinates $x^\mu(\tau)$ and $x^\mu(\tau) + \xi^\mu(\tau)$ (for a given value of the proper time τ, $\xi^\mu(\tau)$ is the displacement vector connecting the two events) it can be shown that, in the case of slowly moving particles,

$$\frac{d^2 \xi^k}{dt^2} \approx -R^k_{0j0}{}^{TT} \xi^j. \tag{2.16}$$

This is a simplified form of the equation of *geodesic deviation*. Hence, the tidal force acting on a particle is:

$$f^k \approx -m R^k_{0j0} \xi^j, \tag{2.17}$$

where m is the mass of the particle. Equation (2.17) corresponds to the standard Newtonian relation for the tidal force acting on a particle in a field Φ.

Keeping this in mind, we will try to visualize the effect of a gravitational wave. Let us first consider two freely falling particles hit by a gravitational wave travelling along the z-direction, with the (+) polarization present only, i.e.,

$$h^{\mu\nu} = h_+ \epsilon^{\mu\nu} \cos[\omega(t-z)]. \tag{2.18}$$

Then, the measured distance ξ^x between the two particles, originally at a distance ξ_0^x, along the x direction, will be

$$\frac{\xi^x}{\xi_0^x} = 1 - \frac{1}{2} h_+ \cos[\omega(t-z)] \quad \text{or} \quad \delta\xi^x = \xi^x - \xi_0^x = -\frac{1}{2} h_+ \cos[\omega(t-z)]\xi_0^x \tag{2.19}$$

which implies that the relative distance $\delta\xi^x$ between the two particles will oscillate with frequency ω. This does not mean that the particles coordinate positions change; instead they remain at rest relative to the coordinates, but the coordinate distance oscillates. If the particles were placed originally along the y-direction the coordinate distance would oscillate according to

$$\frac{\xi^y}{\xi_0^y} = 1 + \frac{1}{2} h_+ \cos[\omega(t-z)] \quad \text{or} \quad \delta\xi^y = \xi^y - \xi_0^y = \frac{1}{2} h_+ \cos[\omega(t-z)]\xi_0^y \tag{2.20}$$

In other words, the coordinate distances along the two axes oscillate out of phase, that is, when the distance between two particles along the x direction is maximum the distance of two other particles along the y direction is minimum, and after half a period, it is the other way around. The effects are similar for the other polarization, where the axes along which the oscillations are out of phase are at an angle of 45^o with respect to the first ones. This can be visualized in Figure 1, where the effect of a passing gravitational wave on a ring of particles is shown as a series of snapshots closely separated in time.

Another way of understanding the effects of gravitational waves is to study the tidal force field lines. In the TT gauge the equation of the geodesic deviation (2.16) takes the simple form

$$\frac{d^2\xi^k}{dt^2} \approx \frac{1}{2} \frac{d^2 h_{jk}^{TT}}{dt^2} \xi^j \tag{2.21}$$

and the corresponding tidal force is

$$f^k \approx \frac{m}{2} \frac{d^2 h_{jk}^{TT}}{dt^2} \xi^j \tag{2.22}$$

For the wave given by equation (2.18) the two nonzero components of the tidal force are

$$f^x \approx \frac{m}{2} h_+ \omega^2 \cos[\omega(t-z)]\xi_0^x, \quad \text{and} \quad f^y \approx -\frac{m}{2} h_+ \omega^2 \cos[\omega(t-z)]\xi_0^y. \tag{2.23}$$

It can be easily proved that the divergence of the tidal force is zero ($\partial f^x/\partial\xi_0^x + \partial f^y/\partial\xi_0^y = 0$). It can therefore be represented graphically by field lines as in Figure 2.

Figure 2: The tidal field lines of force for a gravitational wave with polarization (+) (left panel) and (×) (right panel). The orientation of the field lines changes every half period producing the deformations as seen in Figure 1. Any point accelerates in the directions of the arrows, and the denser are the lines, the strongest is the acceleration. Since the acceleration is proportional to the distance from the center of mass, the force lines get denser as one moves away from the origin. For the polarization (×) the force lines undergo a 45^0 rotation.

Let us now return back to the two polarization states represented by the two matrices $\epsilon_+^{\mu\nu}$ and $\epsilon_\times^{\mu\nu}$. It is impossible to construct the (+) pattern from the (×) pattern and vice versa; they are orthogonal polarization states. By analogy with electromagnetic waves, the two polarizations could be added with phase difference $(\pm\pi/2)$ to obtain circularly polarized waves. The effect of circularly polarized waves on a ring of particles is to deform the ring into a rotating ellipse with either positive or negative helicity. The particles themselves do not rotate; they only oscillate in and out around their initial positions. These circularly polarized waves carry angular momentum the amount of which is $(2/\omega)$ times the energy carried by the wave. If we consider the gravitational field, then, according to quantum field theory, the waves are associated with fundamental particles responsible for the gravitational interaction, and a quantum of the field will have energy $\hbar\omega$ and consequently spin $2\hbar$. This means that the quanta of the gravitational field, the *gravitons*, are spin-2, massless particles (since they travel with the speed of light). Another way of explaining why a graviton should be a spin-2 particle comes from observing Figure 1. One can see that a gravitational wave is invariant under rotations of 180^0 about its direction of propagation; the pattern repeats itself after half period. For comparison, we mention that electromagnetic waves are invariant under rotations of 360^0. In the quantum mechanical description of massless particles, the wavefunction of a particle

is invariant under rotations of $360^0/s$, where s is the spin of the particle. Thus the photon is a spin-1 particle and the graviton is a spin-2 particle. In other relativistic theories of gravity, the wave field has other symmetries and therefore they attribute different spins to the gravitons.

2.2 Properties of gravitational waves

Gravitational waves, once they are generated, propagate almost unimpeded. Indeed, it has been proven that they are even harder to stop than neutrinos! The only significant change they suffer as they propagate is the decrease in amplitude while they travel away from their source, and the *redshift* they feel (cosmological, gravitational or Doppler), as is the case for electromagnetic waves.

There are other effects that marginally influence the gravitational waveforms, for instance, *absorption* by interstellar or intergalactic matter intervening between the observer and the source, which is extremely weak (actually, the extremely weak coupling of gravitational waves with matter is the main reason that gravitational waves have not been observed). *Scattering* and *dispersion* of gravitational waves are also practically unimportant, although they may have been important during the early phases of the universe (this is also true for the absorption). Gravitational waves can be *focused* by strong gravitational fields and also can be *diffracted*, exactly as it happens with the electromagnetic waves.

There are also a number of "exotic" effects that gravitational waves can experience, that are due to the nonlinear nature of Einsteins equations (purely general-relativistic effects), such as: *scattering* by the background curvature, the existence of *tails* of the waves that interact with the waves themselves, *parametric amplification* by the background curvature, *nonlinear coupling of the waves with themselves* (creation of *geons*, that is, bundles of gravitational waves held together by their own self- generated curvature) and even *formation of singularities* by colliding waves (for such exotic phenomena see the extensive review by Thorne[4]). These aspects of nonlinearity affect the majority of the gravitational wave sources and from this point of view our understanding of gravitational-wave generation is based on approximations. However, it is expected that the error in these approximations for most of the processes that generate gravitational waves is quite small. Powerful numerical codes, using state-of-the-art computer software and hardware, have been developed (and continue to be developed) for minimizing all possible sources of error in order to have as accurate as possible an understanding of the processes that generate gravitational waves and of the waveforms produced.

For most of the properties mentioned above there is a correspondence with electromagnetic waves. Gravitational waves are fundamentally different, however, even though they share similar wave properties away from the source. Gravitational waves are emitted by coherent bulk motions of matter (for example, by the implosion of the core of a star during a supernova explosion) or by coherent oscillations of spacetime

curvature, and thus they serve as a probe of such phenomena. By contrast, cosmic electromagnetic waves are mainly the result of incoherent radiation by individual atoms or charged particles. As a consequence, from the cosmic electromagnetic radiation we mainly learn about the form of matter in various regions of the universe, especially about its temperature and density, or about the existence of magnetic fields. Strong gravitational waves, are emitted from regions of spacetime where gravity is very strong and the velocities of the bulk motions of matter are near the speed of light. Since most of the time these areas are either surrounded by thick layers of matter that absorb electromagnetic radiation or they do not emit any electromagnetic radiation at all (black holes), the only way to study these regions of the universe is via gravitational waves.

2.3 Energy flux carried by gravitational waves

Gravitational waves carry energy and cause a deformation of spacetime. The stress-energy carried by gravitational waves cannot be localized within a wavelength. Instead, one can say that a certain amount of stress-energy is contained in a region of the space which extends over several wavelengths. It can be proven that in the TT gauge of linearized theory the stress-energy tensor of a gravitational wave (in analogy with the stress-energy tensor of a perfect fluid that we have defined earlier) is given by

$$t_{\mu\nu}^{GW} = \frac{1}{32\pi}\langle\left(\partial_\mu h_{ij}^{TT}\right)\left(\partial_\nu h_{ij}^{TT}\right)\rangle. \tag{2.24}$$

where the angular brackets are used to indicate averaging over several wavelengths. For the special case of a plane wave propagating in the z direction, which we considered earlier, the stress-energy tensor has only three non-zero components, which take the simple form

$$t_{00}^{GW} = \frac{t_{zz}^{GW}}{c^2} = -\frac{t_{0z}^{GW}}{c} = \frac{1}{32\pi}\frac{c^2}{G}\omega^2\left(h_+^2 + h_\times^2\right), \tag{2.25}$$

where t_{00}^{GW} is the energy density, t_{zz}^{GW} is the momentum flux and t_{0z}^{GW} the energy flow along the z direction per unit area and unit time (for practical reasons we have restored the normal units). The energy flux has all the properties one would anticipate by analogy with electromagnetic waves: (a) it is conserved (the amplitude dies out as $1/r$, the flux as $1/r^2$), (b) it can be absorbed by detectors, and (c) it can generate curvature like any other energy source in Einstein's formulation of relativity. As an example, by using the above relation, we will estimate the energy flux in gravitational waves from the collapse of the core of a supernova to create a 10 $M_\odot$ black hole at a distance of 50-million-light-years ($\sim$15 Mpc) from the earth (at the distance of the Virgo cluster of galaxies). A conservative estimate of the amplitude of the waves on earth (as we will show later) is of the order of 10^{-22} (at a frequency of about 1kHz). This corresponds to a flux of about 3 ergs/cm^2 sec. This

is an enormous amount of energy flux and is about ten orders of magnitude larger than the observed energy flux in electromagnetic waves! The basic difference is the duration of the two signals; gravitational wave signal will last a few milliseconds, whereas an electromagnetic signal lasts many days. This example provides us with a useful numerical formula for the energy flux:

$$F = 3\left(\frac{f}{1\text{kHz}}\right)^2\left(\frac{h}{10^{-22}}\right)^2\frac{\text{ergs}}{\text{cm}^2\text{sec}}, \tag{2.26}$$

from which one can easily estimate the flux on earth, given the amplitude (on earth) and the frequency of the waves.

2.4 Generation of gravitational waves

As we have mentioned earlier, when the gravitational field is strong there are a number on nonlinear effects that influence the generation and propagation of gravitational waves. For example, nonlinear effects are significant during the last phases of black hole formation. The analytic description of such a dynamically changing spacetime is impossible, and until numerical relativity provides us with accurate estimates of the dynamics of gravitational fields under such extreme conditions we have to be content with order of magnitude estimates. Furthermore, there are differences in the predictions of various relativistic theories of gravity in the case of high concentrations of rapidly varying energy distributions. However, all metric theories of gravity, as long as they admit the correct Newtonian limit, make similar predictions for the total amount of gravitational radiation emitted by "weak" gravitational wave sources, that is, sources where the energy content is small enough to produce only small deformations of the flat spacetime and where all motions are slow compared to the velocity of light.

Let us now try to understand the nature of gravitational radiation, by starting from the production of electromagnetic radiation. Electromagnetic radiation emitted by slowly varying charge distributions can be decomposed into a series of multipoles, where the amplitude of the 2^ℓ-pole ($\ell = 0, 1, 2, ...$) contains a small factor a^ℓ, with a equal to the ratio of the diameter of the source to the typical wavelength, namely, a number typically much smaller than 1. From this point of view the strongest electromagnetic radiation would be expected for monopolar radiation ($\ell = 0$), but this is completely absent, because the electromagnetic monopole moment is proportional to the total charge, which does not change with time (it is a conserved quantity). Therefore, electromagnetic radiation consists only of $\ell \geq 1$ multipoles, the strongest being the electric dipole radiation ($\ell = 1$), followed by the weaker magnetic dipole and electric quadrupole radiation ($\ell = 2$). One could proceed with a similar analysis for gravitational waves and by following the same arguments show that mass conservation (which is equivalent to charge conservation in electromagnetic theory) will exclude monopole radiation. Also, the rate of change of the mass dipole moment is

proportional to the linear momentum of the system, which is a conserved quantity, and therefore there cannot be any mass dipole radiation in Einsteins relativity theory. The next strongest form of electromagnetic radiation is the magnetic dipole. For the case of gravity, the change of the magnetic dipole is proportional to the angular momentum of the system, which is also a conserved quantity and thus there is no dipolar gravitational radiation of *any* sort. It follows that gravitational radiation is of quadrupolar or higher nature and is directly linked to the quadrupole moment of the mass distribution.

As early as 1918, Einstein derived the quadrupole formula for gravitational radiation. This formula states that the wave amplitude h_{ij} is proportional to the second time derivative of the quadrupole moment of the source:

$$h_{ij} = \frac{2}{r}\frac{G}{c^4}\ddot{Q}_{ij}^{TT}\left(t - \frac{r}{c}\right) \tag{2.27}$$

where

$$Q_{ij}^{TT}(x) = \int \rho \left(x^i x^j - \frac{1}{3}\delta^{ij} r^2\right) d^3x \tag{2.28}$$

is the quadrupole moment in the TT gauge, evaluated at the retarded time $t - r/c$ and ρ is the matter density in a volume element d^3x at the position x^i. This result is quite accurate for all sources, as long as the reduced wavelength $\tilde{\lambda} = \lambda/2\pi$ is much longer than the source size R. It should be pointed out that the above result can be derived via a quite cumbersome calculation in which we solve the wave equation (2.6) with a source term $T_{\mu\nu}$ on the right-hand side. In the course of such a derivation, a number of assumptions must be used. In particular, the observer must be located at a distance $r \gg \tilde{\lambda}$, far greater than the reduced wavelength (in what is called the radiation zone) and $T_{\mu\nu}$ must not change very quickly.

Using the formulae (2.24) and (2.25) for the energy carried by gravitational waves, one can derive the luminosity in gravitational waves as a function of the third-order time derivative of the quadrupole moment tensor. This is the quadrupole formula

$$L_{GW} = -\frac{dE}{dt} = \frac{1}{5}\frac{G}{c^5}\langle \frac{\partial^3 Q_{ij}}{\partial t^3}\ \frac{\partial^3 Q_{ij}}{\partial t^3}\rangle. \tag{2.29}$$

Based on this formula, we derive some additional formulas, which provide order of magnitude estimates for the amplitude of the gravitational waves and the corresponding power output of a source. First, the quadrupole moment of a system is approximately equal to the mass M of the part of the system that moves, times the square of the size R of the system. This means that the third-order time derivative of the quadrupole moment is

$$\frac{\partial^3 Q_{ij}}{\partial t^3} \sim \frac{MR^2}{T^3} \sim \frac{Mv^2}{T} \sim \frac{E_{\rm ns}}{T}, \tag{2.30}$$

where v is the mean velocity of the moving parts, $E_{\rm ns}$ is the kinetic energy of the component of the source's internal motion which is non spherical, and T is the time

scale for a mass to move from one side of the system to the other. The time scale (or period) is actually proportional to the inverse of the square root of the mean density of the system

$$T \sim \sqrt{R^3/GM}. \tag{2.31}$$

This relation provides a rough estimate of the characteristic frequency of the system $f = 2\pi/T$. Then, the luminosity of gravitational waves of a given source is approximately

$$L_{GW} \sim \frac{G}{c^5}\left(\frac{M}{R}\right)^5 \sim \frac{G}{c^5}\left(\frac{M}{R}\right)^2 v^6 \sim \frac{c^5}{G}\left(\frac{R_{\rm Sch}}{R}\right)^2 \left(\frac{v}{c}\right)^6 \tag{2.32}$$

where $R_{\rm Sch} = 2GM/c^2$ is the Schwarzschild radius of the source. It is obvious that the maximum value of the luminosity in gravitational waves can be achieved if the source's dimensions are of the order of its Schwarzschild radius and the typical velocities of the components of the system are of the order of the speed of light. This explains why we expect the best gravitational wave sources to be highly relativistic compact objects. The above formula sets also an upper limit on the power emitted by a source, which for $R \sim R_{\rm Sch}$ and $v \sim c$ is

$$L_{GW} \sim c^5/G = 3.6 \times 10^{59} \text{ergs/sec}. \tag{2.33}$$

This is an immense power, often called the *luminosity of the universe*.

Using the above order-of-magnitude estimates, we can get a rough estimate of the amplitude of gravitational waves at a distance r from the source:

$$h \sim \frac{G}{c^4}\frac{E_{\rm ns}}{r} \sim \frac{G}{c^4}\frac{\varepsilon E_{\rm kin}}{r} \tag{2.34}$$

where $\varepsilon E_{\rm kin}$ (with $0 \leq \varepsilon \leq 1$), is the fraction of kinetic energy of the source that is able to produce gravitational waves. The factor ε is a measure of the asymmetry of the source and implies that only a time varying quadrupole moment will emit gravitational waves. For example, even if a huge amount of kinetic energy is involved in a given explosion and/or implosion, if the event takes place in a spherically symmetric manner, there will be no gravitational radiation.

Another formula for the amplitude of gravitational waves relation can be derived from the flux formula (2.26). If, for example, we consider an event (perhaps a supernovae explosion) at the Virgo cluster during which the energy equivalent of $10^{-4}M_\odot$ is released in gravitational waves at a frequency of 1 kHz, and with signal duration of the order of 1 msec, the amplitude of the gravitational waves on Earth will be

$$h \approx 10^{-22}\left(\frac{E_{GW}}{10^{-4}M_\odot}\right)^{1/2}\left(\frac{f}{1\text{kHz}}\right)^{-1}\left(\frac{\tau}{1\text{msec}}\right)^{-1/2}\left(\frac{r}{15\text{Mpc}}\right)^{-1}. \tag{2.35}$$

For a detector with arm length of 4 km we are looking for changes in the arm length of the order of

$$\Delta\ell = h \cdot \ell = 10^{-22} \cdot 4\text{km} = 4 \times 10^{-17}\text{!!!}$$

These numbers shows why experimenters are trying so hard to build ultra-sensitive detectors and explains why all detection efforts till today were not successful.

Finally, it is useful to know the damping time, that is, the time it takes for a source to transform a fraction $1/e$ of its energy into gravitational radiation. One can obtain a rough estimate from the following formula

$$\tau = \frac{E_{\text{kin}}}{L_{\text{GW}}} \sim \frac{1}{c} R \left(\frac{R}{R_{\text{Sch}}} \right)^3 . \tag{2.36}$$

For example, for a non-radially oscillating neutron star with a mass of roughly $1.4\text{M}_\odot$ and a radius of 12Km, the damping time will be of the order of $\sim$50msec. Also, by using formula (2.31), we get an estimate for the frequency of oscillation which is directly related to the frequency of the emitted gravitational waves, roughly 2kHz for the above case.

2.5 Rotating binary system

Among the most interesting sources of gravitational waves are binaries. The inspiralling of such systems, consisting of black holes or neutron stars, is, as we will discuss later, the most promising source for the gravitational wave detectors. Binary systems are also the sources of gravitational waves whose dynamics we understand the best. If we assume that the two bodies making up the binary lie in the $x-y$ plane and their orbits are circular (see Figure 3), then the only non-vanishing components of the quadrupole tensor are

$$Q_{xx} = -Q_{yy} = \frac{1}{2}\mu a^2 \cos 2\Omega t, \quad \text{and} \quad Q_{xy} = Q_{yx} = \frac{1}{2}\mu a^2 \sin 2\Omega t, \tag{2.37}$$

where Ω is the orbital angular velocity, $\mu = M_1 M_2/M$ is the reduced mass of the system and $M = M_1 + M_2$ its total mass.

According to equation (2.29) the gravitational radiation luminosity of the system is

$$L^{\text{GW}} = \frac{32}{5}\frac{G}{c^5}\mu^2 a^4 \Omega^6 = \frac{32}{5}\frac{G^4}{c^5}\frac{M^3\mu^2}{a^5}, \tag{2.38}$$

where, in order to obtain the last part of the relation, we have used Kepler's third law, $\Omega^2 = GM/a^3$. As the gravitating system loses energy by emitting radiation, the distance between the two bodies shrinks at a rate

$$\frac{da}{dt} = -\frac{64}{5}\frac{G^3}{c^5}\frac{\mu M^2}{a^3}, \tag{2.39}$$

Figure 3: A system of two bodies orbiting around their common center of gravity. Binary systems are the best sources of gravitational waves.

and the orbital frequency increases accordingly ($\dot{T}/T = 1.5\dot{a}/a$). If, for example, the present separation of the two stars is a_0, then the binary system will coalesce after a time

$$\tau = \frac{5}{256}\frac{c^5}{G^3}\frac{a_0^4}{\mu M^4} \tag{2.40}$$

Finally, the amplitude of the gravitational waves is

$$h = 5 \times 10^{-22} \left(\frac{M}{2.8M_\odot}\right)^{2/3} \left(\frac{\mu}{0.7M_\odot}\right) \left(\frac{f}{100\text{Hz}}\right)^{2/3} \left(\frac{15\text{Mpc}}{r}\right). \tag{2.41}$$

In all these formulae we have assumed that the orbits are circular. In general, the orbits of the two bodies are approximately ellipses, but it has been shown that long before the coalescence of the two bodies, the orbits become circular, at least for long-lived binaries, due to gravitational radiation. Also, the amplitude of the emitted gravitational waves depends on the angle between the line of sight and the axis of angular momentum; formula (2.41) refers to an observer along the axis of the orbital angular momentum. The complete formula for the amplitude contains angular factors of order 1. The relative strength of the two polarizations depends on that angle as well.

If three or more detectors observe the same signal it is possible to reconstruct the full waveform and deduce many details of the orbit of the binary system.

As an example, we will provide some details of the well-studied pulsar PSR 1913+16 (the Hulse-Taylor pulsar), which is expected to coalesce after $\sim 3.5 \times 10^8$ years. The binary system is roughly 5kpc away from Earth, the masses of the two neutron stars are estimated to be $\sim 1.4 M_\odot$ each, and the present period of the system is $\sim$7h and 45min. The predicted rate of period change is $\dot{T} = -2.4 \times 10^{-12}$sec/sec, while the corresponding observed value is in excellent agreement with the predictions, i.e., $\dot{T} = (-2.30 \pm 0.22) \times 10^{-12}$sec/sec; finally the present amplitude of gravitational waves is of the order of $h \sim 10^{-23}$ at a frequency of $\sim 7 \times 10^{-5}$Hz.

Figure 4: A pair of masses joined by a spring can be viewed as the simplest conceivable detector.

3. DETECTION OF GRAVITATIONAL WAVES

The first attempt to detect gravitational waves was undertaken by the pioneer Joseph Weber during the early 1960s. He developed the first resonant mass detector and inspired many other physicists to build new detectors and to explore from a theoretical viewpoint possible cosmic sources of gravitational radiation.

A pair of masses joined by a spring can be viewed as the simplest conceivable detector; see Figure 4. In practice, a cylindrical massive metal bar or even a massive sphere is used instead of this simple system. When a gravitational wave hits such a device, it causes the bar to vibrate. By monitoring this vibration, we can reconstruct the true waveform. The next step, following the idea of resonant mass detectors, was the replacement of the spring by pendulums. In this new detector the motions induced by a passing-by gravitational wave would be detected by monitoring, via laser interferometry, the relative change in the distance of two freely suspended bodies. The use of interferometry is probably the most decisive step in our attempt to detect gravitational wave signals. In what follows, we will discuss both resonant bars and laser interferometric detectors.

Although the basic principle of such detectors is very simple, the sensitivity of detectors is limited by various sources of noise. The internal noise of the detectors can be Gaussian or non-Gaussian. The non-Gaussian noise may occur several times per day such as strain releases in the suspension systems which isolate the detector from any environmental mechanical source of noise, and the only way to remove this type of noise is via comparisons of the data streams from various detectors. The so-called Gaussian noise obeys the probability distribution of Gaussian statistics and can be characterized by a *spectral density* $S_n(f)$. The observed signal at the output of a detector consists of the true gravitational wave strain h and Gaussian noise. The optimal method to detect a gravitational wave signal leads to the following signal-to-noise ratio:

$$\left(\frac{S}{N}\right)^2_{\rm opt} = 2\int_0^\infty \frac{|\tilde{h}(f)|^2}{S_n(f)} df, \tag{3.1}$$

where $\tilde{h}(f)$ is the Fourier transform of the signal waveform. It is clear from this expression that the sensitivity of gravitational wave detectors is limited by noise.

3.1 Resonant detectors

Suppose that a gravitational wave propagating along the z axis with pure (+) polarization impinges on an idealized detector, two masses joined by a spring along the x axis as in Figure 4. We will assume that $h_{\mu\nu}$ describes the strain produced in the spacetime by the passing wave. We will try to calculate the amplitude of the oscillations induced on the spring detector by the wave and the amount of energy absorbed by this detector. The tidal force induced on the detector is given by equation (2.23), and the masses will move according to the following equation of motion:

$$\ddot{\xi} + \dot{\xi}/\tau + \omega_0^2 \xi = -\frac{1}{2}\omega^2 L h_+ e^{i\omega t}, \tag{3.2}$$

where ω_0 is the natural vibration frequency of our detector, τ is the damping time of the oscillator due to frictional forces, L is the separation between the two masses and ξ is the relative change in the distance of the two masses. The gravitational wave plays the role of the driving force for our ideal oscillator, and the solution to the above equation is

$$\xi = \frac{\frac{1}{2}\omega^2 L h_+ e^{i\omega t}}{\omega_0^2 - \omega^2 + i\omega/\tau} \tag{3.3}$$

If the frequency ω of the impinging wave is near the natural frequency ω_0 of the oscillator (near resonance) the detector is excited into large-amplitude motions and it rings like a bell. Actually, in the case of $\omega = \omega_0$, we get the maximum amplitude $\xi_{\max} = \omega_0 \tau L H_+/2$. Since the size of our detector L and the amplitude of the gravitational waves h_+ are fixed, large-amplitude motions can be achieved only by increasing the quality factor $Q = \omega_0 \tau$ of the detector. In practice, the frequency of the detector is fixed by its size and the only improvement we can get is by choosing the type of material so that long relaxation times are achieved.

The *cross section* is a measure of the interception ability of a detector. For the special case of resonance, the average cross section of our test detector, assuming any possible direction of the wave, is

$$\sigma = \frac{32\pi}{15}\frac{G}{c^3}\omega_0 Q M L^2. \tag{3.4}$$

This formula is general; it applies even if we replace our toy detector with a massive metal cylinder, for example Weber's first detector. That detector had the following characteristics: Mass M=1410 kg, length L=1.5 m, diameter 66 cm, resonant frequency ω_0=1660Hz, and quality factor $Q = \omega_0 \tau = 2 \times 10^5$. For these values the calculated cross section is roughly $3 \times 10^{-19}\text{cm}^2$, which is quite small, and even worse, it can be reached only when the frequency of the impinging wave is very close to resonance frequency (the typical resonance width is usually of the order of 0.1-1 Hz).

In reality, the efficiency of a resonant bar detector depends on several other parameters. Here, we will discuss only the more fundamental ones. Assuming perfect

Figure 5: A graph of NAUTILUS in Frascati near Rome. Nautilus is probably the most sensitive resonant detector available.

isolation of the resonant bar detector from any external source of noise (acoustical, seismic, electromagnetic), the thermal noise is the only factor limiting our ability to detect gravitational waves. Thus, in order to detect a signal, the energy deposited by the gravitational wave every τ seconds should be larger than the energy kT due to thermal fluctuations. This leads to a formula for the minimum detectable energy flux of gravitational waves, which, following equation (2.25), leads into a minimum detectable strain amplitude

$$h_{\min} \leq \frac{1}{\omega_0 LQ}\sqrt{\frac{15kT}{M}} \tag{3.5}$$

For Weber's detector, at room temperature this yields a minimum detectable strain of the order of 10^{-20}. However, this estimate of the minimum sensitivity applies only to gravitational waves whose duration is at least as long as the damping time of the bar's vibrations and whose frequency perfectly matches the resonant frequency of the detector. For bursts or for periodic signals which are off-resonance (with regard to the detector) the sensitivity of a resonant bar detector decreases further by several orders of magnitude.

In reality, modern resonant bar detectors are quite complicated devices, consisting of a solid metallic cylinder weighing a few tons and suspended *in vacuo* by a cable that is wrapped under its center of gravity (Figure 5). This suspension system protects the antenna from external mechanical shocks. The whole system is cooled down to temperatures of a few kelvins or even millikelvins. To monitor the vibrations of the bar, piezoelectric transducers (or the more modern capacitive ones) are

attached to the bar. The transducers convert the bar's mechanical energy into electrical energy. The signal is amplified by an ultra-low-frequency amplifier, by using a device called a SQUID (Super-conducting QUantum Interference Device) before it becomes available for data analysis. Transducers and amplifiers of electronic signals require careful design to achieve low noise combined with adequate signal transfer.

The above description of the resonant bar detectors shows that, in order to achieve high sensitivity, one has to:

1. *Create more massive antennas.* Today, most of the antennas are about 50% more massive than the early Webers antenna. There are studies and research plans for future construction of spherical antennae weighing up to tenths of tons.

2. *Obtain higher quality factor Q.* Modern antennas generally use aluminum alloy 5056 ($Q \sim 4 \times 10^7$); although niobium (which is used in the NIOBE detector) is even better ($Q \sim 10^8$) but much more expensive. Silicon or sapphire bars would enhance the quality factor even more, but experimenters must first find a way to produce large single pieces of these crystals.

3. *Lower the temperature of the antenna as much as possible.* Advanced cryogenic techniques have been used and the resonant bar detectors are probably the coolest places in the Universe. Typical cooling temperatures for the most advanced antennae are below the temperature of liquid helium.

4. *Achieve strong coupling between the antenna and the electronics and low electrical noise.* The bar detectors include the best available technology related to transducers and integrate the most recent advances in SQUID technology.

Since the early 1990s, a number of resonant bar detectors have been in nearly continuous operation in several places around the world. They have achieved sensitivities of a few times 10^{-21}, but still there has been no clear evidence of gravitational wave detection. As we will discuss later, they will have a good chance of detecting a gravitational wave signal from a supernova explosion in our galaxy, although, this is a rather rare event (2-5 per century).

The technical specifications of the most sensitive cryogenic bar detectors in operation are as follows:

- ALLEGRO (Baton Rouge, USA) Mass 2296 Kg (Aluminium 5056), length 3 m, bar temperature 4.2 K, mode frequency 896 Hz.

- AURIGA (Legrano, Italy) Mass 2230 Kg (Aluminium 5056), length 2.9 m, bar temperature 0.2 K, mode frequency 913 Hz.

- EXPLORER (CERN, Switzerland) Mass 2270 Kg (Aluminium 5056), length 3 m, bar temperature 2.6K, mode frequency 906Hz.

- NAUTILUS (Frascati, Italy) Mass 2260 Kg (Aluminium 5056), length 3 m, bar temperature 0.1 K, mode frequency 908 Hz.

- NIOBE (Perth, Australia) Mass 1500 Kg (Niobium), length 1.5 m, bar temperature 5K, mode frequency 695Hz.

Also, there are plans for construction of *massive spherical resonant detectors*, the advantages of which will be their high mass, their broader sensitivity (up to 100-200 Hz) and their omnidirectional sensitivity. In a spherical detector, five modes at a time will be excited, which is equivalent to five independent detectors oriented in different ways. This offers the opportunity, in the case of detection, to obtain direct information about the polarization of the wave and the direction to the source. A prototype spherical detector is already in operation in Leiden, Netherlands (mini-GRAIL)[7] with 1 m diameter and mode frequency ∼3.2 kHz. Two other detectors of the same size are under construction in Italy (Sfera) and Brazil (Shenberg).

3.2 Beam detectors

3.2.1 Laser Interferometers

A laser interferometer is an alternative gravitational wave detector that offers the possibility of very high sensitivities over a broad frequency band. Originally, the idea was to construct a new type of resonant detector with much larger dimensions. As one can realize from the relations (3.4) and (3.5), the longer the resonant detector is the more sensitive it becomes. One could then try to measure the relative change in the distance of two well-separated masses by monitoring their separation via a laser beam that continuously bounces back and forth between them. (This technique is actually used in searching for gravitational waves by using the so-called Doppler tracking technique, where a distant interplanetary spacecraft is monitored from earth through a microwave tracking link; the earth and spacecraft act as free particles.) Soon, it was realized that it is much easier to use laser light to measure relative changes in the lengths of two perpendicular arms; see Figure 6. Gravitational waves that are propagating perpendicular to the plane of the interferometer will increase the length of one arm of the interferometer, and at the same time will shorten the other arm, and vice versa. This technique of monitoring the waves is based on Michelson interferometry. L-shaped interferometers are particularly suited to the detection of gravitational waves due to their quadrupolar nature.

Figure 6 shows a schematic design of a Michelson interferometer; the three masses M_0, M_1 and M_2 are freely suspended. Note that the resonant frequencies of these pendulums should be much smaller than the frequencies of the waves that we are supposed to detect since the pendulums are supposed to behave like free masses. Mirrors are attached to M_1 and M_2 and the mirror attached on mass M_0 splits the light (beam splitter) into two perpendicular directions. The light is reflected on the

Figure 6: A schematic design of a Michelson interferometer.

two corner mirrors and returns back to the beam splitter. The splitter now half-transmits and half-reflects each one of the beams. One part of each beam goes back to the laser, while the other parts are combined to reach the photodetector where the fringe pattern is monitored. If a gravitational wave slightly changes the lengths of the two arms, the fringe pattern will change, and so by monitoring the changes of the fringe pattern one can measure the changes in the arm lengths and consequently monitor the incoming gravitational radiation [1].

Let us consider an impinging gravitational wave with amplitude h and (+) polarization, propagating perpendicular to the plane of the detector. We will further assume that the frequency is much higher than the resonant frequency of the pendulums and the wavelength is much longer than the arm length of our detector. Such a wave will generate a change of $\Delta L \sim hL/2$ in the arm length along the x-direction and an opposite change in the arm length along the y-direction, according to equations (2.19) and (2.20). The total difference in length between the two arms will be

$$\frac{\Delta L}{L} \sim h. \tag{3.6}$$

For a gravitational wave with amplitude $h \sim 10^{-21}$ and detector arm- length 4 km (such as LIGO), this will induce a change in the arm-length of about $\Delta L \sim 10^{-16}$. In the general case, when a gravitational wave with arbitrary polarization impinges on the detector from a random direction, the above formula will be modified by some angular coefficients of order 1.

[1] In practice, things are arranged so that when there is no actual change in the arms, all light that returns on the beam splitter from the corner mirrors is sent back into the laser, and only if there is some motion of the masses there is an output at the photodetector

If the light bounces a few times between the mirrors before it is collected in the photodiode, the effective arm length of the detector is increased considerably, and the measured variations of the arm lengths will be increased accordingly. This is a quite efficient procedure for making the arm length longer. For example, a gravitational wave at a frequency of 100 Hz has a wavelength of 3000 Km, and if we assume 100 bounces of the laser beam in the arms of the detector, the effective arm-length of the detector is 100 times larger than the actual arm-length, but still this is 10 times smaller than the wavelength of the incoming wave. The optical cavity that is created between the mirrors of the detector is known as a Fabry-Perot cavity and is used in modern interferometers.

In the remainder of this paragraph we will focus on the Gaussian sources of noise and their expected influence on the sensitivity of laser intereferometers.

a. Photon shot noise. When a gravitational wave produces a change ΔL in the arm-length, the phase difference between the two light beams changes by an amount $\Delta\phi = 2b\Delta L/\tilde{\lambda}$, where $\tilde{\lambda}$ is the reduced wavelength of the laser light ($\sim 10^{-8}$cm) and b is the number of bounces of the light in each arm. It is expected that a detectable gravitational wave will produce a phase shift of the order of 10^{-9}rad. The precision of the measurements, though, is ultimately restricted by fluctuations in the fringe pattern due to fluctuations in the number of detected photons. The number of photons that reach the detector is proportional to the intensity of the laser beam and can be estimated via the relation $N = N_0 \sin^2(\Delta\phi/2)$, where N_0 is the number of photons that the laser supplies and N is the number of detected photons. Inversion of this equation leads to an estimation of the relative change of the arm lengths ΔL by measuring the number of the emerging photons N. However, there are statistical fluctuations in the population of photons, which are proportional to the square root of the number of photons. This implies an uncertainty in the measurement of the arm length

$$\delta(\Delta L) \sim \frac{\tilde{\lambda}}{2b\sqrt{N_0}} \tag{3.7}$$

Thus, the minimum gravitational wave amplitude that we can measure is

$$h_{\min} = \frac{\delta(\Delta L)}{L} = \frac{\Delta L}{L} \sim \frac{\tilde{\lambda}}{bLN_0^{1/2}} \sim \frac{1}{bL}\left(\frac{\hbar c\tilde{\lambda}}{\tau I_0}\right)^{1/2}, \tag{3.8}$$

where I_0 is the intensity of the laser light (∼5-10 W) and τ is the duration of the measurement. This limitation in the detector's sensitivity due to the photon counting uncertainty is known as *photon shot noise*. For a typical laser interferometer the photon shot noise is the dominant source of noise for frequencies above 200 Hz, while its power spectral density $S_n(f)$ for frequencies 100-200Hz is of the order of $\sim 3 \times 10^{-23}\sqrt{\text{Hz}}$.

b. Radiation pressure noise: According to formula (3.8), the sensitivity of a detector can be increased by increasing the intensity of the laser. However, a very powerful laser produces a large radiation pressure on the mirrors. Then an uncertainty in the measurement of the momentum deposited on the mirrors leads to a proportional uncertainty in the position of the mirrors or, equivalently, in the measured change in the arm-lengths. Then, the minimum detectable strain is limited by

$$h_{\min} \sim \frac{\tau}{m}\frac{b}{L}\left(\frac{\tau\hbar I_0}{c\tilde{\lambda}}\right)^{1/2}, \tag{3.9}$$

where m is the mass of the mirrors.

As we have seen, the photon shot noise decreases as the laser power increases, while the inverse is true for the noise due to radiation pressure fluctuations. If we try to minimize these two types of noise with respect to the laser power, we get a minimum detectable strain for the optimal power via the very simple relation

$$h_{\min} \sim \frac{1}{L}\left(\frac{\tau\hbar}{m}\right)^{1/2} \tag{3.10}$$

which for the LIGO detector (where the mass of the mirrors is ∼100 kg and the arm length is 4 km), for observation time of 1 ms, gives $h_{\min} \approx 10^{-23}$.

c. Quantum limit. An additional source of uncertainty in the measurements is set by Heisenberg's principle, which says that the knowledge of the position and the momentum of a body is restricted from the relation $\Delta x \cdot \Delta p \geq \hbar$. For an observation that lasts some time τ, the smallest measurable displacement of a mirror of mass m is ΔL; assuming that the momentum uncertainty is $\Delta p \approx m \cdot \Delta L/\tau$, we get a minimum detectable strain due to quantum uncertainties

$$h_{\min} = \frac{\Delta L}{L} \sim \frac{1}{L}\left(\frac{\tau\hbar}{m}\right)^{1/2}. \tag{3.11}$$

Surprisingly, this is identical to the optimal limit that we calculated earlier for the other two types of noise. The standard quantum limit does set a fundamental limit on the sensitivity of beam detectors. An interesting feature of the quantum limit is that it depends only on a single parameter, the mass of the mirrors.

d. Seismic noise. At frequencies below 60 Hz, the noise in the interferometers is dominated by seismic noise. This noise is due to geological activity of the earth, and human sources, e.g., traffic and explosions. The vibrations of the ground couple to the mirrors via the wire suspensions which support them. This effect is strongly suppressed by properly designed suspension systems. Still, seismic noise is very difficult to eliminate at frequencies below 5-10 Hz.

e. Residual gas-phase noise. The statistical fluctuations of the residual gas density induce a fluctuation of the refraction index and consequently of the monitored

phase shift. Hence, the residual gas pressure through which the laser beams travel should be extremely low. For this reason the laser beams are enclosed in pipes over their entire length. Inside the pipes a high vacuum of the order of 10^{-9} Torr guarantees elimination of this type of noise.

Prototype laser interferometric detectors have been already constructed in the USA, Germany and UK more than 15 years ago. These detectors have an arm length of a few tens of meters and they have achieved sensitivities of the order of $h \sim 10^{-19}$. The construction of the new generation of laser interferometric detectors is near completion and some of them have already collected data. It is expected that in a year or so they will be in full operation. The US project named LIGO [8](Laser Interferometer Gravitational Observatory) consists of two detectors with arm length of 4 Km, one in Hanford, Washington, and one in Livingston, Louisiana. The detector in Hanford includes, in the same vacuum system, a second detector with arm length of 2 km. The detectors are already in operation and they have recently achieved the designed sensitivity.

The Italian/French EGO (VIRGO) detector [9] of arm-length 3 km at Cascina near Pisa is designed to have better sensitivity at lower frequencies is about to commence operation next year. GEO600 is the German/British detector build in Hannover [10]. It has 600 m arm length and is collecting data in collaboration with LIGO [11]. The TAMA300[12] detector in Tokyo has arm length of 300 m and it was the first major interferometric detector in operation. There are already plans for improving the sensitivities of all the above detectors and the construction of new interferometers in the near future.

3.2.2 Space Detectors

Both bars and laser interferometers are high-frequency detectors, but there are a number of interesting gravitational waves sources which emit signals at lower frequencies. The seismic noise provides an insurmountable obstacle in any earth-based experiment and the only way to surpass this barrier is to fly a laser interferometer in space. LISA [13] (Laser Interferometer Space Antenna) is such a system. It has been proposed by European and American scientists and has been adopted by ESA (European Space Agency) as a cornerstone mission, while recently NASA joined the effort and the launch date is expected to be around 2011.

LISA will consist of three identical drag-free spacecrafts forming an equilateral triangle with one spacecrafts at each vertex (Figure 7). The distance between the two vertices (the arm length) is 5×10^6 km. The spacecrafts will be placed into the same heliocentric orbit as earth, but about 20^o behind earth. The equilateral triangle will be inclined at an angle of 60^o with respect to Earth's orbital plane. The three spacecraft would track each other optically by using laser beams. Because of the diffraction losses it is not feasible to reflect the beams back and forth as is done

Figure 7: A schematic design of the space interferometer LISA.

with LIGO. Instead, each spacecraft will have its own laser. The lasers will be phase locked to each other, achieving the same kind of phase coherence as LIGO does with mirrors. The configuration will function as three, partially independent and partially redundant, gravitational wave interferometers.

At frequencies $f \geq 10^{-3}$, LISA's noise is mainly due to photon shot noise. The sensitivity curve steepens at $f \sim 3 \times 10^{-2}$ Hz because at larger frequencies the gravitational waves period is shorter than the round-trip light travel time in each arm. For $f \leq \times 10^{-2}$ Hz, the noise is due to buffeting-induced random motions of the spacecraft, and cannot be removed by the drag- compensation system. LISA's sensitivity is roughly the same as that of LIGO, but at 10^5 times lower frequency. Since the gravitational waves energy flux scales as $F \sim f^2 h^2$, this corresponds to 10^{10} times better energy sensitivity than LIGO.

3.2.3 Satellite Tracking

The Doppler delay of communication signals between the earth-based stations and spacecraft underlies another type of gravitational wave detector. A radio signal of frequency f_0 is transmitted to a spacecraft and is coherently transported back to earth, where it is received and its frequency is measured with a highly stable clock (typically a hydrogen maser). The relative change $\Delta f/f_0$ as function of time is monitored. A gravitational wave propagating through the solar system causes small perturbations in $\Delta f/f_0$. The relative shift in the frequency of the signals is proportional to the amplitude of gravitational waves. With this technique, broad-band searches are possible in the millihertz frequency band, and thanks to the very stable atomic clocks, it is possible to achieve sensitivities of order $h_{\min} \sim 10^{-13} - 10^{-15}$. Noise sources that affect the sensitivity of Doppler tracking experiments can be divided into two broad

classes a) instrumental and b) related to propagation. At the high-frequency end of the band accessible to Doppler tracking, thermal noise dominates over all other noise sources, typically at about 0.1 Hz. Among all other sources of instrumental noise (transmitter and receiver, mechanical stability of the antenna, stability of the spacecraft etc), clock noise has been shown to be the most important instrumental source of frequency fluctuations. The propagation noise is due to fluctuations in the index of refraction of the troposphere, ionosphere, and the interplanetary solar plasma. Both NASA and ESA have performed such measurements and there is a continued effort in this direction.

3.2.4 Pulsar Timing

Pulsars are extremely stable clocks and by measuring irregularities in their pulses we expect to set upper limits on the background gravitational waves (see next section). If an observer monitors simultaneously two or more pulsars, the correlation of their signals could be used to detect gravitational waves. Since such observation requires timescales of the order of 1 year, this means that the waves have to be of extremely low frequencies.

4. ASTRONOMICAL SOURCES OF GRAV. WAVES

The new generation of gravitational wave detectors (LIGO, VIRGO) have very good chances of detecting gravitational waves, but until these expectations are fulfilled, we can only make educated guesses as to the possible astronomical sources of gravitational waves. The detectability of these sources depends on three parameters: their intrinsic gravitational wave luminosity, their event rate, and their distance from the Earth. The luminosity can be approximately estimated via the quadrupole formula that we discussed earlier. Even though there are certain restrictions in its applicability (weak field, slow motion), it provides a very good order-of-magnitude estimate for the expected gravitational wave flux on Earth. The rate, at which various events with high luminosity in gravitational waves take place is extrapolated from astronomical observations in the electromagnetic spectrum. Still, there might be a number of *gravitationally luminous sources*, for example binary black holes, for which we have no direct observations in the electromagnetic spectrum. Finally, the amplitude of gravitational wave signals decreases as one over the distance to the source. Thus, a signal from a supernova explosion might be clearly detectable if the event takes place in our galaxy (2-3 events per century), but it is highly unlikely to be detected if the supernova explosion occurs at far greater distances, of order 100 Mpc, where the event rate is high and at least a few events per day take place. All three factors have to be taken into account when discussing sources of gravitational waves.

It was mentioned earlier that the frequency of gravitational waves is proportional to the square root of the mean density of the emitting system; this is approximately

true for any gravitating system. For example, neutron stars usually have masses around $1.4M_\odot$ and radii in the order of 10 km; thus if we use these numbers in the relation $f \sim \sqrt{GM/R^3}$ we find that an oscillating neutron star will emit gravitational waves primarily at frequencies of 2-3 kHz. By analogy, a black-hole with a mass $\sim 100M_\odot$, will have a radius of ∼300 km and the natural oscillation frequency will be ~ 100 Hz. Finally, for a binary system Kepler's law (see section 2.5) provides a direct and accurate estimation of the frequency of the emitted gravitational waves. For two $1.4M_\odot$ neutron stars orbiting around each other at a distance of 160 Km, Keplers law predicts an orbital frequency of 50 Hz, which leads to an observed gravitational wave frequency of 100 Hz.

4.1 Radiation from gravitational collapse

Type II supernovae are associated with the core collapse of a massive star together with a shock-driven expansion of a luminous shell which leaves behind a rapidly rotating neutron star or a black hole, if the core has mass of $> 2-3M_\odot$. The typical signal from such an explosion is broadband and peaked at around 1 kHz. Detection of such a signal was the goal of detector development over the last three decades. However, we still know little about the efficiency with which this process produces gravitational waves. For example, an exactly spherical collapse will not produce any gravitational radiation at all. The key question is what is the kinetic energy of the nonspherical motions, since the gravitational wave amplitude is proportional to this [equation (2.30). After 30 years of theoretical and numerical attempts to simulate gravitational collapse, there is still no great progress in understanding the efficiency of this process in producing gravitational waves. For a conservative estimate of the energy in non-spherical motions during the collapse, relation (2.32) leads to events of an amplitude detectable in our galaxy, even by bar detectors. The next generation of laser interferometers would be able to detect such signals from Virgo cluster at a rate of a few events per month.

The main source for deviations from spherical or axial symmetry during the collapse is the angular momentum. During the contraction phase, the angular momentum is conserved, and the star spins up to rotational periods of the order of 1 msec. In this case, consequent processes with large luminosity might take place in this newly born neutron star. A number of instabilities, such as the so-called *bar mode instability* and the *r-mode instability*, may occur which radiate copious amounts of gravitational radiation immediately after the initial burst. Gravitational wave signals from these rotationally induced stellar instabilities are detectable from sources in our galaxy and are marginally detectable if the event takes place in the nearby cluster of about 2500 galaxies, the Virgo cluster, 15 Mpc away from the Earth. Additionally, there will be weaker but extremely useful signals due to subsequent oscillations of the neutron star; *f*, *p* and *w* modes are some of the main patterns of oscillations (normal modes) of the neutron star that observers might search for.

These modes have been studied in detail and once detected in the signal, they would provide a sensitive probe of the neutron star structure and its supranuclear equation of state. Detectors with high sensitivity in the kHz band will be needed in order to fully develop this so-called gravitational wave asteroseismology.

If the collapsing central core is unable to drive off its surrounding envelope, then the collapse continues and finally a black hole forms. In this case the instabilities and oscillations that we discussed above are absent and the newly formed black hole radiates away, within a few milliseconds, any deviations from axisymmetry and ends up as a rotating or *Kerr* black hole. The characteristic oscillations of black holes (normal modes) are well studied, and this unique ringing down of a black hole could be used as a direct probe of their existence. The frequency of the signal is inversely proportional to the black hole mass. For example, it has been stated earlier that a $100M_{\odot}$ black hole will oscillate at a frequency of ∼100 Hz (an ideal source for LIGO), while a supermassive one with mass $10^7 M_{\odot}$, which might be excited by an infalling star, will ring down at a frequency of 10^{-3} Hz (an ideal source for LISA). The analysis of such a signal should reveal directly the two parameters that characterize any (uncharged) black hole; namely its mass and angular momentum.

4.2 Radiation from binary systems

Binary systems are the best sources of gravitational waves because they emit copious amounts or gravitational radiation, and for a given system we know exactly what is the amplitude and frequency of the gravitational waves in terms of the masses of the two bodies and their separation (see section 2.5). If a binary system emits detectable gravitational radiation in the bandwidth of our detectors, we can easily identify the parameters of the system. According to the formulas of section 2.5, the observed frequency change will be

$$\dot{f} \sim f^{11/3} \mathcal{M}^{5/3}, \tag{4.1}$$

and the corresponding amplitude will be

$$h \sim \frac{\mathcal{M}^{5/3} f^{2/3}}{r} = \frac{\dot{f}}{r f^3}, \tag{4.2}$$

where $\mathcal{M}^{5/3} = \mu M^{2/3}$ is a combination of the total and reduced mass of the system, called *chirp mass*. Since both frequency f and its rate of change $\dot{f}$ are measurable quantities, we can immediately compute the chirp mass (from the first relation), thus obtaining a measure of the masses involved. The second relation provides a direct estimate of the distance of the source. These relations have been derived using the Newtonian theory to describe the orbit of the system and the quadrupole formula for the emission of gravitational waves. Post-Newtonian theory inclusion of the most important relativistic corrections in the description of the orbit can provide more accurate estimates of the individual masses of the components of the binary system.

When analyzing the data of periodic signals the *effective amplitude* is not the amplitude of the signal alone but $h_c = \sqrt{n} \cdot h$, where n is the number of cycles of the signal within the frequency range where the detector is sensitive. A system consisting of two typical neutron stars will be detectable by LIGO when the frequency of the gravitational waves is ∼10Hz until the final coalescence around 1000Hz. This process will last for about 15 min and the total number of observed cycles will be of the order of 10^4, which leads to an enhancement of the detectability by a factor 100. Binary neutron star systems and binary black hole systems with masses of the order of $50M_\odot$ are the primary sources for LIGO. Given the anticipated sensitivity of LIGO, binary black hole systems are the most promising sources and could be detected as far as 200 Mpc away. The event rate with the present estimated sensitivity of LIGO is probably a few events per year, but future improvement of detector sensitivity (the LIGO II phase) could lead to the detection of at least one event per month. Supermassive black hole systems of a few million solar masses are the primary source for LISA. These binary systems are rare, but due to the huge amount of energy released, they should be detectable from as far as the boundaries of the observable universe.

4.3 Radiation from spinning neutron stars

A perfectly axisymmetric rotating body does not emit any gravitational radiation. Neutron stars are axisymmetric configurations, but small deviations cannot be ruled out. Irregularities in the crust (perhaps imprinted at the time of crust formation), strains that have built up as the stars have spun down, off-axis magnetic fields, and/or accretion could distort the axisymmetry. A bump that might be created at the surface of a neutron star spinning with frequency f will produce gravitational waves at a frequency of $2f$ and such a neutron star will be a weak but continuous and almost monochromatic source of gravitational waves. The radiated energy comes at the expense of the rotational energy of the star, which leads to a spin down of the star. If gravitational wave emission contributes considerably to the observed spin down of pulsars, then we can estimate the amount of the emitted energy. The corresponding amplitude of gravitational waves from nearby pulsars (a few kpc away) is of the order of $h \sim 10^{-25} - 10^{-26}$, which is extremely small. If we accumulate data for sufficiently long time, e.g., 1 month, then the effective amplitude, which increases as the square root of the number of cycles, could easily go up to the order of $h_c \sim 10^{-22}$. We must admit that at present we are extremely ignorant of the degree of asymmetry in rotating neutron stars, and these estimates are probably very optimistic. On the other hand, if we do not observe gravitational radiation from a given pulsar we can place a constraint on the amount of non axisymmetry of the star.

4.4 Cosmological gravitational waves

One of the strongest pieces of evidence in favor of the Big Bang scenario is the 2.7 K cosmic microwave background radiation. This thermal radiation first bathed the

universe around 380,000 years after the Big Bang. By contrast, the gravitational radiation background anticipated by theorists was produced at Planck times, i.e., at 10^{-32} sec or earlier after the Big Bang. Such gravitational waves have travelled almost unimpeded through the universe since they were generated. The observation of cosmological gravitational waves will be one of the most important contributions of gravitational wave astronomy. These primordial gravitational waves will be, in a sense, another source of noise for our detectors and so they will have to be much stronger than any other internal detector noise in order to be detected. Otherwise, confidence in detecting such primordial gravitational waves could be gained by using a system of two detectors and cross-correlating their outputs. The two LIGO detectors are well placed for such a correlation.

Acknowledgements

An Introduction to General Relativity, Gravitational Waves and Detection Principles

Dr Martin Hendry

University of Glasgow, UK

martin@astro.gla.ac.uk

Overview

These lectures present an introduction to General Relativity (GR) and its implications for the basic design properties of gravitational wave detectors.

In Sections 1 to 5 we discuss the foundations of GR and its key physical idea – that gravity manifests itself as a curvature of spacetime. We introduce the mathematical machinery necessary to describe this curvature and then briefly discuss the formulation and solution of Einstein's field equations, which encode the relationship between the curvature of spacetime and its matter and energy content.
In Sections 6 to 9 we then investigate the characteristics of *non-stationary* spacetimes. Although for simplicity we restrict our discussion to the **weak-field approximation**, we nevertheless derive a number of key results for gravitational wave research:

- We show that the free-space solutions for the metric perturbations of a 'nearly flat' spacetime take the form of a wave equation, propagating at the speed of light. This encapsulates the central physical idea of General Relativity: that the instantaneous 'spooky action at a distance' of Newton's gravitational force is replaced in Einstein's theory by spacetime curvature. Moreover, changes in this curvature – the so-called 'ripples in spacetime' beloved of popular accounts of gravitational waves – propagate outward from their source at the speed of light in a vacuum.

- We consider carefully the mathematical characteristics of our metric perturbation, and show that a coordinate system (known as the **Transverse–Traceless gauge**) can be chosen in which its 16 components reduce to only 2 independent components (which correspond to 2 distinct **polarisation states**).

- We investigate the geodesic equations for nearby test particles in a 'nearly flat' spacetime, during the passage of a gravitational wave. We demonstrate the quadrupolar nature of the wave disturbance and the change in the proper

distance between test particles which it induces, and explore the implications of our results for the basic design principles of gravitational wave detectors.

- As a 'taster' for the lectures to follow, we derive some basic results on the generation of gravitational waves from a simple astrophysical source: a binary star system. In particular, we estimate the amplitude and frequency from e.g. a binary neutron star system, and demonstrate that any gravitational waves detected at the Earth from such an astrophysical source will be extremely weak.

These lectures are extracted, adapted and extended from a 20 lecture undergraduate course on General Relativity and a short graduate course on gravitational waves – both of which I have taught in recent years at the University of Glasgow. Anyone who wishes to may access the complete lecture notes for the undergraduate course via the following websites:

Part 1: Introduction to General Relativity.

`http://www.astro.gla.ac/users/martin/teaching/gr1/gr1_index.html`

Part 2: Applications of General Relativity.

`http://www.astro.gla.ac.uk/users/martin/teaching/gr2/gr2_index.html`

Both websites are password-protected, with username and password 'honours'.

Suggested Reading

Much of the material covered in these lectures can be found, in much greater depth, in Bernard Schutz' classic textbook '*A first Course in General Relativity*' (CUP; ISBN 0521277035). For an even more comprehensive treatment see also '*Gravitation*', by Misner, Thorne and Wheeler (Freeman; ISBN 0716703440) – although this book is not for the faint-hearted (quite literally, as it has a mass of several kg!)

Notation, Units and Conventions

In these lectures we will follow the convention adopted in Schutz' textbook and use a metric with signature $(-,+,+,+)$. Although we will generally present equations in component form, where appropriate we will write one forms, vectors and tensors in bold face (e.g. $\tilde{\mathbf{p}}$ and $\vec{\mathbf{V}}$ and $\mathbf{T}$ respectively). We will adopt throughout the standard Einstein summation convention that an upper and lower repeated index implies summation over that index. We will normally use Roman indices to denote spatial components (i.e. $i = 1, 2, 3$ etc) and Greek indices to denote 4-dimensional components (i.e. $\mu = 0, 1, 2, 3$ etc).

We will generally use commas to denote partial differentiation and semi-colons to denote covariant differentation, when expressions are given in component form. We will also occasionally follow the notation adopted in Schutz, and denote the covariant derivative of e.g. the vector field $\vec{\mathbf{V}}$ by $\nabla\vec{\mathbf{V}}$. Similarly, we will denote the covariant derivative of a vector $\vec{\mathbf{V}}$ along a curve with tangent vector $\vec{\mathbf{U}}$ by $\nabla_{\vec{\mathbf{U}}}\vec{\mathbf{V}}$

Finally, in most situations we will use so-called **geometrised units** in which $c = 1$ and $G = 1$. Thus we effectively measure time in units of **length** – specifically, the distance travelled by light in that time. Thus

$$1 \text{ second} \equiv 3 \times 10^8 \text{ m} .$$

Recall that the gravitational constant, G, in SI units is

$$G \simeq 6.67 \times 10^{-11}\,\mathrm{N\,m^2\,kg^{-2}}$$

but the Newton is a composite SI unit; i.e.

$$1\,\mathrm{N} = 1\,\mathrm{kg\,m\,s^{-2}}$$

so that

$$G \simeq 6.67 \times 10^{-11}\,\mathrm{m^3\,kg^{-1}\,s^{-2}}$$

Replacing our unit of time with the unit of length defined above, gives

$$G \simeq 7.41 \times 10^{-28}\,\mathrm{m\,kg^{-1}}$$

So by setting $G = 1$ we are effectively measuring *mass* also in units of length. It follows that, in these new units

$$1\ \mathrm{kg} = 7.41 \times 10^{-28}\ \mathrm{m}\ .$$

In summary, then, our geometrised units take the form

$$\begin{array}{lrcl} \text{Unit of length:} & 1\ \mathrm{m} & & \\ \text{Unit of time:} & 1\ \mathrm{m} & \equiv & 3.33 \times 10^{-9}\ \mathrm{s} \\ \text{Unit of mass:} & 1\ \mathrm{m} & \equiv & 1.34 \times 10^{27}\ \mathrm{kg} \end{array}$$

1 Foundations of General Relativity

General relativity (GR) is Albert Einstein's theory of gravitation, which he published in 1916, 11 years after publishing his Special Theory of Relativity. While the latter theory probably has had wider cultural impact (*everyone* has heard of "E equals mc squared"!) GR is widely recognised among physicists as Einstein's real masterwork: a truly remarkable achievement, greater than all the feats of his 'Annus Mirabilis' in 1905. It was described by Max Born as "the greatest feat of human thinking about nature, the most amazing combination of philosophical penetration, physical intuition and mathematical skill".

GR explains gravitation as a consequence of the curvature of spacetime, while in turn spacetime curvature is a consequence of the presence of matter. Spacetime curvature affects the movement of matter, which reciprocally determines the geometric properties and evolution of spacetime. We can sum this up neatly (slightly paraphrasing a quotation due to John Wheeler) as follows:

Spacetime tells matter how to move,
and matter tells spacetime how to curve

A useful metaphor for gravity as spacetime curvature is to visualise a stretched sheet of rubber, deformed by the presence of a massive body (see Figure 1).

To better understand how Einstein arrived at this remarkable theory we should first briefly consider his Special Theory of Relativity.

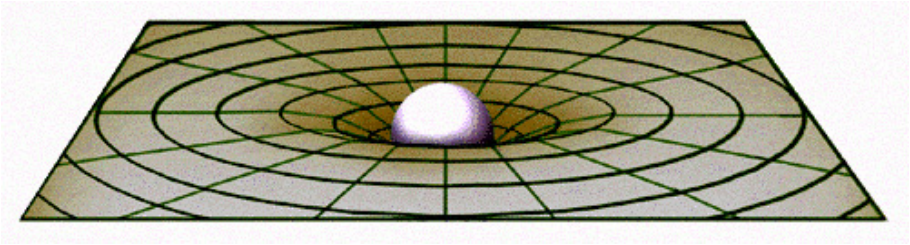

Figure 1: Familiar picture of spacetime as a stretched sheet of rubber, deformed by the presence of a massive body. A particle moving in the gravitational field of the central mass will follow a curved – rather than a straight line – trajectory as it moves across the surface of the sheet and approaches the central mass.

1.1 Special relativity

GR is a generalisation of special relativity (SR), in which Einstein set out to formulate the laws of physics in such a way that they be valid in all **inertial reference frames** – i.e. all frames in which Newton's first and second laws of motion hold – independently of their relative motion. At the heart of SR is the fundamental postulate of relativity: that the speed of light in the vacuum be the same for every inertial observer. Einstein showed that, as a consequence of this postulate, the Newtonian concept of a rigid framework of space and time against which physical phenomena were played out was no longer tenable: measurements of time and space cannot be absolute, but depend on the observer's motion and are related via the **Lorentz transformations**. Space and time as distinct entities gave way to a unified spacetime, and only the **spacetime interval** between events is independent of the observer's reference frame (referred to as **Lorentz frame**). For neighbouring events taking place at spacetime coordinates (t, x, y, z) and $(t + dt, x + dx, y + dy, z + dz)$, the interval is defined by

$$ds^2 = -c^2dt^2 + dx^2 + dy^2 + dz^2 \tag{1}$$

Another inertial observer using a different coordinate system (t', x', y', z') (i.e. in a different Lorentz frame) will find the same value for the spacetime interval between the events, despite measuring them to have a different spatial and temporal

separation. Moreover:

- Intervals between neighbouring events with $ds^2 < 0$ are **timelike**; there exists a Lorentz frame ($\mathcal{A}$) in which the events occur at the same spatial coordinates, and in frame $\mathcal{A}$ the coordinate time separation of the events is equal to the **proper time** interval between them. Furthermore, the two events could lie on the **worldline** (i.e. the trajectory through spacetime) of a material particle.

- Intervals between neighbouring events with $ds^2 > 0$ are **spacelike**; there exists a Lorentz frame ($\mathcal{B}$) in which the events occur at the same coordinate time, and in frame $\mathcal{B}$ the spatial separation of the events is equal to the **proper distance** between them. The two events could *not* lie on the worldline of a material particle (since in frame $\mathcal{B}$ the particle would appear to be in two places at once!).

- Intervals between neighbouring events with $ds^2 = 0$ are **null** or **lightlike**; the two events could lie on the worldline of a photon

The geometry described by equation (1) differs markedly from that of 'flat' Euclidean space, and is known as Minkowski spacetime. We can re-write equation (1) more generally as

$$ds^2 = g_{\mu\nu} dx^\mu dx^\nu \tag{2}$$

where summation over the indices μ and ν is implied and both indices range over $0, 1, 2, 3$, corresponding to t, x, y, z. In equation (2) the $g_{\mu\nu}$ are components of the **metric** (we will provide a more formal definition of the metric shortly) which describes how intervals are measured in our spacetime. In general these components may be complicated functions of the spacetime coordinates but for Minkowski spacetime, in Cartesian coordinates and setting $c = 1$, the metric takes a very simple form

$$g_{\mu\nu} = \mathrm{diag}(-1, 1, 1, 1) \tag{3}$$

How does Newtonian gravity fit into this SR picture? We see immediately that the answer is "not well". Newtonian gravity is inherently non-relativistic since it describes the gravitational force between two masses as acting instantaneously and as depending on the distance separating the two masses. Different inertial observers would not agree about either point, and so would not agree about the force of gravity between the two masses. And what about *non-inertial* observers? The elegant geometry of Minkowski spacetime applied only to observers in uniform relative motion, not to accelerated motion. Yet Einstein sought a **fully covariant** theory, capable of describing the laws of physics (including gravity) in *any* coordinate system and for *any* relative motion. The key step towards achieving this came with Einstein's realisation that gravity and accleration are fundamentally equivalent – an idea enshrined in the **principle of equivalence**.

1.2 The equivalence principles

The principle of equivalence is often presented in two distinct forms: the **weak equivalence principle** and the **strong equivalence principle**.

1.2.1 The weak equivalence principle

In Newtonian physics the **inertial mass** of a body is a measure of its resistance to acceleration, and is the quantity that appears on the right hand side of the equation describing Newton's second law: "force equals mass times acceleration". The gravitational mass of a body, on the other hand, is the quantity that appears in Newton's law of universal gravitation. There is no *a priori* reason, in Newtonian physics, why these two masses should be equal and yet experimentally they are found to be identically so, to extremely high precision.

The **weak equivalence principle** (WEP) takes the equivalence of inertial and gravitational mass as axiomatic, stating that the inertial mass, m_I, and the gravi-

tational mass, m_G, of a body are indeed identically equal.

A profound result follows immediately from the WEP: a massive object 'freely falling' in a uniform gravitational field (e.g. a lift plummeting Earthwards after its cable has been snapped, or the interior of a spacecraft orbiting the Earth) will obey Newton's first and second laws of motion. In other words **the freely falling object inhabits an inertial frame in which all gravitational forces have disappeared**.

We call the reference frame inhabited by our freely-falling object a **local inertial frame** (LIF): the reference frame is only inertial over the region of spacetime for which the gravitational field is uniform. (The effective size of the LIF therefore depends on how rapidly the gravitational field varies as a function of position, and on how accurately we can measure the separation and velocity of freely-falling bodies).

The WEP has a number of important, and testable, physical consequences:

1. The empirically observed equality of gravitational and inertial mass is explained.

2. The acceleration of a test mass[1] in a gravitational field is entirely independent of its nature, mass and composition.

3. The path of a light ray will be bent by the gravitational field of a massive body.

4. A light ray emitted from the surface of a massive body will be *redshifted* (the effect is referred to as the **gravitational redshift**) when its wavelength is measured by a distant observer.

Experimental verification of the second point has a long and illustrious history (from Galileo to Apollo 15!). Experimental measurement of the gravitational redshift has

[1] i.e. an object with mass that is sufficiently small that it produces no measurable change in the gravitational field of the larger body towards which it is attracted.

been carried out from various astrophysical sources, as well as terrestrially via the Pound-Rebka experiment. (See e.g. Wikipedia for a clear and concise overview). We will briefly discuss gravitational light deflection later, in the context of the so-called *Schwarzschild solution* of Einstein's equations.

1.2.2 The strong equivalence principle

The strong equivalence principle (SEP) goes further and states that locally (i.e. in a LIF) *all* the laws of physics have their usual special relativistic form – except for gravity, which simply disappears. Moreover, the SEP states that there is *no* experiment that we can carry out to distinguish between a LIF which is freely-falling in a uniform gravitational field and an inertial frame which is in a region of the Universe far from any gravitating masses (and therefore well-described by the SR geometry of Minkowski spacetime).

Conversely, if we are inside a spaceship in our remote region of the cosmos free from gravity, we can *simulate* gravity by giving the rocket an acceleration; this acceleration will be indistinguishable from a uniform gravitational field with equal (but opposite) gravitational acceleration – gravity and acceleration are equivalent.

1.3 From special to general relativity

So the equivalence principles tell us that – provided our gravitational field is uniform (or can be reasonably approximated to be uniform) we can define a LIF: a coordinate system within which gravity has locally been 'transformed away', the laws of physics agree with SR and the metric of spacetime can be reduced to the simple Minkowski form of equation (3). Yet this is only the first step towards a fully covariant theory of gravity. In general gravitational fields are decidedly *not* uniform (the inertial frames defined by two freely-falling lifts in London and Sydney are very different) so we can *only* transform away their effects locally.

In order to be an effective theory of gravity, GR must provide us with the means to 'stitch together' LIFs across extended regions of spacetime, containing non-uniform gravitational fields. This stitching process turns the locally 'flat' geometry of Minkowski spacetime – which can be applied to each LIF – into the curved geometry that characterises the gravitational field of extended regions.

To describe spacetime curvature rigorously will require mathematical tools from the field of differential geometry: essentially extending the familiar description of physical quantities in terms of scalars and vectors to **tensors**. We will discuss tensors and their properties sparingly, in order not to get too bogged down in mathematics and too far removed from the physics of GR, but some discussion of tensors will be essential if we are to fully understand GR and its theoretical importance for the study of gravitational waves.

Before we introduce tensors to our mathematical toolbox, however, we can first gain some further physical insight into the relationship between gravity, acceleration and spacetime curvature by considering in a simplified way the trajectories of freely falling particles – paths known in GR as **geodesics**.

2 Introduction to Geodesic Deviation

2.1 Basic concepts of geodesics

According to Newton's laws the 'natural' trajectory of a particle which is not being acted upon by any external force is a straight line. In GR, since gravity manifests itself as spacetime curvature, these 'natural' straight line trajectories generalise to curved paths known as **geodesics**. These are defined physically as the trajectories followed by freely falling particles – i.e. particles which are not being acted upon by any *non-gravitational* external force.

Geodesics are defined *mathematically* as spacetime curves that parallel transport their own tangent vectors – concepts that we will explain in Section 3. For metric spaces (i.e. spaces on which a metric function can be defined) we can also define geodesics as extremal paths in the sense that – along the geodesic between two events E_1, and E_2, the elapsed proper time is an extremum, i.e.

$$\delta \int_{E_1}^{E_2} d\tau = 0 \tag{4}$$

Mathematically, the curvature of spacetime can be revealed by considering the deviation of neighbouring geodesics. The behaviour of geodesic deviation is represented qualitatively in Figure 2, which shows three 2-dimensional surfaces of different intrinsic curvature on which two ants are moving along neighbouring, initially parallel trajectories. On the leftmost surface, a flat piece of paper with zero intrinsic curvature, the separation of the ants remains constant as they move along their neighbouring geodesics. On the middle surface, a spherical tennis ball with positive intrinsic curvature, the ants' separation *decreases* with time – i.e. the geodesics move towards each other. On the rightmost surface, a 'saddle' shape with negative intrinsic curvature, the ants' separation *increases* with time – i.e. the geodesics move apart.

Specifically it is the **acceleration of the deviation between neighbouring**

geodesics which is a signature of spacetime curvature, or equivalently (as we would describe it in Newtonian physics) the presence of a non-uniform gravitational field. This latter point is important: geodesic deviation cannot distinguish between a *zero* gravitational field and a *uniform* gravitational field; in the latter case the acceleration of the geodesic deviation is also zero. Only for a non-uniform, or **tidal** gravitational field does the geodesic deviation accelerate. We will see later that it is precisely these tidal variations to which gravitational wave detectors are sensitive.

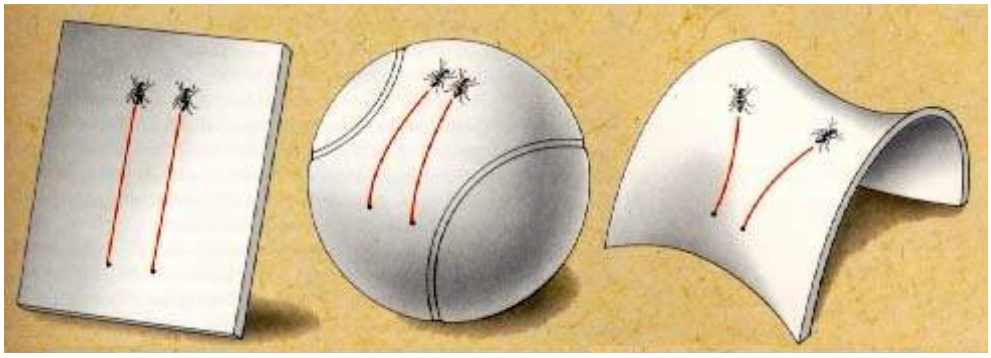

Figure 2: Geodesic deviation on surfaces of different intrinsic curvature. On a flat surface, with zero curvature, the separation of the ants remains constant – i.e. neighbouring geodesics remain parallel. On the surface of a sphere, with positive curvature, the separation of the ants decreases – i.e. neighbouring geodesics converge. On the surface of a saddle, with negative curvature, the separation of the ants increases – i.e. neighbouring geodesics diverge.

Before we consider a full GR description of the relationship between geodesic deviation and spacetime curvature, it is instructive to consider a rather simpler illustration: a Newtonian description of the behaviour of neighbouring free-falling particles in a non-uniform gravitational field.

2.2 Geodesic deviation in Newtonian gravity

Figure 3 is a (hugely exaggerated) cartoon illustration of two test particles that are initially suspended at the same height above the Earth's surface (assumed to be spherical) and are released from rest. According to Newtonian physics, the separation of these test particles will reduce as they freely fall towards the Earth, because they are falling in a non-uniform gravitational field. (The gravitational force on each particle is directed towards the centre of the Earth, which means that their acceleration vectors are not parallel).

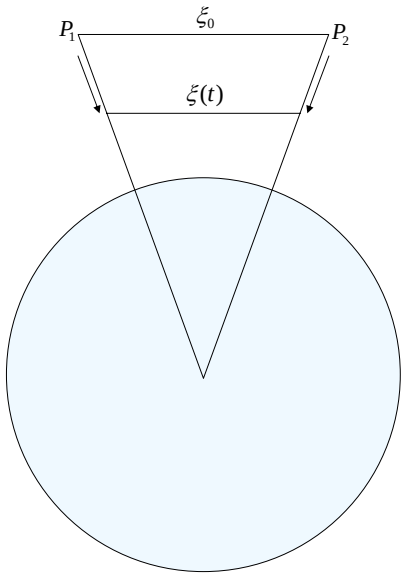

Figure 3: Cartoon illustrating how in Newtonian physics the separation of test particles will change in time if they are falling freely in a non-uniform gravitational field.

Suppose the initial separation of the test particles is ξ_0 and their distance from the centre of the Earth is r_0, while after some time t their separation is $\xi(t)$ and their distance from the centre of the Earth is $r(t)$. From similar triangles we can see that

$$\frac{\xi(t)}{r(t)} = \frac{\xi_0}{r_0} = k \tag{5}$$

where k is a constant. Taking derivatives with respect to time gives

$$\ddot{\xi} = k\ddot{r} = -\frac{kGM}{r^2} \tag{6}$$

where M is the mass of the Earth. Substituting for $k = \xi/r$ gives

$$\ddot{\xi} = -\frac{\xi}{r}\,\frac{GM}{r^2} = -\frac{GM\xi}{r^3} \tag{7}$$

If the test particles are released close to the Earth's surface then $r \approx R$, where R is the radius of the Earth, so $\ddot{\xi} = -GM\xi/R^3$. We can re-define our time coordinate and express this equation as

$$\frac{d^2\xi}{d(ct)^2} = -\frac{GM}{R^3c^2}\,\xi \tag{8}$$

Notice that in equation (8) the coefficient of ξ on the right hand side has dimensions [length]$^{-2}$. Evaluated at the Earth's surface this quantity equals about 2×10^{-23} m^{-2}.

2.3 Intrinsic curvature and the gravitational field

We can begin to understand the physical significance of equation (8) by making use of a 2-dimensional analogy. Suppose P_1 and P_2 are on the equator of a sphere of radius a (see Figure 4). Consider two geodesics – 'great circles' of constant longitude perpendicular to the equator, passing through P_1 and P_2, and separated by a distance ξ_0 at the equator. The arc distance along each geodesic is denoted by s and the separation of the geodesics at s is $\xi(s)$.

Evidently the geodesic separation is not constant as we change s and move towards the north pole N. We can write down the differential equation which governs the change in this geodesic separation. If the (small) difference in longitude between the two geodesics is $d\phi$ (in radians) then $\xi_0 = a\,d\phi$. At latitude θ (again, in radians) corresponding to arc length s, on the other hand, the geodesic separation is

$$\xi(s) = a\cos\theta\,d\phi = \xi_0\cos\theta = \xi_0\cos s/a \tag{9}$$

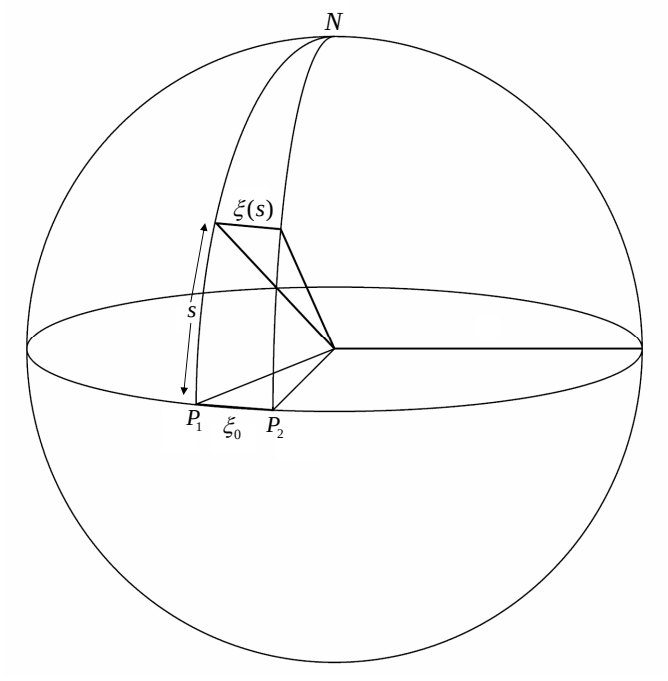

Figure 4: Illustration of the change in geodesic separation as we move along great circles of constant longitude on the surface of a sphere.

Differentiating $\xi(s)$ twice with respect to s yields

$$\frac{d^2\xi}{ds^2} = -\frac{1}{a^2}\xi \tag{10}$$

Comparing equations (8) and (9) we see that in some sense the quantity

$$\mathcal{R} = \left\{ \frac{GM}{R^3c^2} \right\}^{-\frac{1}{2}} \tag{11}$$

represents the *radius of curvature of spacetime* at the surface of the Earth. Evaluating this radius for the Earth we find that $\mathcal{R} \sim 2 \times 10^{11}$ m. The fact that this value is so much larger than the physical radius of the Earth tells us that spacetime is 'nearly' flat in the vicinity of the Earth – i.e. the Earth's gravitational field is rather weak. (By contrast, if we evaluate $\mathcal{R}$ for e.g. a white dwarf or neutron star then we see evidence that their gravitational fields are much stronger).

We will soon return to the subject of spacetime curvature and consider how it is expressed in GR. Before we can do that, however, we need to expand the mathematical armoury at our disposal.

3 A mathematical toolbox for GR

To deal rigorously with the geometrical properties of curved spacetimes we need to introduce a number of mathematical concepts and tools. We begin with the concept of a **manifold**.

3.1 Manifolds

A manifold is a continuous space which is locally flat. More generally we can regard a manifold as any set which can be continuously parametrised: the number of independent parameters is the *dimension* of the manifold, and the parameters themselves are the *coordinates* of the manifold. A *differentiable manifold* is one which is both continuous and differentiable. This means that we can define a scalar function (or *scalar field*) – ϕ, say – at each point of the manifold, and that ϕ is differentiable.

> **Mathematical Aside:** The formal mathematics of defining coordinates need not concern us in these lectures, but the interested reader can find useful discussions in any introductory textbook on differential geometry. Loosely speaking, it involves covering the points of the manifold by a collection of *open sets*, $\mathbf{U^i}$, each of which is mapped onto $\mathbf{R^n}$ by a one-to-one mapping, ϕ^i. The pair $(\mathbf{U^i}, \phi^i)$ is called a *chart*, and the collection of charts an *atlas*. One can think of each chart as defining a different coordinate system.

In GR we are concerned with a particular class of differentiable manifolds known as **Riemannian manifolds**. A Riemannian manifold is a differentiable manifold on which a *distance*, or *metric*, has been defined.

We can see why the mathematics of Riemannian manifolds are appropriate for GR. According to the WEP spacetime is locally flat and the interval between spacetime events is described by a metric, following equation (2). Moreover, any dynamical

theory of gravity will involve space and time derivatives; hence our description of spacetime should be differentiable. Riemannanian manifolds meet all three criteria.

3.2 Scalar functions on a manifold

One can define a function, f, on a manifold, $\mathbf{M}$. At any point, P, of the manifold the function takes a real value

$$f : \mathbf{M} \rightarrow \mathbf{R} \tag{12}$$

In a particular coordinate representation, P has coordinates $\{x^1, x^2, ..., x^n\}$. We may then write simply

$$f_P \quad = \quad f(x^1, x^2, ..., x^n) \tag{13}$$

Here f is called a *scalar* function; this means that its numerical value at each point of the manifold is the same real number, no matter which coordinate representation is used.

3.3 Vectors in curved spaces

The intuitive picture of a vector which we have learned in elementary maths and physics courses is based on the simple idea of an arrow representing a *displacement* between two points in space. Moreover a vector, $\vec{a}$, exists independently of our choice of coordinate system, but the *components* of $\vec{a}$ take different values in different coordinate systems, and we can define a transformation law for the components of the vector.

Consider, for example, the displacement vector, $\Delta\vec{x}$, with components Δx^μ and $\Delta x'^\mu$ in an unprimed and primed coordinate system respectively. Then, by the chain rule for differentiation

$$\Delta x'^\mu = \frac{\partial x'^\mu}{\partial x^\alpha} \Delta x^\alpha \tag{14}$$

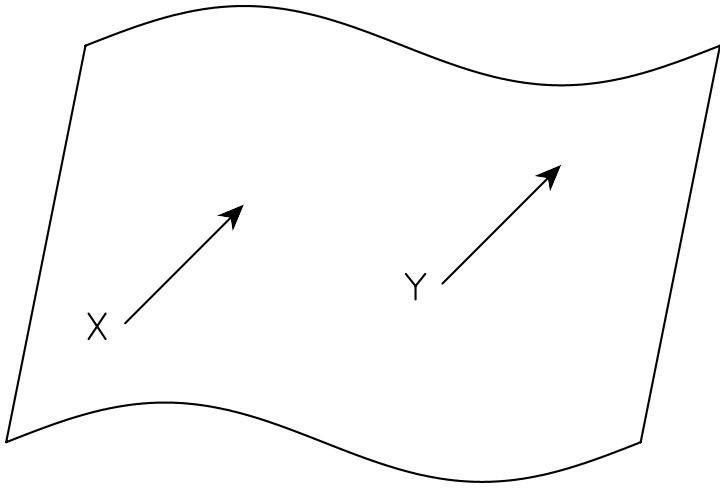

Figure 5: Vectors on a curved manifold. In general the components of $\Delta\vec{x}$ at X and of $\Delta\vec{y}$ at Y will be different, because they are defined at different points in the manifold.

Consider now two displacement vectors, $\Delta\vec{x}$ and $\Delta\vec{y}$. How can we decide if $\Delta\vec{x}$ and $\Delta\vec{y}$ are equal when – as shown in Figure 5 – they are defined at different points on our manifold? For vectors in flat space with Cartesian coordinates, for example, we can simply 'translate' $\Delta\vec{y}$ to X and compare the components of $\Delta\vec{y}$ with those of $\Delta\vec{x}$. This will **not** be valid for a general curved manifold, however, because the coefficients of the transformation law in equation (14) are in general functions of position. In other words, the transformation law between the primed and unprimed coordinate systems is in general *different* at different points of the manifold. Thus, it is *not* enough to define the components of a vector; we also need to specify the point of the manifold at which the vector (and its components) are defined.

The fact that the transformation law coefficients of equation (14) are in general functions of position also means that we have no 'universal' set of coordinate basis vectors on a curved manifold, as is the case for Euclidean space. There is, however, a means of defining a natural set of basis vectors for each point of the manifold

which allows us to develop a more general picture of what we mean by a vector – and one which is equally valid in a curved spacetime.

3.4 Tangent vectors

Suppose we have a scalar function, ϕ, defined at a point, P, of a Riemannian manifold, where P has coordinates $\{x^1, x^2, ..., x^n\}$ in some coordinate system. Since our manifold is differentiable we can evaluate the derivative of ϕ with respect to each of the coordinates, x^i, for $i = 1, ..., n$. In fact, since ϕ is completely arbitrary, we can think of the derivatives as a set of n 'operators', denoted by

$$\frac{\partial}{\partial x^i}$$

These operators can act on any scalar function, ϕ, and yield the rate of change of the function with respect to the x^i.

We can now define a **tangent vector** at point, P, as a linear operator of the form

$$a^\mu \frac{\partial}{\partial x^\mu} \equiv a^1 \frac{\partial}{\partial x^1} + a^2 \frac{\partial}{\partial x^2} + ... + a^n \frac{\partial}{\partial x^n} \tag{15}$$

(Note the use of the summation convention). This tangent vector operates on any function, ϕ, and essentially gives the rate of change of the function – or the *directional derivative* – in a direction which is defined by the numbers $(a^1, a^2, ..., a^n)$. We can define the addition of two tangent vectors in the obvious way

$$a^\mu \frac{\partial}{\partial x^\mu} + b^\mu \frac{\partial}{\partial x^\mu} = (a^\mu + b^\mu) \frac{\partial}{\partial x^\mu} \tag{16}$$

> **Mathematical Aside:** With this straightforward definition of addition, a little formal mathematics easily shows that the set of all tangent vectors form a *vector space*

Thus, the operator,

$$a^\mu \frac{\partial}{\partial x^\mu}$$

behaves like a vector, the components of which are $(a^1, a^2, ..., a^n)$. We can therefore write

$$\vec{a} = a^\mu \frac{\partial}{\partial x^\mu} \tag{17}$$

The n operators $\frac{\partial}{\partial x^\mu}$ can be thought of as forming a set of basis vectors, $\{\vec{e_\mu}\}$, spanning the vector space of tangent vectors at P.

What exactly do these basis vectors represent? We can find a simple geometrical picture for the $\vec{e_\mu}$ by first crystallising the notion of a *curve*, C, defined on our manifold. Our intuitive notion of a curve is simply of a connected series of points on the manifold; in the mathematical literature, however, we call this a *path*, and the term *curve* is instead reserved for the particular case of a path which has been *parametrised*.

Thus, a curve is a function which maps an interval of the real line into the manifold. Putting this more simply, a curve is a path with a real number (s, say) associated with each point of the path; we call s the parameter of the curve. Note also that once we choose a coordinate system each point on the curve has coordinates, $\{x^\mu\}$, which may also be expressed as functions of the parameter, s, i.e.

$$x^\mu = x^\mu(s) \quad \mu = 1, ..., n \tag{18}$$

Once we specify our coordinate system, we can consider a particular set of curves which use the *coordinates themselves* as their parameter. For example, point P with coordinates $\{x^1, x^2, ..., x^n\}$ lies on the n curves which we obtain by allowing only the value of x^i to vary along the i^{th} curve ($i = 1, ..., n$) and fixing all other coordinate values to be equal to their values at P. (To visualise a simple example, think of circles of equal latitude and longitude on the 2-sphere manifold). The basis vector, $\vec{e_i} \equiv \frac{\partial}{\partial x^i}$ can be thought of simply as the *tangent* to the i^{th} curve. This geometrical

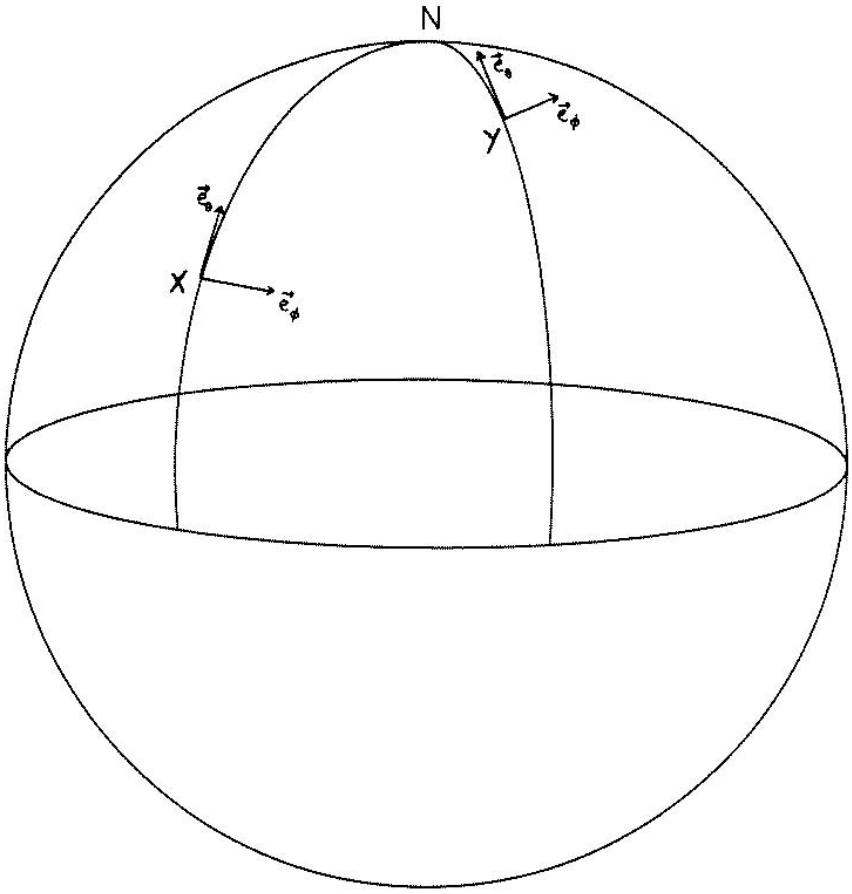

Figure 6: Illustration of the coordinate basis vectors defined at two points X and Y on the surface of a sphere. Note that the basis vectors $\vec{e_\phi}$ and $\vec{e_\theta}$ are *different* at points X and Y.

picture is illustrated in Figure 6, again for the straightforward example of the 2-sphere. Note that the basis vectors $\vec{e_\phi}$ and $\vec{e_\theta}$ are *different* at points X and Y of the manifold.

And what of a more general curve in the manifold? Here we simply connect the notion, introduced above, of a tangent vector as a directional derivative to our straightforward geometrical picture of a tangent to a curve. Figure 7 (adapted from Schutz) shows a curve, with parameter s, and with tangent vectors drawn at points with different parameter values. Suppose the coordinates of the points on the curve are $\{x^\mu(s)\}$, for $\mu = 1, ..., n$. Then the components, T^μ, of the tangent vector with

respect to the basis $\{\vec{e_\mu}\} \equiv \{\frac{\partial}{\partial x^\mu}\}$ are simply given by

$$T^\mu = \frac{dx^\mu}{ds} \tag{19}$$

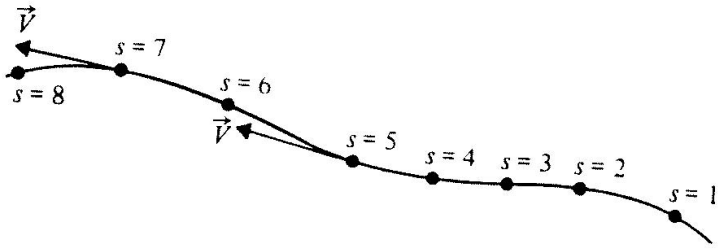

Figure 7: Schematic representation of a curve, parametrised by s, and showing tangent vectors drawn at $s = 5$ and $s = 7$.

To sum up, we can represent vectors as tangent vectors of curves in our manifold. Once we have specified our coordinate system, we can write down the components of a vector defined at any point of the manifold with respect to the natural basis generated by the derivative operators $\{\frac{\partial}{\partial x^\mu}\}$ at that point. A vector **field** can then be defined by assigning a tangent vector at *every* point of the manifold.

3.5 Transformation law for vectors

Suppose we change to a new coordinate system $\{x'^1, x'^2, ..., x'^n\}$. Our basis vectors are now

$$\vec{e'_\mu} \equiv \frac{\partial}{\partial x'^\mu}. \tag{20}$$

How do the components, $\{a^1, a^2, ..., a^n\}$, transform in our new coordinate system? To see how the law arises within the framework of our tangent vector description, let the vector $\vec{a}$ operate on an arbitrary scalar function, ϕ. Then

$$\vec{a}(\phi) = a^\nu \frac{\partial \phi}{\partial x^\nu} \tag{21}$$

By the chain rule for differentiation we may write this as

$$\vec{a}(\phi) = a^{\nu} \frac{\partial x'^{\mu}}{\partial x^{\nu}} \frac{\partial \phi}{\partial x'^{\mu}} \tag{22}$$

However, if we write $\vec{a}$ directly in terms of coordinate basis $\{\vec{e'_{\mu}}\} = \{\frac{\partial}{\partial x'^{\mu}}\}$, we have

$$\vec{a}(\phi) = a'^{\mu} \frac{\partial \phi}{\partial x'^{\mu}} \tag{23}$$

Comparing equation (22) with (23) we see that

$$a'^{\mu} = \frac{\partial x'^{\mu}}{\partial x^{\nu}} a^{\nu} \tag{24}$$

Thus the components of the tangent vector transform according to equation (24). We call this equation the transformation law for a **contravariant vector**, and say that the components of $\vec{a}$ transform **contravariantly**. (The term 'contravariant' is used to distinguish these vectors from another type of geometrical object – covariant vectors or 'covectors' – which we will meet in the next subsection. The more modern name for covariant vectors, however, is 'one-forms', and we will generally adopt that name in order to avoid this source of ambiguity). We denote the components of a contravariant vector using superscripts.

Equation (24) is the prototype transformation law for *any* contravariant vector. Any set of n components, A^{μ}, which can be evaluated in any coordinate system, and which transform according to the transformation law of equation (24), we call a contravariant vector.

3.6 Transformation law for one-forms

What is the relationship between the basis vectors $\vec{e'_{\mu}}$ and $\vec{e_{\mu}}$ in the primed and unprimed coordinate systems? From equation (20) we have

$$\vec{e'_{\mu}} = \frac{\partial x^{\nu}}{\partial x'^{\mu}} \vec{e_{\nu}} \tag{25}$$

Thus we see that the basis vectors do *not* transform in the same way as the components of a contravariant vector. This should not be too surprising, since the transformation of a basis and the transformation of components are different things: the former is the expression of *new* vectors in terms of *old* vectors; the latter is the expression of the *same* vector in terms of a new basis.

In fact, the form of the transformation in equation (25) is the same as the transformation law for another type of geometrical object, which we call a **covariant vector**, **covector**, or (in more modern literature) a **one-form**. Any set of n components, A_μ, which can be evaluated in any coordinate system, is said to be a one-form if the components transform according to the equation

$$A'_\mu = \frac{\partial x^\nu}{\partial x'^\mu} A_\nu \tag{26}$$

One can simply regard equation (26) as *defining* a one-form. Many modern textbooks on differential geometry, however, begin by defining a one-form as a linear mapping which acts on a vector to give a real number. Starting from this definition one can then arrive at equation (26).

One-forms are usually denoted by a tilde above a symbol, just as vectors are denoted by an arrow above a symbol. Thus e.g. $\tilde{p}(\vec{a})$ is a real number.

3.7 Transformation law for tensors

Having defined what we mean by vectors and one-forms, in terms of how their components transform under a general coordinate transformation, we can now extend our definition to the more general class of geometrical object which we call *tensors*.

A tensor of type (l, m), defined on an n dimensional manifold, is a linear operator which maps l one-forms and m (contravariant) vectors into a real number (i.e.

scalar). Such a tensor has a total of n^{l+m} components.

The transformation law for a general (l, m) tensor follows from its linearity, and from the transformation laws for a vector and one-form, in order that the scalar quantity obtained when the tensor operates on l one-forms and m vectors is independent of one's choice of coordinate system. We can write this general transformation law as follows

$$A'^{u_1\, u_2 \ldots u_l}_{r_1\, r_2 \ldots r_m} = \frac{\partial x'^{u_1}}{\partial x^{t_1}} \ldots \frac{\partial x'^{u_l}}{\partial x^{t_l}} \frac{\partial x^{q_1}}{\partial x'^{r_1}} \ldots \frac{\partial x^{q_m}}{\partial x'^{r_m}} A^{t_1\, t_2 \ldots t_l}_{q_1\, q_2 \ldots q_m} \tag{27}$$

This rather intimidating equation appears much more straightforward for some specific cases. First note that a contravariant vector is in fact a $(1, 0)$ tensor (since it operates on a one-form to give a scalar). Similarly a one-form is a $(0, 1)$ tensor (and more trivially a *scalar* is a $(0, 0)$ tensor).

A $(2, 0)$ tensor, say T^{ij}, is called a *contravariant* tensor of rank 2 and transforms according to the transformation law

$$T'^{ij} = \frac{\partial x'^i}{\partial x^k} \frac{\partial x'^j}{\partial x^l} T^{kl} \tag{28}$$

A $(0, 2)$ tensor, say B_{ij}, is called a *covariant* tensor of rank 2, and transforms according to the law

$$B'_{ij} = \frac{\partial x^k}{\partial x'^i} \frac{\partial x^l}{\partial x'^j} B_{kl} \tag{29}$$

An important example of a $(0, 2)$ tensor is the *metric tensor*, $g_{\mu\nu}$, which we already met in Section 1. This is a symmetric tensor, i.e.

$$g_{\mu\nu} = g_{\nu\mu} \quad \text{for all } \mu, \nu \tag{30}$$

We can now see that the form of equation (2) makes sense: the small displacements dx^μ and dx^ν transform as contravariant vectors; the metric tensor operates on these

vectors to give a scalar (the interval) which is invariant.

A tensor which has both upper and lower indices, which means that it has both contravariant and covariant terms in its transformation law, is known as a *mixed tensor*. The simplest example (after the trivial case of a $(0,0)$ tensor) is a $(1,1)$ tensor, D^i_j, say. Its transformation law is

$$D'^i_j = \frac{\partial x'^i}{\partial x^k}\frac{\partial x^l}{\partial x'^j}D'^k_l \tag{31}$$

An important example of a $(1,1)$ tensor is the Kronecker delta, δ^i_j, which has the property (in *any* coordinate system)

$$\delta^l_j = 1 \text{ when } j = l, \text{ and 0 otherwise} \tag{32}$$

3.8 Contraction of tensors

We can take the **inner product**, or **contraction** of a vector and one-form; i.e. we form the quantity A^iB_i (where, as usual, the summation convention is implied). This quantity is invariant in the sense that

$$A'^jB'_j = A^iB_i \tag{33}$$

We can generalise the operation of contraction to the case of any two tensors, and over an arbitrary number of indices, provided that an equal number of upper and lower indices are selected. In general, contraction over k indices will produce from a tensor of type (l,m) a new tensor of type $(l-k, m-k)$. For example, the contraction of the two tensors G^{ijk}_{lm} and R^s_{tu} over the indices i and t, j and u and l and s will give the $(1,1)$ tensor $G^{ijk}_{lm}R^l_{ij}$, where now only the indices k and m are free indices.

3.9 Raising and lowering indices

Given any contravariant vector A^μ it is possible to define, via the metric tensor, an associated one-form, which we denote as A_ν and which is defined by

$$A_\nu = g_{\mu\nu} A^\mu \tag{34}$$

This operation is often called *lowering the index*.

Similarly by using g^{ij} we can raise the index of a covariant quantity B_i to obtain a contravariant quantity B^i, viz.

$$B^i = g^{ij} B_j \tag{35}$$

The process of raising or lowering indices can be carried out with tensors of any rank and type. For example

$$D^{ijk\cdot\cdot}_{lm} = g_{lp} g_{mq} D^{ijkpq} \tag{36}$$

Some care must be taken in positioning the indices. The dots have been placed here to indicate the indices over which contraction has taken place, although in general we shall omit the dots and just write D^{ijk}_{lm}. Note that $D^{\cdot\cdot ijk}_{lm}$ defined by

$$D^{\cdot\cdot ijk}_{lm} = g_{lp} g_{mq} D^{pqijk} \tag{37}$$

is not the same as $D^{ijk\cdot\cdot}_{lm}$ unless D^{ijkpq} possesses some symmetry.

The *magnitude* of a vector with components A^μ is $g_{\mu\nu} A^\mu A^\nu$, which is of course invariant, since $g_{\mu\nu}$ is a $(0,2)$ tensor and A^μ and A^ν are both $(1,0)$ tensors. Notice that

$$g_{\mu\nu} A^\mu A^\nu = A_\mu A^\nu = g^{\mu\nu} A_\nu A_\nu \tag{38}$$

The quantity $g_{\mu\nu} A^\mu B^\nu$ is the scalar product of the two vectors.

3.10 Covariant differentiation and parallel transport

Any dynamical physical theory must deal in time varying quantities and, if this theory is also to be relativistic, spatially varying quantities too. Since GR is a covariant theory, we are confronted with the problem of constructing quantities that represent rates of change, but which can be defined in any coordinate system. In other words, we need to define a *derivative* which transforms covariantly under a general coordinate transformation: we call this a **covariant derivative**.

For any scalar function, say ϕ, defined on the manifold, the partial derivative

$$\phi_{,\nu} \equiv \frac{\partial \phi}{\partial x^\nu}$$

transforms as a $(0,1)$ tensor, i.e.

$$\phi'_{,\nu} \equiv \frac{\partial \phi'(x')}{\partial x'^\nu} = \frac{\partial x^\mu}{\partial x'^\nu}\frac{\partial \phi(x)}{\partial x^\mu} \equiv \frac{\partial x^\mu}{\partial x'^\nu}\phi_{,\mu} \tag{39}$$

On the other hand, partial derivatives of the components of a contravariant vector transform as:

$$A'^i_{,j} = \frac{\partial x'^i}{\partial x^k}\frac{\partial x^l}{\partial x'^j}A^k_{,l} + \frac{\partial x^l}{\partial x'^j}\frac{\partial^2 x'^i}{\partial x^l \partial x^k}A^k \tag{40}$$

The presence of the second term of equation (40),

$$\frac{\partial x^l}{\partial x'^j}\frac{\partial^2 x'^i}{\partial x^l \partial x^k}A^k,$$

is the reason why $A^i_{,j}$ does not transform as a tensor. The root of the problem is that computing the derivative involves subtracting vectors at two neighbouring points, at each of which the transformation law will in general be different. To overcome this problem we need to transport one of the vectors to the neighbouring point, so that they are subtracted at the *same* point in the manifold. This can be achieved by the

so-called **parallel transport** procedure, which transports the vector components along a curve in the manifold in a manner which preserves the angle between vectors.

Suppose we have a point with coordinates x^i while its neighbour has coordinates $x^i + dx^i$. It is easiest to consider first the parallel transport of the components of a *covariant* vector, or one-form, from $x^i + dx^i$ to x^i. Suppose that the change, δB_k, in the components will be a linear function of the original components, B_j, and of the displacement dx^i, so we can write

$$\delta B_k = -\Gamma^j_{ik} B_j dx^i \tag{41}$$

The coefficients Γ^j_{ik} are called the **Christoffel symbols** and they describe how the basis vectors at different points in the manifold change as one moves across the manifold, i.e.

$$\frac{\partial \vec{e}_\alpha}{\partial x^\beta} = \Gamma^\mu_{\alpha\beta}\ \vec{e}_\mu \tag{42}$$

It then follows that the covariant derivative of a one-form may be written as

$$B_{i;k} = B_{i,k} - \Gamma^j_{ik} B_j \tag{43}$$

i.e. $B_{i,k} - \Gamma^j_{ik} B_j$ transforms as a $(0,2)$ tensor. Given that the covariant and partial derivatives of a scalar are identical, it is then straightforward to show that the covariant derivative of a vector takes the form

$$A^i_{;k} = A^i_{,k} + \Gamma^i_{jk} A^j \tag{44}$$

which transforms as a $(1,1)$ tensor. The generalisation of equations (43) and (44) to tensors of arbitrary rank is straightforward.

It is also straightforward to show that the covariant derivative of the metric tensor is equal to zero, i.e. for all α, β, γ

$$g_{\alpha\beta;\gamma} = 0 \quad \text{and} \quad g^{\alpha\beta}_{;\gamma} = 0 \tag{45}$$

and this result can be used to obtain an expression for the Christoffel symbols in terms of the metric and its partial derivatives

$$\Gamma^i_{jk} = \frac{1}{2} g^{il}(g_{lj,k} + g_{lk,j} - g_{jk,l}) \tag{46}$$

3.11 The geodesic equation

As we discussed in Section 2, material particles not acted on by forces other than gravitational forces have worldlines that are **geodesics**. Similarly photons also follow geodesics. One can define a geodesic as an extremal path between two events, in the sense that the proper time along the path joining the two events is an extremum. Equivalently, one can define a geodesic as a **curve along which the tangent vector to the curve is parallel-transported**. In other words, if one parallel transports a tangent vector along a geodesic, it remains a tangent vector.

3.11.1 Geodesics of material particles

The worldline of a material particle may be written with the proper time, τ, as parameter along the worldline. The **four velocity** of the particle is the tangent vector to the worldline. One may show that the geodesic equation for the particle is

$$\frac{d^2x^\mu}{d\tau^2} + \Gamma^\mu_{\alpha\beta}\frac{dx^\alpha}{d\tau}\frac{dx^\beta}{d\tau} = 0 \tag{47}$$

3.11.2 Geodesics of photons

For photons, the proper time τ cannot be used to parametrise their worldline, since $d\tau$ for a photon is zero. We need to find some other way to parametrise the worldline of the photon (e.g. an angular coordinate along the trajectory) so that, with respect to this parameter (λ, say) the geodesic equation is satisfied, i.e.

$$\frac{d^2x^\mu}{d\lambda^2} + \Gamma^\mu_{\alpha\beta}\frac{dx^\alpha}{d\lambda}\frac{dx^\beta}{d\lambda} = 0 \tag{48}$$

The parameter λ is known as an **affine parameter**.

4 Spacetime Curvature in GR

4.1 The Riemann Christoffel tensor

In our simple example of Section 2 the curvature of our spherical surface depended on only a single parameter: the radius a of the sphere. More generally, the curvature of spacetime can be described by the **Riemann Christoffel tensor**, **R** (often also referred to simply as the **Riemann tensor**), which depends on the metric and its first and second order partial derivatives. The functional form of the Riemann Christoffel tensor can be derived in several different ways:

1. by parallel transporting of a vector around a closed loop in our manifold
2. by considering the commutator of the second order covariant derivative of a vector field
3. by computing the deviation of two neighbouring geodesics in our manifold

In view of our previous discussion we will focus on the third method for deriving **R**, although there are close mathematical similarities between all three methods. Also, the first method has a particularly simple pictorial representation. Figure 8 (adapted from Schutz) shows the result of parallel transporting a vector around a closed triangle. Panel (a) shows a flat surface of zero curvature; when the vector is parallel transported from A to B to C and then back to point A, the final vector is parallel to the original one. Panel (b) on the other hand shows a spherical surface of positive curvature; when we parallel transport a vector from A to B to C and back to A, the final vector is *not* parallel to the original one. We can express the net change in the components of the vector, after transport around the closed loop, in terms of the Riemann Christoffel tensor.

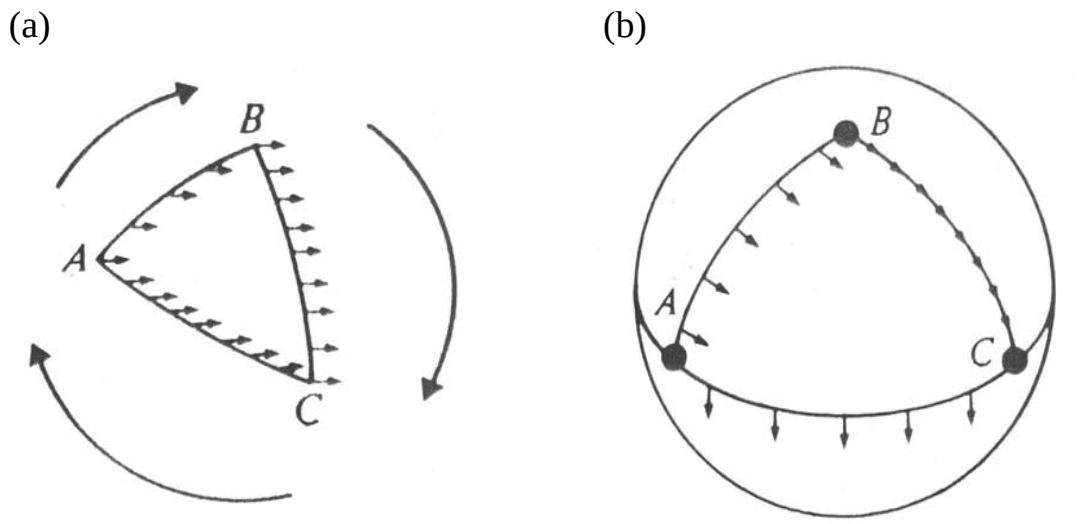

Figure 8: Parallel transport of a vector around a closed curve in a flat space (panel a) and a curved space (panel b).

4.2 Acceleration of the geodesic deviation

To see how we can derive the form of the Riemann Christoffel tensor via method 3, consider two test particles (labelled 1 and 2) moving along nearby geodesics. Let $\xi^\mu(\tau)$ denote the (infinitesimal) separation of the particles at proper time τ, so that

$$x_2^\mu(\tau) = x_1^\mu(\tau) + \xi^\mu(\tau) \tag{49}$$

Now the worldline of each particle is described by the geodesic equation, i.e.

$$\frac{d^2x_1^\mu}{d\tau^2} + \Gamma^\mu_{\alpha\beta}(x_1)\frac{dx_1^\alpha}{d\tau}\frac{dx_1^\beta}{d\tau} = 0 \tag{50}$$

and

$$\frac{d^2x_2^\mu}{d\tau^2} + \Gamma^\mu_{\alpha\beta}(x_2)\frac{dx_2^\alpha}{d\tau}\frac{dx_2^\beta}{d\tau} = 0 \tag{51}$$

Note also that, by Taylor expanding the Christoffel symbols at x_1 in terms of ξ, we may write

$$\Gamma^\mu_{\alpha\beta}(x_2) = \Gamma^\mu_{\alpha\beta}(x_1 + \xi) = \Gamma^\mu_{\alpha\beta}(x_1) + \Gamma^\mu_{\alpha\beta,\gamma}\xi^\gamma \tag{52}$$

Subtracting equation (50) from equation (51), substituting from equation (52) and keeping only terms up to first order in ξ yields the following equation for the acceleration of ξ^μ (dropping the subscript 1)

$$\frac{d^2\xi^\mu}{d\tau^2} + \Gamma^\mu_{\alpha\beta} v^\alpha \frac{d\xi^\beta}{d\tau} + \Gamma^\mu_{\alpha\beta} v^\beta \frac{d\xi^\alpha}{d\tau} + \Gamma^\mu_{\alpha\beta,\gamma} \xi^\gamma v^\alpha v^\beta = 0 \tag{53}$$

where we have used the fact that $v^\alpha \equiv dx^\alpha/d\tau$.

Equation (53) is not a tensor equation, since the Christoffel symbols and their derivatives do not transform as a tensor. We can develop the corresponding covariant expression, however, by taking *covariant* derivatives of the geodesic deviation. To this end, consider the covariant derivative of a general vector field $\vec{\mathbf{A}}$ along a geodesic with tangent vector $\vec{\mathbf{v}} \equiv d\vec{\mathbf{x}}/d\tau$. We write this covariant derivative as $\nabla_{\vec{\mathbf{v}}}\vec{\mathbf{A}}$, or in component form, introducing the covariant operator $D/D\tau$

$$\frac{DA^\mu}{D\tau} = v^\beta A^\mu_{;\beta} = \frac{dA^\mu}{d\tau} + \Gamma^\mu_{\alpha\beta} A^\alpha \frac{dx^\beta}{d\tau} \tag{54}$$

Now consider the second covariant derivative of the geodesic deviation, evaluated along the geodesic followed by test particle 1. From equation (54) in component form

$$\frac{D\xi^\mu}{D\tau} = \frac{d\xi^\mu}{d\tau} + \Gamma^\mu_{\alpha\beta} \xi^\alpha \frac{dx^\beta}{d\tau} \tag{55}$$

It then follows that

$$\frac{D^2\xi^\mu}{D\tau^2} = \frac{D}{D\tau}\left(\frac{D\xi^\mu}{D\tau}\right) = \frac{d}{d\tau}\left(\frac{D\xi^\mu}{D\tau}\right) + \Gamma^\mu_{\sigma\delta} \frac{D\xi^\sigma}{D\tau} v^\delta \tag{56}$$

Substituting again for $D\xi^\mu/D\tau$ we obtain

$$\frac{D^2\xi^\mu}{D\tau^2} = \frac{d}{d\tau}(\frac{d\xi^\mu}{d\tau} + \Gamma^\mu_{\alpha\beta}\xi^\alpha v^\beta) + \Gamma^\mu_{\sigma\delta}(\frac{d\xi^\sigma}{d\tau} + \Gamma^\sigma_{\alpha\beta}\ \xi^\alpha v^\beta)v^\delta \tag{57}$$

Now, applying the product rule for differentiation

$$\frac{d}{d\tau}(\Gamma^\mu_{\alpha\beta}\xi^\alpha v^\beta) = \Gamma^\mu_{\alpha\beta,\gamma}\frac{dx^\gamma}{d\tau}\xi^\alpha v^\beta + \Gamma^\mu_{\alpha\beta}\frac{d\xi^\alpha}{d\tau}v^\beta + \Gamma^\mu_{\alpha\beta}\xi^\alpha\frac{dv^\beta}{d\tau} \tag{58}$$

Since each particle's worldline is a geodesic we also know that

$$\frac{dv^\beta}{d\tau} = \frac{d^2x^\beta}{d\tau^2} = -\Gamma^\beta_{\sigma\delta}v^\sigma v^\delta \tag{59}$$

where again we have written $v^\beta = dx^\beta/d\tau$.

Substituting equations (58) and (59) into (57) and permuting some repeated indices, we obtain

$$\begin{aligned}\frac{D^2\xi^\mu}{D\tau^2} = \frac{d^2\xi^\mu}{d\tau^2} + \Gamma^\mu_{\alpha\beta,\gamma}v^\gamma\xi^\alpha v^\beta + \Gamma^\mu_{\alpha\beta}\frac{d\xi^\alpha}{d\tau}v^\beta + \Gamma^\mu_{\sigma\delta}\frac{d\xi^\sigma}{d\tau}v^\delta \\ +(\Gamma^\mu_{\beta\delta}\Gamma^\beta_{\alpha\sigma} - \Gamma^\mu_{\alpha\beta}\Gamma^\beta_{\alpha\delta})v^\sigma v^\delta\xi^\alpha\end{aligned} \tag{60}$$

However we can now use the result we obtained in equation (53) i.e.

$$\frac{d^2\xi^\mu}{d\tau^2} = -(\Gamma^\mu_{\alpha\beta}v^\alpha\frac{d\xi^\beta}{d\tau} + \Gamma^\mu_{\alpha\beta}v^\beta\frac{d\xi^\alpha}{d\tau} + \Gamma^\mu_{\alpha\beta,\gamma}\xi^\gamma v^\alpha v^\beta) \tag{61}$$

so that finally we obtain the compact expression

$$\frac{D^2\xi^\mu}{D\tau^2} = R^\mu{}_{\alpha\beta\gamma}\,v^\alpha\,v^\beta\,\xi^\gamma \tag{62}$$

where

$$R^\mu{}_{\alpha\beta\gamma} = \Gamma^\sigma_{\alpha\gamma}\Gamma^\mu_{\sigma\beta} - \Gamma^\sigma_{\alpha\beta}\Gamma^\mu_{\sigma\gamma} + \Gamma^\mu_{\alpha\gamma,\beta} - \Gamma^\mu_{\alpha\beta,\gamma} \tag{63}$$

One also frequently encounters the notation (see e.g. Schutz, Chapter 6)

$$\nabla_{\vec{\mathbf{v}}}\,\nabla_{\vec{\mathbf{v}}}\,\xi^\mu \;=\; R^\mu{}_{\alpha\beta\gamma}\,v^\alpha\,v^\beta\,\xi^\gamma \tag{64}$$

The $(1,3)$ tensor, $\mathbf{R}$, in equations (62) – (64) is the Riemann Christoffel tensor referred to at the beginning of this section. It is a tensor of rank 4, with 256 components – although the symmetries inherent in any astrophysical example greatly reduce the number of independent components.

If spacetime is flat then

$$R^{\mu}{}_{\alpha\beta\gamma} = 0 \tag{65}$$

i.e. all components of the Riemann Christoffel tensor are identically zero. We then see from equation (64) that the acceleration of the geodesic deviation is identically zero – i.e. the separation between neighbouring geodesics remains constant. Conversely, however, if the spacetime is curved then the geodesic separation changes along the worldline of neighbouring particles.

Equations (62) and (64) are of fundamental importance in GR. In a sense they are the properly covariant mathematical expression of the physical idea embodied in Wheeler's phrase *"spacetime tells matter how to move"*. Although we derived them by considering the geodesics of neighbouring material particles, we can equally apply them to determine how changes in the spacetime curvature will influence the geodesic deviation of photons. In that case in equation (62) we simply need to replace the proper time τ along the geodesic by another suitable affine parameter λ (say), and we also replace v^{α} by $dx^{\alpha}/d\lambda$. Otherwise, the form of equation (62) is unchanged.

The second part of Wheeler's statement – *"matter tells spacetime how to curve"* – has its mathematical embodiment in Einstein's equations, which relate the **Einstein tensor** (and thus, as we will see, implicitly the Riemann Christoffel tensor) to the **energy momentum tensor**. We consider Einstein's equations in the next section.

5 Einstein's equations

5.1 The energy momentum tensor

The energy momentum tensor (also known as the stress energy tensor) is the *source* of spacetime curvature. It describes the presence and motion of gravitating matter. In these lectures we will discuss the energy momentum tensor for the particular case of a **perfect fluid**, which is a mathematical idealisation but one which is a good approximate description of the gravitating matter in many astrophysical situations.

5.1.1 Perfect fluids

Many Newtonian gravitational problems can be considered simply as the interaction of a small number of point-like massive particles. Even in Newtonian theory, however, there are many contexts (e.g. the motion of stars in the Galaxy) where the number of gravitating 'particles' is too large to follow their individual trajectories. Instead we treat the system as a smooth continuum, or **fluid**, and describe its behaviour in terms of the locally averaged properties (e.g. the *density*, *velocity* or *temperature*) of the particles in each **fluid element** – by which we mean a small region of the fluid surrounding some point in the continuum within which the behaviour of the particles is fairly homogeneous.

This fluid description is also useful for many-particle systems in special relativity, although we must be careful about defining quantities such as density and velocity which are frame-dependent – i.e. we need to find a *covariant* description of the fluid (which, we will see, is why we require a *tensor* to describe the gravitating matter).

The simplest type of relativistic fluid is known as **dust**. To a physicist, a fluid element of dust means a collection of particles which are all at rest with respect to some Lorentz frame. Many textbooks (including Schutz) refer to this Lorentz frame as the **momentarily comoving rest frame** (MCRF) of the fluid element.

This name helps to reinforce the point that the fluid element as a whole may possess a bulk motion with respect to the rest of the fluid, and indeed this relative motion may not be uniform – i.e. the fluid element may be accelerating. At any moment, however, the instantaneous velocity of the fluid element allows us to define its MCRF, although the MCRF of neighbouring elements will in general be different at that instant, and the MCRF of the fluid element will also in general be different at different times. If the fluid element is dust, however, then at any instant in the MCRF of the fluid element the individual particles are taken to possess no random motions of their own.

Generally, however, the particles within a fluid element *will* have random motions, and these will give rise to **pressure** in the fluid (c.f. motions of the molecules in an ideal gas). A fluid element may also be able to exchange energy with its neighbours via **heat conduction**, and there may be **viscous forces** present between neighbouring fluid elements. When viscous forces exist they are directed parallel to the interface between neighbouring fluid elements, and result in a **shearing** of the fluid.

A relativistic fluid element is said to be a **perfect fluid** if, in its MCRF, the fluid element has *no* heat conduction or viscous forces. It follows from this definition that dust is the special case of a pressure-free perfect fluid.

5.1.2 Definition of the energy momentum tensor

We can define the energy momentum tensor, $\mathbf{T}$, in terms of its components in some coordinate system, $\{x^1, x^2, ..., x^n\}$, for each fluid element. Thus we define $T^{\alpha\beta}$ for a fluid element to be equal to the **flux of the α component of four momentum of all gravitating matter**[2] **across a surface of constant x^β**.

[2]By 'gravitating matter' we mean here all material particles, plus (from the equivalence of matter and energy) any electromagnetic fields and particle fields which may be present

Thus, the change, Δp^α, in the α component of the four momentum due to the flux through a surface element, ΔS_ν, at constant x^ν, is given by

$$\Delta p^\alpha = T^{\alpha\nu}\Delta S_\nu \tag{66}$$

(Note the use of the summation convention).

5.1.3 Components of T in the MCRF for dust

In this case the energy momentum tensor takes a very simple form. Since the particles in the fluid element are at rest, there is no momentum transfer. (For a general fluid, even if the particles are at rest there can be a flux of energy and momentum through heat conduction, but not for dust, which is a perfect fluid). Also there is no momentum flux, which means that $T^{ij} = 0$, $(i, j = 1, 2, 3)$. In fact the only non-zero component is $T^{00} = \rho$, the energy density of the fluid element.

5.1.4 Components of T in the MCRF for a general perfect fluid

This case is only slightly less straightforward than that of dust. Again the T^{00} component is equal to the energy density, ρ. Since there is no bulk motion of the fluid element and there is no heat conduction for a perfect fluid, the energy flux $T^{0i} = 0$ for $i = 1, 2, 3$. Moreover, from the symmetry of $\mathbf{T}$ we also have that the momentum density, $T^{i0} = 0$, for $i = 1, 2, 3$. For the spatial components, $T^{ij} = 0$ if $i \neq j$, since these terms correspond to viscous forces parallel to the interface between fluid elements and these forces are zero for a perfect fluid. Thus T^{ij} is a diagonal matrix. But T^{ij} must be diagonal in all reference frames – e.g. under all possible rotations. This is possible only if T^{ij} is a scalar multiple of the identity matrix, i.e. $T^{11} = T^{22} = T^{33}$.

Thus, T^{ii} is the flux of the i^{th} component of momentum in the x^i direction, perpendicular to the fluid element interface. Equivalently, it is the *force per unit area*,

perpendicular to the interface. This is just the **pressure**, P, exerted by the random motions of the particles in the fluid element. Hence we can write $\mathbf{T}$ as

$$\mathbf{T} = \begin{pmatrix} \rho & 0 & 0 & 0 \\ 0 & P & 0 & 0 \\ 0 & 0 & P & 0 \\ 0 & 0 & 0 & P \end{pmatrix}. \tag{67}$$

5.1.5 Components of T in a general Lorentz frame

Extending our expression for $T^{\alpha\beta}$ from the MCRF to a general Lorentz frame is fairly straightforward, but the interested reader is referred e.g. to Schutz for the details and here we just state the result. If $\vec{u} = \{u^\alpha\}$ is the *four* velocity of a fluid element in some Lorentz frame, then

$$T^{\alpha\beta} = (\rho + P)u^\alpha u^\beta + P\eta^{\alpha\beta}, \tag{68}$$

where $\eta^{\alpha\beta}$ is the Minkowski metric of SR, as given by equation (3) but with raised indices.

Conservation of energy and momentum requires that

$$T^{\alpha\beta}_{,\beta} = 0. \tag{69}$$

i.e. the **divergence** of the energy momentum tensor is equal to zero.

5.1.6 Extending to GR

In Section 1 we introduced the strong principle of equivalence which stated that, in a LIF, all physical phenomena are in agreement with special relativity. In the light of our discussion of tensors, we can write down an immediate consequence of the strong principle of equivalence as follows

Any physical law which can be expressed as a tensor equation in SR has exactly the same form in a local inertial frame of a curved spacetime

This statement holds since, in the LIF, physics – and hence the form of physical laws – is indistinguishable from the physics of SR. This is a very important result because it allows us to generalise the form of physical laws involving tensors which are valid in SR to the case of GR, with semi-colons (denoting covariant derivatives) replacing commas (denoting partial derivatives) where appropriate.

How is this extension justified? From the principle of covariance a tensorial description of physical laws must be equally valid in any reference frame. Thus, if a tensor equation holds in one frame it must hold in any frame. In particular, a tensor equation derived in a LIF (i.e. assuming SR) remains valid in an arbitrary reference frame (i.e. assuming GR).

Hence, the energy momentum tensor for a perfect fluid in GR takes the form

$$T^{\mu\nu} = (\rho + P)u^\mu u^\nu + Pg^{\mu\nu}, \tag{70}$$

where $g^{\mu\nu}$ denotes the contravariant metric tensor for a general curved spacetime (which of course reduces locally to $\eta^{\mu\nu}$, according to the WEP).

We can extend to GR in this way the result of equation (69), on the conservation of energy and momentum. Thus, for a fluid element in a general curved spacetime

$$T^{\mu\nu}_{\;;\nu} = 0. \tag{71}$$

If this were *not* the case – i.e. if there existed some point, P, at which $T^{\mu\nu}_{\;;\nu} \neq 0$ – then we could construct a LIF at P in which all Christoffel symbols are zero. In this new frame covariant derivatives reduce to partial derivatives, implying that $T^{\mu\nu}_{\;,\nu} \neq 0$, which contradicts equation (69).

The general technique of using the principles of covariance and equivalence to extend the validity of tensor equations from SR to GR, usually by evaluating their components in the LIF where Christoffel symbols vanish, is a very powerful one and is commonly met in the relativity literature. It is sometimes referred to informally as the 'comma goes to semi colon rule'.

5.2 The Einstein tensor and Einstein's equations

We have seen that the Riemann Christoffel tensor, $R^{\mu}{}_{\alpha\beta\gamma}$, describes the curvature of spacetime. Given Wheeler's phrase *"matter tells spacetime how to curve"*, we expect the Riemann Christoffel tensor and energy momentum tensor to be related, and indeed they are via Einstein's equations. But we saw in Section 5.1 that $\mathbf{T}$ is a $(2,0)$ tensor. Thus, Einstein's equations must involve various *contractions* of the Riemann Christoffel tensor.

First we can contract the Riemann Christoffel tensor to form a $(0,2)$ tensor, which we call the **Ricci tensor** defined by

$$R_{\alpha\gamma} = R^{\mu}_{\alpha\mu\gamma} \tag{72}$$

i.e. contracting on the *second* of the lower indices. (N.B. some authors choose to define $R_{\alpha\gamma}$ as minus this value). We can also write the components of the Ricci tensor as

$$R_{\alpha\gamma} = g^{\sigma\delta} R_{\sigma\alpha\delta\gamma} \tag{73}$$

It is easy to show that $R_{\alpha\beta} = R_{\beta\alpha}$, i.e. the Ricci tensor is symmetric.

By further contracting the Ricci tensor with the contravariant components of the metric, one obtains the **curvature scalar**, viz:

$$R = g^{\alpha\beta} R_{\alpha\beta} \tag{74}$$

One may also use the metric to raise the indices of the Ricci tensor, and thus express

it in contravariant form, viz:

$$R^{\mu\nu} = g^{\mu\alpha} g^{\nu\beta} R_{\alpha\beta} \tag{75}$$

$R^{\mu\nu}$ is also symmetric.

Using the contravariant form of the Ricci tensor, we define the **Einstein tensor**, **G** as follows

$$G^{\mu\nu} = R^{\mu\nu} - \frac{1}{2} g^{\mu\nu} R \tag{76}$$

where R is the curvature scalar. Note that since $R^{\mu\nu}$ is symmetric, so too is $G^{\mu\nu}$.

The Einstein tensor is of crucial physical significance in GR, since it can be shown from the Bianchi identities (see Appendix 1) that

$$G^{\mu\nu}_{\ ;\nu} = 0 \tag{77}$$

Thus we have immediately **Einstein's equations** which state that

$$T^{\mu\nu}_{\ ;\nu} = G^{\mu\nu}_{\ ;\nu} \tag{78}$$

Einstein took the solution of these equations to be of the form

$$G^{\mu\nu} = kT^{\mu\nu} \tag{79}$$

where we can determine the constant k by requiring that we should recover the laws of Newtonian gravity and dynamics in the limit of a weak gravitational field and non-relativistic motion. In fact k turns out to equal $8\pi G/c^4$.

5.3 Solving Einstein's equations

Solving Einstein's equations is in general a highly non-trivial task. Provided that the metric tensor is known, or assumed, for the system in question, then we can directly compute the Christoffel symbols, Riemann Christoffel tensor and Einstein tensor, and use these to determine the geodesics of material particles and photons.

Given the Einstein tensor we can also compute the components of the energy momentum tensor, and thus determine the spatial and temporal dependence of physical characteristics such as the density and pressure of the system.

Proceeding in the other direction, however, is considerably more difficult. Given, or assuming, a form for the energy momentum tensor, Einstein's equations immediately yield the Einstein tensor, but from that point solving for the Riemann Christoffel tensor and the metric is in general intractable.

Certain exact analytic solutions exist (e.g. the Schwarzschild, Kerr and Robertson-Walker metrics) and these are applicable to a range of astrophysical problems. The Schwarzschild metric, for example, can be applied to derive some of the classical predictions of GR, including the advance of pericentre of planetary orbits and the gravitational deflection of light. (Appendix 2 derives the form of the Schwarzschild metric and briefly considers these classical GR predictions in more detail.)

However, as we mentioned on Page 2, the description of sources of gravitational waves requires a *non-stationary* metric (see below for a precise definition) for which we must resort to approximate methods if we are to make progress analytically.

Fortunately we will see that we can describe very well at least the *detection* of gravitational waves within the so-called **weak field approximation**, in which we assume that the gravitational wave results from deviations from the flat spacetime of Special Relativity which are small.

As we will see in the following sections, the weak field approximation greatly simplifies our analysis and permits gravitational waves detected at the Earth to be described as a linear perturbation to the Minkowski metric of Special Relativity.

6 Wave Equation for Gravitational Radiation

We show that the free-space solutions for the metric perturbations of a 'nearly flat' spacetime take the form of a wave equation, propagating at the speed of light.

6.1 Non-stationarity

The Schwarzschild solution for the spacetime exterior to a point mass is an example of a **static metric**, defined as a metric for which we can find a time coordinate, t, satisfying

1. all metric components are independent of t
2. the metric is unchanged if we apply the transformation $t \mapsto -t$

A metric which satisfies property (1) but not property (2) is known as **stationary**. An example is the metric of a spherically symmetric star which is *rotating*: reversing the time coordinate changes the sense of the rotation, even though one can find a coordinate system in which the metric components are all independent of time. The Kerr metric, which can be used to describe the exterior spacetime around a rotating black hole, is an example of a stationary metric.

In these lectures we explore some consequences of also relaxing the assumption of property (1), by considering spacetimes in which the metric components are time dependent – as can happen when the source of the gravitational field is varying. Such a metric is known as **non-stationary**.

6.2 Weak gravitational fields

6.2.1 'Nearly' flat spacetimes

Since spacetime is flat in the absence of a gravitational field, a weak gravitational field can be defined as one in which spacetime is 'nearly' flat. What we mean

by 'nearly' here is that we can find a coordinate system in which the metric has components

$$g_{\alpha\beta} = \eta_{\alpha\beta} + h_{\alpha\beta} \tag{80}$$

where

$$\eta_{\alpha\beta} = \text{diag } (-1, 1, 1, 1) \tag{81}$$

is the Minkowski metric of Special Relativity, and $|h_{\alpha\beta}| << 1$ for all α and β.

A coordinate system which satisfies equations (80) and (81) is referred to as a **nearly Lorentz** coordinate system. Notice that we say that we can find *a* coordinate system satisfying these equations. It certainly does *not* follow that for *any* choice of coordinate system we can write the metric components of the nearly flat spacetime in the form of equations (80) and (81). Indeed, even if the spacetime is precisely Minkowski, we could adopt (somewhat unwisely perhaps!) a coordinate system in which the metric components were very far from the simple form of equation (81).

In some coordinate systems, therefore, the components may be enormously more complicated than in others. The secret to *solving* tensor equations in General Relativity is, often, to first choose a coordinate system in which the components are as simple as possible. In that sense, equations (80) and (81) represent a 'good' choice of coordinate system; just as equation (81) represents the simplest form we can find for the metric components in flat spacetime, so equation (80) represents the metric components of a nearly flat spacetime in their simplest possible form.

The coordinate system in which one may express the metric components of a nearly flat spacetime in the form of equations (80) and (81) is certainly not unique. If we have identified such a coordinate system then we can find an infinite family of others by carrying out particular coordinate transformations. We next consider two types of coordinate transformations which preserve the properties of equations (80) and (81). These are known respectively as **Background Lorentz transformations** and **Gauge transformations**.

6.2.2 Background Lorentz transformations

Suppose we are in the Minkowski spacetime of Special Relativity, and we define the inertial frame, S, with coordinates (t, x, y, z). Suppose we then transform to another inertial frame, S', corresponding to a **Lorentz boost** of speed v in the direction of the positive x-axis. Under the Lorentz transformation S' has coordinates given by, in matrix form

$$(t', x', y', z')^T = \begin{pmatrix} \gamma & -v\gamma & 0 & 0 \\ -v\gamma & \gamma & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} (t, x, y, z)^T \tag{82}$$

where $\gamma = (1 - v^2)^{-1/2}$. (Remember that we are taking $c = 1$). We can write this in more compact notation as

$$x'^{\alpha} = \Lambda^{\alpha'}_{\beta} x^{\beta} \quad \equiv \quad \frac{\partial x'^{\alpha}}{\partial x^{\beta}} x^{\beta} \tag{83}$$

The Lorentz matrix has inverse, corresponding to a boost of speed v along the *negative* x-axis, given by

$$(t, x, y, z)^T = \begin{pmatrix} \gamma & v\gamma & 0 & 0 \\ v\gamma & \gamma & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} (t', x', y', z')^T \tag{84}$$

or

$$x^{\alpha} = \Lambda^{\alpha}_{\beta'} x'^{\beta} \quad \equiv \quad \frac{\partial x^{\alpha}}{\partial x'^{\beta}} x'^{\beta} \tag{85}$$

Now suppose we are in a nearly flat spacetime in which we have identified nearly Lorentz coordinates (t, x, y, z) satisfying equations (80) and (81). We then transform to a new coordinate system (t', x', y', z') defined such that

$$x'^{\alpha} = \Lambda^{\alpha'}_{\beta} x^{\beta} \tag{86}$$

i.e. where the transformation matrix is identical in form to equation (82) for some constant v. In this new coordinate system the metric components take the form

$$g'_{\alpha\beta} = \Lambda^{\mu}_{\alpha'}\Lambda^{\nu}_{\beta'}g_{\mu\nu} = \frac{\partial x^{\mu}}{\partial x'^{\alpha}}\frac{\partial x^{\nu}}{\partial x'^{\beta}}g_{\mu\nu} \tag{87}$$

Substituting from equation (80) we can write this as

$$g'_{\alpha\beta} = \frac{\partial x^{\mu}}{\partial x'^{\alpha}}\frac{\partial x^{\nu}}{\partial x'^{\beta}}\eta_{\mu\nu} + \frac{\partial x^{\mu}}{\partial x'^{\alpha}}\frac{\partial x^{\nu}}{\partial x'^{\beta}}h_{\mu\nu} \tag{88}$$

Because of the particular form of the coordinate transformation in this case, it follows that

$$g'_{\alpha\beta} = \eta'_{\alpha\beta} + \frac{\partial x^{\mu}}{\partial x'^{\alpha}}\frac{\partial x^{\nu}}{\partial x'^{\beta}}h_{\mu\nu} = \eta_{\alpha\beta} + h'_{\alpha\beta} \tag{89}$$

(The last equation follows because the components of the Minkowski metric are the same in any Lorentz frame).

Thus, provided we consider **only** transformations of the form of equation (82) the components of $h_{\mu\nu}$ transform **as if** they are the components of a $(0,2)$ tensor defined on a background flat spacetime. Moreover, provided $v << 1$, then if $|h_{\alpha\beta}| << 1$ for all α and β, then $|h'_{\alpha\beta}| << 1$ also.

Hence, our original nearly Lorentz coordinate system remains nearly Lorentz in the new coordinate system. In other words, a spacetime which looks nearly flat to one observer still looks nearly flat to any other observer in uniform relative motion with respect to the first observer.

6.2.3 Gauge transformations

Suppose now we make a very small change in our coordinate system by applying a coordinate transformation of the form

$$x'^{\alpha} = x^{\alpha} + \xi^{\alpha}(x^{\beta}) \tag{90}$$

i.e. where the components ξ^{α} are functions of the coordinates $\{x^{\beta}\}$. It then follows that

$$\frac{\partial x'^{\alpha}}{\partial x^{\beta}} = \delta^{\alpha}_{\beta} + \xi^{\alpha}_{,\beta} \tag{91}$$

From equation (90) we can also write

$$x^{\alpha} = x'^{\alpha} - \xi^{\alpha}(x^{\beta}) \tag{92}$$

If we now demand that the ξ^{α} are small, in the sense that

$$|\xi^{\alpha}{}_{,\beta}| << 1 \quad \text{for all} \quad \alpha, \beta \tag{93}$$

then it follows by the chain rule that

$$\frac{\partial x^{\alpha}}{\partial x'^{\gamma}} = \delta^{\alpha}_{\gamma} - \frac{\partial x^{\beta}}{\partial x'^{\gamma}} \frac{\partial \xi^{\alpha}}{\partial x^{\beta}} \simeq \delta^{\alpha}_{\gamma} - \xi^{\alpha}_{,\gamma} \tag{94}$$

where we have neglected terms higher than first order in small quantities. We have also used the fact that the components of the Kronecker delta are the same in any coordinate system.

Suppose now that the unprimed coordinate system is nearly Lorentz – i.e. the metric components satisfy equations (80) and (81). What about the metric components in the primed coordinate system?

Since the metric is a tensor, we know that

$$g'_{\alpha\beta} = \frac{\partial x^{\mu}}{\partial x'^{\alpha}} \frac{\partial x^{\nu}}{\partial x'^{\beta}} g_{\mu\nu} \tag{95}$$

Substituting from equations (80) and (94) this becomes, to first order

$$g'_{\alpha\beta} = \left(\delta^{\mu}_{\alpha}\delta^{\nu}_{\beta} - \xi^{\mu}_{,\alpha}\delta^{\nu}_{\beta} - \xi^{\nu}_{,\beta}\delta^{\mu}_{\alpha}\right)\eta_{\mu\nu} + \delta^{\mu}_{\alpha}\delta^{\nu}_{\beta}h_{\mu\nu} \tag{96}$$

This further simplifies to

$$g'_{\alpha\beta} = \eta_{\alpha\beta} + h_{\alpha\beta} - \xi_{\alpha,\beta} - \xi_{\beta,\alpha} \tag{97}$$

Note that in equation (97) we have defined

$$\xi_{\alpha} = \eta_{\alpha\nu}\xi^{\nu} \tag{98}$$

i.e. we have used the Minkowski metric, rather than the full metric $g_{\alpha\nu}$ to lower the index on the vector components ξ^{ν}. This is permitted because we are working to first order, and both the metric perturbation $h_{\alpha\nu}$ and the components ξ^{ν} are small. We have also used the fact that all the partial derivatives of $\eta_{\alpha\nu}$ are zero.

Thus, equation (98) has the same form as equation (80) provided that we write

$$h'_{\alpha\beta} = h_{\alpha\beta} - \xi_{\alpha,\beta} - \xi_{\beta,\alpha} \tag{99}$$

Note that if $|\xi^{\alpha}{}_{,\beta}|$ are small, then so too are $|\xi_{\alpha,\beta}|$, and hence $h'_{\alpha\beta}$. Thus, our new primed coordinate system is *still* nearly Lorentz.

The above results tell us that – once we have identified a coordinate system which is nearly Lorentz – we can add an arbitrary small vector ξ^{α} to the coordinates x^{α} without altering the validity of our assumption that spacetime is nearly flat. We can, therefore, choose the components ξ^{α} to make Einstein's equations as simple as possible. We call this step choosing a **gauge** for the problem – a name which has resonance with a similar procedure in electromagnetism – and coordinate transformations of the type given by equation (99) are known as **gauge transformation**. We will consider below specific choices of gauge which are particularly useful.

6.3 Einstein's equations for a weak gravitational field

If we can work in a nearly Lorentz coordinate system for a nearly flat spacetime this simplifies Einstein's equations considerably, and will eventually lead us to spot that the deviations from the metric of Minkowski spacetime – the components $h_{\alpha\beta}$ in equation (80) – obey a **wave equation**.

Before we arrive at this key result, however, we have some algebraic work to do first. We begin by deriving an expression for the Riemann Christoffel tensor in a weak gravitational field.

6.3.1 Riemann Christoffel tensor for a weak gravitational field

In its fully covariant form the Riemann Christoffel tensor is given by

$$R_{\alpha\beta\gamma\delta} = g_{\alpha\mu} R^{\mu}_{\beta\gamma\delta} = g_{\alpha\mu} \left[\Gamma^{\sigma}_{\beta\delta} \Gamma^{\mu}_{\sigma\gamma} - \Gamma^{\sigma}_{\beta\gamma} \Gamma^{\mu}_{\sigma\delta} + \Gamma^{\mu}_{\beta\delta,\gamma} - \Gamma^{\mu}_{\beta\gamma,\delta} \right] \tag{100}$$

Recall from the previous section that, if we are considering Background Lorentz transformations – i.e. if we restrict our attention only to the class of coordinate transformations which obey equation (86) – then the metric perturbations $h_{\alpha\beta}$ transform as if they are the components of a $(0, 2)$ tensor defined on flat, Minkowski spacetime. In this case the Christoffel symbols of the first two bracketed terms on the right hand side of equation (100) are equal to zero. It is then straightforward to show that, to first order in small quantities, the Riemann Christoffel tensor reduces to

$$R_{\alpha\beta\gamma\delta} = \frac{1}{2} \left(h_{\alpha\delta,\beta\gamma} + h_{\beta\gamma,\alpha\delta} - h_{\alpha\gamma,\beta\delta} - h_{\beta\delta,\alpha\gamma} \right) \tag{101}$$

Moreover, it is also quite easy to show that equation (101) is invariant under gauge transformations – i.e. the components of the Riemann Christoffel tensor are independent of the choice of gauge. This follows from the form of equation (99) and the

fact that partial derivatives are commutative – i.e.

$$\frac{\partial^2 f}{\partial x \partial y} = \frac{\partial^2 f}{\partial y \partial x}$$

Hence, our choice of gauge will **not** fundamentally change our determination of the curvature of spacetime or the behaviour of neighbouring geodesics.

6.3.2 Einstein tensor for a weak gravitational field

From equations (100) and (101) we can contract the Riemann Christoffel tensor and thus obtain an expression for the Ricci tensor in linearised form. This can be shown (see Appendix 3) to take the form

$$R_{\mu\nu} = \frac{1}{2}\left(h^{\alpha}_{\mu\,,\nu\alpha} + h^{\alpha}_{\nu\,,\mu\alpha} - h_{\mu\nu,\alpha}{}^{,\alpha} - h_{,\mu\nu}\right) \tag{102}$$

where we have written

$$h \equiv h^{\alpha}_{\alpha} = \eta^{\alpha\beta} h_{\alpha\beta} \tag{103}$$

Recalling equation (81) we see that h is essentially the *trace* of the perturbation $h_{\alpha\beta}$. Note also that again we have raised the indices of the components $h_{\alpha\beta}$ using $\eta^{\alpha\beta}$ and not $g^{\alpha\beta}$. This is justified since $h_{\alpha\beta}$ behaves like a $(0,2)$ tensor defined on a flat spacetime, for which the metric is $\eta^{\alpha\beta}$. The derivation of equation (102) also uses the fact that all partial derivatives of $\eta^{\alpha\nu}$ are zero.

Note further that we have introduced the notation, generalising the definition of equation (98)

$$f^{\alpha} = \eta^{\alpha\nu} f_{\nu} \tag{104}$$

where f^{α} are the components of a vector. We can also extend this notation for raising and lowering indices to the components of more general geometrical objects, and to their partial derivatives. For example, in equation (102)

$$h_{\mu\nu,\alpha}{}^{,\alpha} \;=\; \eta^{\alpha\sigma}\left(h_{\mu\nu,\alpha}\right)_{,\sigma} \;=\; \eta^{\alpha\sigma}\, h_{\mu\nu,\alpha\sigma} \tag{105}$$

After a further contraction of the Ricci tensor, to obtain the curvature scalar, R, where

$$R = \eta^{\alpha\beta} R_{\alpha\beta} \tag{106}$$

and substitution into the equation

$$G_{\mu\nu} = R_{\mu\nu} - \frac{1}{2}\eta_{\mu\nu} R \tag{107}$$

we obtain, after further algebraic manipulation (see Appendix 3 for the details) an expression for the Einstein tensor, $G_{\mu\nu}$, in linearised, fully covariant form

$$G_{\mu\nu} = \frac{1}{2}\left[h_{\mu\alpha,\nu}{}^{,\alpha} + h_{\nu\alpha,\mu}{}^{,\alpha} - h_{\mu\nu,\alpha}{}^{,\alpha} - h_{,\mu\nu} - \eta_{\mu\nu}\left(h_{\alpha\beta}{}^{,\alpha\beta} - h_{,\beta}{}^{,\beta}\right)\right] \tag{108}$$

This rather messy expression for the Einstein tensor can be simplified a little by introducing a modified form for the metric perturbation defined by

$$\overline{h}_{\mu\nu} \equiv h_{\mu\nu} - \frac{1}{2}\eta_{\mu\nu} h \tag{109}$$

after which (see Appendix 3) equation (108) becomes

$$G_{\mu\nu} = -\frac{1}{2}\left[\overline{h}_{\mu\nu,\alpha}{}^{,\alpha} + \eta_{\mu\nu}\overline{h}_{\alpha\beta}{}^{,\alpha\beta} - \overline{h}_{\mu\alpha,\nu}{}^{,\alpha} - \overline{h}_{\nu\alpha,\mu}{}^{,\alpha}\right] \tag{110}$$

6.3.3 Linearised Einstein equations

Having ploughed our way through all of the above algebra, we can now write down Einstein's equations in their linearised, fully covariant form for a weak gravitational field, in terms of the (re-scaled) metric perturbations $\overline{h}_{\mu\nu}$. Since

$$G_{\mu\nu} = 8\pi T_{\mu\nu} \tag{111}$$

it follows that

$$-\overline{h}_{\mu\nu,\alpha}{}^{,\alpha} - \eta_{\mu\nu}\overline{h}_{\alpha\beta}{}^{,\alpha\beta} + \overline{h}_{\mu\alpha,\nu}{}^{,\alpha} + \overline{h}_{\nu\alpha,\mu}{}^{,\alpha} = 16\pi T_{\mu\nu} \tag{112}$$

Can we simplify equation (112) any further? Fortunately the answer is 'yes'.

We saw in Sections 6.2.3 and 6.3.1 that we can carry out a gauge transformation in a nearly Lorentz coordinate system and the new coordinate system is still nearly Lorentz, with (to first order) identical curvature. It would be useful, therefore, to find a gauge transformation which eliminated the last three terms on the left hand side of equation (112). In Appendix 4 we show that a transformation with this property always exists, and in fact is equivalent to finding a coordinate system in which

$$\overline{h}^{\mu\alpha}{}_{,\alpha} = 0 \tag{113}$$

We call this gauge transformation the **Lorentz gauge**, and it plays an important role in simplifying Einstein's equations for a weak gravitational field:

- Suppose we begin with arbitrary metric perturbation components $h_{\mu\nu}^{(\mathrm{old})}$ (defined on a background Minkowski spacetime).
- We transform $h_{\mu\nu}^{(\mathrm{old})}$ to the Lorentz gauge by finding vector components ξ^μ which satisfy the **Lorentz gauge condition**, explained in detail in Appendix 4. The new metric perturbation components $h_{\mu\nu}^{(\mathrm{LG})}$, in the Lorentz gauge, are given by

$$h_{\mu\nu}^{(\mathrm{LG})} \;=\; h_{\mu\nu}^{(\mathrm{old})} \;-\; \xi_{\mu,\nu} \;-\; \xi_{\nu,\mu} \tag{114}$$

- We convert $h_{\mu\nu}^{(\mathrm{LG})}$ to $\overline{h}_{\mu\nu}^{(\mathrm{LG})}$ using equation (109), i.e.

$$\overline{h}_{\mu\nu}^{(\mathrm{LG})} \;=\; h_{\mu\nu}^{(\mathrm{LG})} \;-\; \frac{1}{2}\eta_{\mu\nu}\, h^{(\mathrm{LG})} \tag{115}$$

- Provided the ξ^μ satisfy the Lorentz gauge condition, then the $\overline{h}^{(\mathrm{LG})}_{\mu\nu}$ components will satisfy equation (113). This in turn means that – when our metric perturbation is expressed in terms of $\overline{h}^{(\mathrm{LG})}_{\mu\nu}$ – the last three terms on the left hand side of equation (112) are all zero.

Thus, in the Lorentz gauge, the linearised Einstein field equations reduce to the somewhat simpler form (dropping the label '(LG)' for clarity)

$$-\overline{h}_{\mu\nu,\alpha}{}^{,\alpha} = 16\pi T_{\mu\nu} \tag{116}$$

6.3.4 Solution to Einstein's equations in free space

In free space we can take the energy momentum tensor to be identically zero. The free space solutions of equation (116) are, therefore, solutions of the equation

$$\overline{h}_{\mu\nu,\alpha}{}^{,\alpha} = 0 \tag{117}$$

or, using equation (105)

$$\overline{h}_{\mu\nu,\alpha}{}^{,\alpha} \quad \equiv \quad \eta^{\alpha\alpha}\overline{h}_{\mu\nu,\alpha\alpha} \tag{118}$$

In fact, when we write out equation (118) explicitly, it takes the form

$$\left(-\frac{\partial^2}{\partial t^2} \; + \; \nabla^2 \right) \overline{h}_{\mu\nu} \quad = \quad 0 \tag{119}$$

which is often also written as

$$\Box\, \overline{h}_{\mu\nu} \quad = \quad 0 \tag{120}$$

where the operator $\Box$ is known as the *D'Alembertian*.

Remembering that we are taking $c = 1$, if instead we write

$$\eta^{00} = -\frac{1}{c^2} \tag{121}$$

then equation (119) can be re-written as

$$\left(-\frac{\partial^2}{\partial t^2} \; + \; c^2 \, \nabla^2 \right) \overline{h}_{\mu\nu} \quad = \quad 0 \tag{122}$$

This is a key result. Equation (122) has the mathematical form of a wave equation, propagating with speed c. Thus, we have shown that the metric perturbations – the 'ripples' in spacetime produced by disturbing the metric – propagate at the speed of light as waves in free space.

7 The Transverse – Traceless Gauge

We show that a coordinate system can be chosen in which the 16 components of a linear metric perturbation reduce to only 2 independent components.

We now explore further the properties of solutions to equation (119). The simplest solutions are **plane waves**

$$\overline{h}_{\mu\nu} = \mathrm{Re}\left[A_{\mu\nu} \, \exp\left(i k_\alpha x^\alpha \right) \right] \tag{123}$$

where 'Re' denotes the real part, and the constant components $A_{\mu\nu}$ and k_α are known as the **wave amplitude** and **wave vector** respectively. (Note that, as they appear in equation (123), the k_α are the components of a one-form. However, since we are considering the weak field limit of a background Minkowski spacetime, converting between covariant and contravariant components is very straightforward).

Equation (123) may appear to restrict the metric perturbations to a particular mathematical form, but *any* $\overline{h}_{\mu\nu}$ can be Fourier-expanded as a superposition of plane waves.

The wave amplitude and wave vector components are not arbitrary. Firstly, $A_{\mu\nu}$ is symmetric, since $\overline{h}_{\mu\nu}$ is symmetric. This immediately reduces the number of independent components from 16 to 10. Next, given that

$$\overline{h}_{\mu\nu,\alpha}{}^{,\alpha} = \eta^{\alpha\sigma}\,\overline{h}_{\mu\nu,\alpha\sigma} = 0 \tag{124}$$

it is easy to show that

$$k_\alpha\,k^\alpha = 0 \tag{125}$$

i.e. the wave vector is a **null vector**.

Thus, equation (123) describes a plane wave of frequency

$$\omega = k^t = \left(k_x^2 + k_y^2 + k_z^2\right)^{1/2} \tag{126}$$

propagating in direction $(1/k^t)\,(k_x, k_y, k_z)$.

Also, it follows from the Lorentz gauge condition

$$\overline{h}^{\mu\alpha}{}_{,\alpha} = 0 \tag{127}$$

that

$$\left(\overline{h}^{\alpha}_{\mu}\right)_{,\alpha} = 0 \tag{128}$$

from which it then follows that

$$A_{\mu\alpha}\,k^\alpha = 0 \tag{129}$$

i.e. the wave amplitude components must be orthogonal to the wave vector $\mathbf{k}$.

Equation (129) is, in fact, four linear equations – one for each value of the free coordinate index μ. This means that we have sufficient freedom to fix the values of four components of $A_{\mu\nu}$, thus reducing from 10 to 6 the number of independent components $A_{\mu\nu}$.

Can we restrict the components of the wave amplitude further still? The answer is again 'yes', since still we have some additional freedom remaining in our choice of gauge transformation.

Note that the transformation defined by equation (134) does **not** determine ξ^μ uniquely. We saw in Appendix 3 that the Lorentz gauge condition requires that the ξ^μ satisfy

$$\left(-\frac{\partial^2}{\partial t^2} \; + \; \nabla^2 \right) \xi^\mu \quad = \quad \overline{h}^{(\mathrm{old})\mu\nu}_{\quad ,\nu} \tag{130}$$

However, to any set of components ξ^μ which satisfy equation (130), we could add the components ψ^μ to define a new transformation

$$x'^\mu \quad \mapsto \quad x^\mu + \zeta^\mu \quad = \quad x^\mu + \xi^\mu + \psi^\mu \tag{131}$$

and provided the ψ^μ satisfy

$$\left(-\frac{\partial^2}{\partial t^2} \; + \; \nabla^2 \right) \psi^\mu \quad = \quad 0 \tag{132}$$

then ζ^μ will *still* satisfy

$$\left(-\frac{\partial^2}{\partial t^2} \; + \; \nabla^2 \right) \zeta^\mu \quad = \quad \overline{h}^{(\mathrm{old})\mu\nu}_{\quad ,\nu} \tag{133}$$

so that the modified metric perturbation

$$h^{(\mathrm{TT})}_{\mu\nu} \; = \; h^{(\mathrm{old})}_{\mu\nu} \; - \; \zeta_{\mu,\nu} \; - \; \zeta_{\nu,\mu} \tag{134}$$

still express the Einstein tensor in the simplified, Lorentz gauge form of equation (122).

The label '(TT)' stands for **Transverse Traceless**, and the gauge transformation ψ^μ (or equivalently ζ^μ) defines the **Transverse Traceless gauge**. The reason

for this name, and the importance of the Transverse Traceless gauge for describing gravitational waves will become clear shortly.

Equation (132) gives us four additional equations with which we can adjust the components of our gauge transformation, in order to choose a coordinate system which makes $\overline{h}_{\mu\nu}$ – and hence $A_{\mu\nu}$ – as simple as possible. In fact, it can be shown that the freedom we retain in our choice of ψ^{μ}, while still satisfying the Lorentz gauge conditions, allows us to restrict further $A_{\mu\nu}$ by fixing the values of four more of its components, thus reducing it to having only two independent components.

Specifically, if **U** is some arbitrarily chosen four vector with components U^{β}, then we have sufficient freedom in choosing the components of ψ to ensure that the wave amplitude tensor satisfies

$$A_{\alpha\beta}\, U^{\beta} = 0 \tag{135}$$

Moreover, we can also choose the components of ψ so that

$$A^{\mu}_{\mu} = \eta^{\mu\nu}\, A_{\mu\nu} = 0 \tag{136}$$

i.e. we can set the trace of **A** to be equal to zero. (This is the origin of the 'Traceless' part of the name Transverse Traceless gauge).

To fix our ideas and to see explicitly the form of $A_{\alpha\beta}$ which emerges from our adoption of the Transverse Traceless gauge, consider a test particle experiencing the passage of a gravitational wave in a nearly flat region of spacetime. Suppose we now transform to the background Lorentz frame in which the test particle is at rest – i.e. its four-velocity U^{β} has components $(1, 0, 0, 0)$, which we may also write as

$$U^{\beta} = \delta^{\beta}_{t} \tag{137}$$

Equations (135) and (137) then imply that

$$A_{\alpha t} = 0 \quad \text{for all} \quad \alpha \tag{138}$$

Next suppose we orient our spatial coordinate axes so that the wave is travelling in the positive z-direction, i.e.

$$k^t = \omega\,, \quad k^x = k^y = 0\,, \quad k^z = \omega \tag{139}$$

and

$$k_t = -\omega\,, \quad k_x = k_y = 0\,, \quad k_z = \omega \tag{140}$$

It then follows from equation (129) that

$$A_{\alpha z} = 0 \quad \text{for all } \alpha \tag{141}$$

i.e. there is no component of the metric perturbation in the direction of propagation of the wave. This explains the origin of the 'Transverse' part of the Transverse Traceless gauge; in this gauge the metric perturbation is entirely transverse to the direction of propagation of the gravitational wave.

To summarise, in the Transverse Traceless gauge equation (123) simplifies to become

$$\overline{h}^{(\mathrm{TT})}_{\mu\nu} = A^{(\mathrm{TT})}_{\mu\nu} \cos\left[\omega(t-z)\right] \tag{142}$$

Equations (138) and (141), combined with the symmetry of $A_{\mu\nu}$, imply that the only non-zero components of $A_{\mu\nu}$ are A_{xx}, A_{yy} and $A_{xy} = A_{yx}$. Moreover, the traceless condition, equation (136), implies that $A_{xx} = -A_{yy}$. Hence, the components of $A_{\mu\nu}$ in the Transverse Traceless gauge are

$$A^{(\mathrm{TT})}_{\mu\nu} = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & A^{(\mathrm{TT})}_{xx} & A^{(\mathrm{TT})}_{xy} & 0 \\ 0 & A^{(\mathrm{TT})}_{xy} & -A^{(\mathrm{TT})}_{xx} & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \tag{143}$$

It then follows trivially that

$$\overline{h}^{(\mathrm{TT})}_{\mu\nu} = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & \overline{h}^{(\mathrm{TT})}_{xx} & \overline{h}^{(\mathrm{TT})}_{xy} & 0 \\ 0 & \overline{h}^{(\mathrm{TT})}_{xy} & -\overline{h}^{(\mathrm{TT})}_{xx} & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \tag{144}$$

where

$$\overline{h}^{(\mathrm{TT})}_{xx} = A^{(\mathrm{TT})}_{xx} \cos\left[\omega(t-z)\right] \tag{145}$$

and

$$\overline{h}^{(\mathrm{TT})}_{xy} = A^{(\mathrm{TT})}_{xy} \cos\left[\omega(t-z)\right] \tag{146}$$

Finally, we should note that in the Transverse Traceless gauge it is trivial to relate the components $\overline{h}_{\mu\nu}$ to the original metric perturbation $h_{\mu\nu}$. Following equation (103) and substituting from equation (109) we define

$$\overline{h} = \eta^{\alpha\beta}\,\overline{h}_{\alpha\beta} = \eta^{\alpha\beta}\left(h_{\alpha\beta} - \frac{1}{2}\eta_{\alpha\beta}\,h\right) = h - 2h = -h \tag{147}$$

Clearly, then, for the particular case of the Transverse Traceless gauge, both $\overline{h}$ and h are identically zero. (We should not be surprised by this, because of how we constructed h and $\overline{h}$ in the first place). It then follows trivially that for all $\alpha\,,\ \beta$

$$\overline{h}^{(\mathrm{TT})}_{\alpha\beta} = h^{(\mathrm{TT})}_{\alpha\beta} \tag{148}$$

8 Effect of Gravitational Waves on Free Particles

We investigate the geodesic equations for the trajectories of material particles and photons in a nearly flat spacetime, during to the passage of a gravitational wave.

There is a danger that the mathematical details of the previous section might appear rather abstract, and detached from practical issues relating to the design and operation of gravitational wave detectors. However, nothing could be further from the truth. The simplifications introduced by the adoption of the Transverse Traceless gauge have important practical consequences for detector design, as we will now illustrate.

8.1 Proper distance between test particles

We saw from equations (144) – (146) that the amplitude of the metric perturbation is described by just two independent constants, A_{xx} and A_{xy}. We can understand the physical significance of these constants by examining the effect of the gravitational wave on a free particle, in an initially wave-free region of spacetime.

We choose a background Lorentz frame in which the particle is initially at rest – i.e. the initial four-velocity of the particle is given by equation (137) – and we set up our coordinate system according to the Transverse Traceless Lorentz gauge.

The free particle's trajectory satisfies the geodesic equation

$$\frac{dU^\beta}{d\tau} + \Gamma^\beta_{\mu\nu} U^\mu U^\nu = 0 \tag{149}$$

where τ is the proper time. The particle is initially at rest, i.e. initially $U^\beta = \delta^\beta_t$.

Thus, the initial acceleration of the particle is

$$\left(\frac{dU^\beta}{d\tau}\right)_0 = -\Gamma^\beta_{tt} = -\frac{1}{2}\eta^{\alpha\beta}\left(h_{\alpha t,t} + h_{t\alpha,t} - h_{tt,\alpha}\right) \tag{150}$$

However, from equation (138)

$$A_{\alpha t} = 0 \quad \Rightarrow \quad \overline{h}_{\alpha t} = 0 \tag{151}$$

Also, recall that $h = \overline{h} = 0$. Therefore it follows that

$$h_{\alpha t} = 0 \quad \text{for all } \alpha \tag{152}$$

which in turn implies that

$$\left(\frac{dU^{\beta}}{d\tau}\right)_0 = 0 \tag{153}$$

Hence a free particle, initially at rest, will remain at rest indefinitely. However, 'being at rest' in this context simply means that the *coordinates* of the particle do *not* change. This is simply a consequence of our judicious choice of coordinate system, via the adoption of the Transverse Traceless Lorentz gauge. As the gravitational wave passes, this coordinate system adjusts itself to the ripples in the spacetime, so that any particles remain 'attached' to their initial coordinate positions. Coordinates are merely frame-dependent labels, however, and do not directly convey any invariant geometrical information about the spacetime.

Suppose instead we consider the **proper distance** between two nearby particles, both initially at rest, in this coordinate system: one at the origin and the other at spatial coordinates $x = \epsilon\,,\ y = z = 0$. The proper distance between the particles is then given by

$$\Delta\ell = \int \left| g_{\alpha\beta} dx^{\alpha} dx^{\beta} \right|^{1/2} \tag{154}$$

i.e.

$$\Delta\ell = \int_0^{\epsilon} |g_{xx}|^{1/2} \quad \simeq \quad \sqrt{g_{xx}(x=0)}\ \epsilon \tag{155}$$

Now

$$g_{xx}(x=0) = \eta_{xx} + h^{(\mathrm{TT})}_{xx}(x=0) \tag{156}$$

so

$$\Delta\ell \simeq \left[1 + \frac{1}{2}h^{(\mathrm{TT})}_{xx}(x=0)\right]\epsilon \tag{157}$$

Since $h^{(\mathrm{TT})}_{xx}(x=0)$ in general is **not** constant, it follows that the proper distance between the particles will change as the gravitational wave passes. It is essentially this change in the proper distance between test particles which gravitational wave detectors attempt to measure.

8.2 Geodesic deviation of test particles

We can study the behaviour of test particles more formally using the idea of **geodesic deviation**, first introduced in Section 2. We define the vector ξ^α which connects the two particles introduced above. Then, for a weak gravitational field, from equation (62) and taking proper time approximately equal to coordinate time

$$\frac{\partial^2\xi^\alpha}{\partial t^2} = R^\alpha_{\mu\nu\beta}\,U^\mu\,U^\nu\,\xi^\beta \tag{158}$$

where U^μ are the components of the four-velocity of the two particles. Since the particles are initially at rest, then

$$U^\mu \quad = \quad (1,0,0,0)^T \tag{159}$$

and

$$\xi^\beta \quad = \quad (0,\epsilon,0,0)^T \tag{160}$$

Equation (158) then simplifies to

$$\frac{\partial^2\xi^\alpha}{\partial t^2} = \epsilon R^\alpha_{ttx} = -\epsilon R^\alpha_{txt} \tag{161}$$

Substituting from equation (101) for a weak gravitational field, we can write down the relevant components of the Riemann Christoffel tensor in terms of the non-zero components of the metric perturbation (remembering always that we are working in the Transverse Traceless gauge)

$$R^x_{txt} = \eta^{xx} R_{xtxt} = -\frac{1}{2} h^{(\mathrm{TT})}_{xx,tt} \tag{162}$$

$$R^y_{txt} = \eta^{yy} R_{ytxt} = -\frac{1}{2} h^{(\mathrm{TT})}_{xy,tt} \tag{163}$$

Hence, two particles initially separated by ϵ in the x-direction, have a geodesic deviation vector which obeys the differential equations[3]

$$\frac{\partial^2}{\partial t^2}\,\xi^x \;=\; \frac{1}{2}\epsilon \frac{\partial^2}{\partial t^2} h^{(\mathrm{TT})}_{xx} \tag{164}$$

and

$$\frac{\partial^2}{\partial t^2}\,\xi^y \;=\; \frac{1}{2}\epsilon \frac{\partial^2}{\partial t^2} h^{(\mathrm{TT})}_{xy} \tag{165}$$

Similarly, it is straightforward to show that two particles initially separated by ϵ in the y-direction, have a geodesic deviation vector which obeys the differential equations

$$\frac{\partial^2}{\partial t^2}\,\xi^x \;=\; \frac{1}{2}\epsilon \frac{\partial^2}{\partial t^2} h^{(\mathrm{TT})}_{xy} \tag{166}$$

and

$$\frac{\partial^2}{\partial t^2}\,\xi^y \;=\; -\frac{1}{2}\epsilon \frac{\partial^2}{\partial t^2} h^{(\mathrm{TT})}_{xx} \tag{167}$$

[3]We are being a little sloppy in our notation here, as we have defined ξ as a $(1,0)$ tensor and $\mathbf{h}$ as a $(0,2)$ tensor. However, since we are in a background Lorentz spacetime, the x and y components of vectors and one-forms are identical.

8.3 Ring of test particles: polarisation of gravitational waves

We can further generalise equations (164) – (167) to consider the geodesic deviation of two particles – one at the origin and the other initially at coordinates $x = \epsilon \cos\theta$, $y = \epsilon \sin\theta$ and $z = 0$, i.e. in the x-y plane – as a gravitational wave propagates in the z-direction. We can show that ξ^x and ξ^y obey the differential equations

$$\frac{\partial^2}{\partial t^2}\,\xi^x \;=\; \frac{1}{2}\epsilon\cos\theta\frac{\partial^2}{\partial t^2}h^{(\mathrm{TT})}_{xx} \;+\; \frac{1}{2}\epsilon\sin\theta\frac{\partial^2}{\partial t^2}h^{(\mathrm{TT})}_{xy} \tag{168}$$

and

$$\frac{\partial^2}{\partial t^2}\,\xi^y \;=\; \frac{1}{2}\epsilon\cos\theta\frac{\partial^2}{\partial t^2}h^{(\mathrm{TT})}_{xy} \;-\; \frac{1}{2}\epsilon\sin\theta\frac{\partial^2}{\partial t^2}h^{(\mathrm{TT})}_{xx} \tag{169}$$

Substituting from equations (146) and (148), we can identify the solution

$$\xi^x \;=\; \epsilon\cos\theta + \frac{1}{2}\epsilon\cos\theta\,A^{(\mathrm{TT})}_{xx}\cos\omega t \;+\; \frac{1}{2}\epsilon\sin\theta\,A^{(\mathrm{TT})}_{xy}\cos\omega t \tag{170}$$

and

$$\xi^y \;=\; \epsilon\sin\theta + \frac{1}{2}\epsilon\cos\theta\,A^{(\mathrm{TT})}_{xy}\cos\omega t \;-\; \frac{1}{2}\epsilon\sin\theta\,A^{(\mathrm{TT})}_{xx}\cos\omega t \tag{171}$$

Suppose we now vary θ between 0 and 2π, so that we are considering an initially circular ring of test particles in the x-y plane, initially equidistant from the origin. Figure 9 shows the effect of the passage of a plane gravitational wave, propagating along the z-axis, on this ring of test particles.

The upper panel shows the case where the metric perturbation has $A^{(\mathrm{TT})}_{xx} \neq 0$ and $A^{(\mathrm{TT})}_{xy} = 0$. In this case the solutions for ξ^x and ξ^y reduce to

$$\xi^x \;=\; \epsilon\cos\theta\left(\,1 \;+\; \frac{1}{2}A^{(\mathrm{TT})}_{xx}\cos\omega t\,\right) \tag{172}$$

and

$$\xi^y \;=\; \epsilon\sin\theta\left(\,1 \;-\; \frac{1}{2}A^{(\mathrm{TT})}_{xx}\cos\omega t\,\right) \tag{173}$$

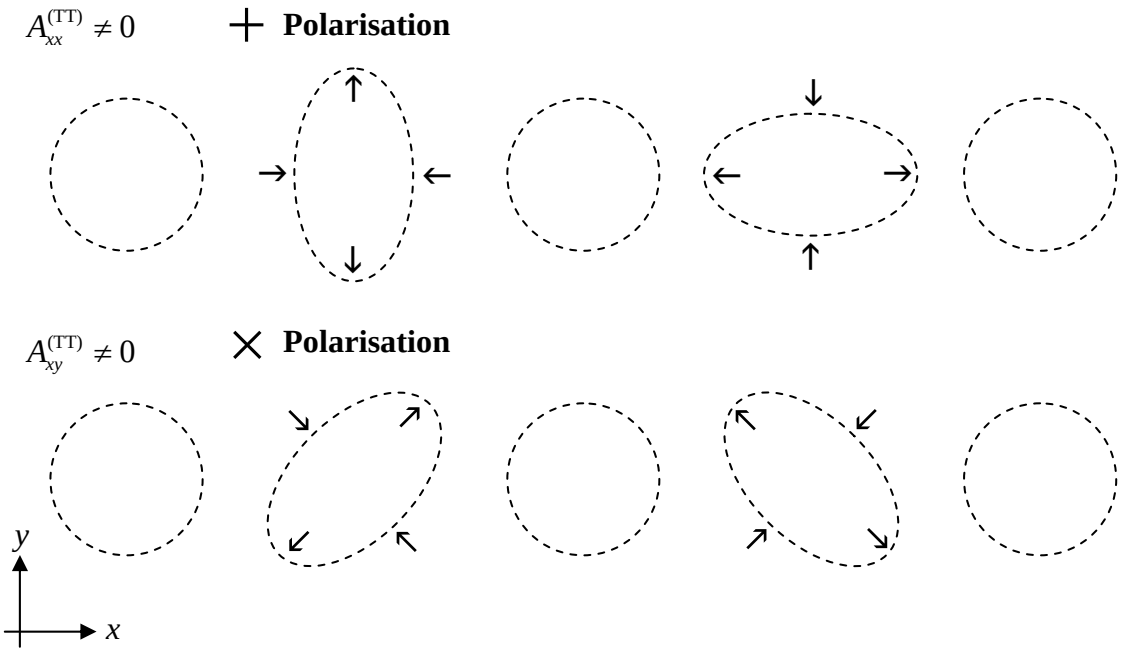

Figure 9: Cartoon illustrating the effect of a gravitational wave on a ring of test particles. The upper panel shows a wave for which $A_{xx}^{(\mathrm{TT})} \neq 0$ and $A_{xy}^{(\mathrm{TT})} = 0$, which we denote as the '+' polarisation. The lower panel shows a wave for which $A_{xy}^{(\mathrm{TT})} \neq 0$ and $A_{xx}^{(\mathrm{TT})} = 0$, which we denote as the '$\times$' polarisation.

Each of the five rings across the upper panel of Figure 9 corresponds to a different phase (i.e. different value of ωt) in the oscillation of the wave: the first, third and fifth phases shown are all odd multiples of $\pi/2$, so that the $\cos \omega t$ terms in equations (172) and (173) vanish. The second and fourth rings, on the other hand, correspond to a phase of π and 2π respectively. At phase π we can see from equations (172) and (173) that the effect of the wave will be to move test particles on the x-axis inwards – i.e. the gravitational wave *reduces* their proper distance from the centre of the ring – while test particles on the y-axis are moved outwards – i.e. the gravitational wave *increases* their proper distance from the centre of the ring. At phase 2π, on the

other hand, the wave will produce an opposite effect, increasing the proper distance from the ring centre of particles on the x-axis and reducing the proper distance of particles on the y-axis.

The lower panel of Figure 9 shows the contrasting case where the metric perturbation has $A^{(\mathrm{TT})}_{xy} \neq 0$ and $A^{(\mathrm{TT})}_{xx} = 0$. Again, the ring of test particles is shown for five different phases in the oscillation of the gravitational wave: $\pi/2$, π, $3\pi/2$, 2π and $5\pi/2$ respectively. In this case the solutions for ξ^x and ξ^y reduce to

$$\xi^x \;=\; \epsilon\cos\theta \;+\; \frac{1}{2}\epsilon\sin\theta\, A^{(\mathrm{TT})}_{xy}\cos\omega t \tag{174}$$

and

$$\xi^y \;=\; \epsilon\sin\theta \;+\; \frac{1}{2}\epsilon\cos\theta\, A^{(\mathrm{TT})}_{xy}\cos\omega t \tag{175}$$

To understand the relationship between these solutions and those for $A^{(\mathrm{TT})}_{xx} \neq 0$, we define new coordinate axes x' and y' by rotating the x and y axes through an angle of $-\pi/4$, so that

$$x' = \frac{1}{\sqrt{2}}\,(x - y) \tag{176}$$

and

$$y' = \frac{1}{\sqrt{2}}\,(x + y) \tag{177}$$

If we write the solutions for $A^{(\mathrm{TT})}_{xx} \neq 0$ in terms of the new coordinates x' and y', after some algebra we find that

$$\xi'^x \;=\; \epsilon\cos\left(\theta + \frac{\pi}{4}\right) \;+\; \frac{1}{2}\epsilon\sin\left(\theta + \frac{\pi}{4}\right)\, A^{(\mathrm{TT})}_{xy}\cos\omega t \tag{178}$$

and

$$\xi'^y \;=\; \epsilon\sin\left(\theta + \frac{\pi}{4}\right) \;+\; \frac{1}{2}\epsilon\cos\left(\theta + \frac{\pi}{4}\right)\, A^{(\mathrm{TT})}_{xy}\cos\omega t \tag{179}$$

Comparing equations (178) and (179) with equations (174) and (175) we see that our solutions with $A_{xy}^{(\mathrm{TT})} \neq 0$ are identical to the solutions with $A_{xx}^{(\mathrm{TT})} \neq 0$ apart from the rotation of $\pi/4$ – as can be seen from the lower panel of Figure 9.

We note some important features of the results of this section.

- The two solutions, for $A_{xx}^{(\mathrm{TT})} \neq 0$ and $A_{xy}^{(\mathrm{TT})} \neq 0$ represent two independent gravitational wave **polarisation states**, and these states are usually denoted by '+' and '×' respectively. In general any gravitational wave propagating along the z-axis can be expressed as a linear combination of the '+' and '×' polarisations, i.e. we can write the wave as

$$\mathbf{h} \;=\; a\,\mathbf{e}_+ \;+\; b\,\mathbf{e}_\times \tag{180}$$

  where a and b are scalar constants and the *polarisation tensors* $\mathbf{e}_+$ and $\mathbf{e}_\times$ are

$$\mathbf{e}_+ \;=\; \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \tag{181}$$

  and

$$\mathbf{e}_\times \;=\; \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \tag{182}$$

- We can see from the panels in Figure 9 that the distortion produced by a gravitational wave is **quadrupolar**. This is a direct consequence of the fact that gravitational waves are produced by changes in the curvature of spacetime, the signature of which is acceleration of the deviation between neighbouring geodesics. Recall our comment in Section 2.1 that geodesic deviation cannot

distinguish between a zero gravitational field and a uniform gravitational field: only for a non-uniform, **tidal** gravitational field does the geodesic deviation accelerate. Such tidal variations are quadrupolar in nature. In Section 9.1 below we discuss briefly a useful analogy with electromagnetic radiation that helps to explain why gravitational radiation is (at lowest order) quadrupolar.

- We can also see from Figure 9 that, at any instant, a gravitational wave is invariant under a rotation of 180° about its direction of propagation (in this case, the z-axis). By contrast, an electromagnetic wave is invariant under a rotation of 360°, and a *neutrino* wave is invariant under a rotation of 720°. This behaviour can be understood in terms of the *spin states* of the corresponding **gauge bosons**: the particles associated with the quantum mechanical versions of these waves.

  In general, the classical radiation field of a particle of spin, S, is invariant under a rotation of $360°/S$. Moreover, a radiation field of spin S has precisely two independent polarisation states, which are inclined to each other at an angle of $90°/S$. Thus, for an electromagnetic wave, corresponding to a photon of spin $S = 1$, the independent polarisation modes are inclined at 90° to each other.

  We can, therefore, deduce from the inclination of the gravitational wave polarisation states, that the **graviton** (which is, as yet undiscovered, since we do not yet have a fully developed theory of quantum gravity!) must be a spin $S = 2$ particle. The fact that electromagnetic waves correspond to a spin $S = 1$ field and gravitational waves correspond to a spin $S = 2$ field is also intimately connected to their mathematical description in terms of geometrical objects: spin $S = 1$ fields are **vector fields**, which is why we require only a vector description for the electromagnetic field; spin $S = 2$ fields, on the other hand, are **tensor fields**, which is why we required to introduce tensors

to describe the properties of the gravitational field.

8.4 The design of gravitational wave detectors: basic considerations

As we stated in Section 8.1, a change in the proper separation of test particles during the passage of a gravitational wave is the physical quantity which gravitational wave detectors are designed to measure. As will be discussed in detail in the subsequent lectures, in most of the gravitational wave detectors currently operational or planned for the future (e.g. LIGO, GEO600, VIRGO, LISA) these changes in the proper separation are monitored via measurement of the *light travel time* of a laser beam travelling back and forth along the arms of a Michelson Interferometer. Differences in the light travel time along perpendicular arms will produce interference fringes in the laser output of the interferometer.

We illustrate this in Figure 10, which shows in cartoon form the basic design of a Michelson interferometer gravitational wave detector. Here we suppose that gravitational wave with the '+' polarisation is propagating along the z-axis. Laser light of wavelength λ enters the apparatus at A, and is split into two perpendicular beams which are bounced off test mass mirrors M_1 and M_2 at the end of the arms (each of proper length L in the absence of any gravitational wave). The two beams are then re-combined and exit the system at B.

The three panels of Figure 10 denote three different phases of the wave as it passes through the system. In the left panel the wave causes no change in the proper length of the arms; in the middle panel the horizontal arm is shortened by ΔL while the vertical arm is lengthened by the same proper distance. In the right hand panel

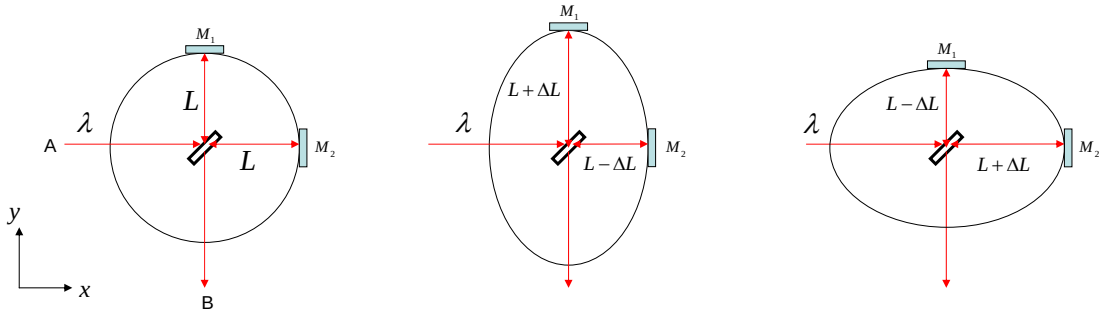

Figure 10: Cartoon illustration of the basic design features of a Michelson interferometer gravitational wave detector. See text for details.

we see the opposite: the horizontal and vertical arms are lengthened and shortened respectively by ΔL.

How are the physical dimensions of the interferometer related to the amplitude of the gravitational wave? Consider, for example, a gravitational wave $\mathbf{h} = h\mathbf{e}_+$ propagating along the z-axis. If we place two test masses along the x-axis, initially separated by proper distance L, we can see from equation (172) that the minimum and maximum proper distance between the test masses, as the gravitational wave passes, is $L - h/2$ and $L + h/2$ respectively. Thus, the fractional change $\Delta L/L$ in the proper separation of the test masses satisfies

$$\frac{\Delta L}{L} = \frac{h}{2} \tag{183}$$

Of course in general the arms of a gravitational wave detector will *not* be optimally aligned with the polarisation and direction of propagation of an incoming wave. Figure 11 sketches the orientation of one axis of a gravitational wave detector with respect to an incoming wave propagating along the z-axis. The detector axis is defined by standard spherical polar angles θ and ϕ. If the incoming wave has '+'

polarisation, i.e. $\mathbf{h} = h\,\mathbf{e}_+$, then the detector 'sees' an effective amplitude of

$$h_+ \;=\; h\,\sin^2\theta\,\cos 2\phi \tag{184}$$

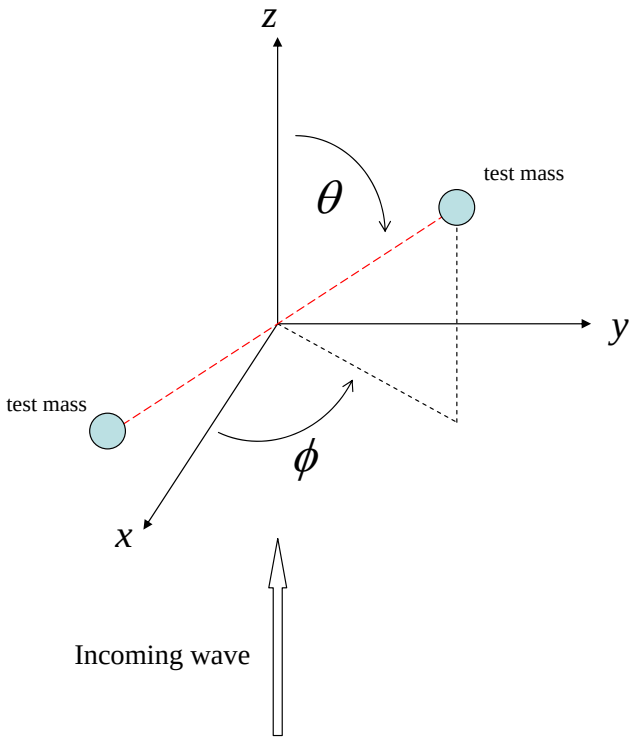

Figure 11: Cartoon illustration showing the relative orientation of a detector arm and the direction of propagation of a gravitational wave.

So we see that the wave produces a maximum response in the detector arm if $\theta = \pi/2$ and $\phi = 0$, and produces a *null* response for $\theta = 0$ or $\phi = \pi/4$. This makes sense when we consider Figure 11; we already commented previously that a metric perturbation produces no disturbance along its direction of propagation.

If, on the other hand, the incoming wave has the '$\times'$ polarisation, then in this case the detector 'sees' an effective amplitude of

$$h_\times \;=\; h\,\sin^2\theta\,\sin 2\phi \tag{185}$$

Now the wave produces a maximum response for $\theta = \pi/2$ and $\phi = \pi/4$, while the response is null for $\theta = 0$ or $\phi = 0$.

How large do we expect h to be? We have developed our understanding of the physics and mathematics of gravitational waves within the framework of the weak field approximation, which requires that $h << 1$. But how small is small? Much of the remainder of this School will focus on the enormous technical challenge which the detection of gravitational waves presents because h is indeed a tiny quantity: unless we are extraordinarily lucky, then from even the most cataclysmic astrophysical sources we expect h to be no larger than one part in 10^{20}.

To end these lectures, therefore, and as a pre-cursor to the more detailed treatments which will follow in later lectures, in the final section below we briefly consider the expected magnitude and character of gravitational waves from astrophysical sources.

9 The Production of Gravitational Waves

We discuss qualitatively the reasons why gravitational radiation is quadrupolar to lowest order, and we estimate the amplitude of the gravitational wave signal from a binary neutron star system.

9.1 The quadrupolar nature of gravitational waves

We can understand something important about the nature of gravitational radiation by drawing analogies with the formulae that describe electromagnetic radiation. This approach is crude at best since the electromagnetic field is a vector field while the gravitational field is a tensor field, but it is good enough for our present purposes. Essentially, we will take familiar electromagnetic radiation formulae and simply replace the terms which involve the Coulomb force by their gravitational analogues from Newtonian theory.

9.1.1 Electric and magnetic dipoles

In electromagnetic theory, the dominant form of radiation from a moving charge or charges is **electric dipole radiation**. For a single particle (e.g. an electron) of charge, e, with acceleration, $\mathbf{a}$, and dipole moment changing as $\ddot{\mathbf{d}} = e\,\ddot{\mathbf{x}} = e\,\mathbf{a}$, the power output, or luminosity, is given by

$$L_{\text{electric dipole}} \propto e^2\,\mathbf{a}^2 \tag{186}$$

For a general distribution of charges, with net dipole moment, $\mathbf{d}$, the luminosity is

$$L_{\text{electric dipole}} \propto e^2\,\dddot{\mathbf{d}}^2 \tag{187}$$

The next strongest types of electromagnetic radiation are **magnetic dipole** and **electric quadrupole radiation**. For a general distribution of charges, the luminosity arising from magnetic dipole radiation is proportional to the second time

derivative of the magnetic dipole moment, i.e.

$$L_{\text{magnetic dipole}} \propto \ddot{\mu} \tag{188}$$

where μ is given by a sum (or integral) over a distribution of charges:-

$$\mu \;=\; \sum_{q_i} \text{(position of } q_i) \times \text{(current due to } q_i) \tag{189}$$

9.1.2 Gravitational analogues

The gravitational analogue of the electric dipole moment is the **mass dipole moment**, **d**, summed over a distribution of particles, $\{A_i\}$

$$\mathbf{d} \;=\; \sum_{A_i} m_i \mathbf{x}_i \tag{190}$$

where m_i is the rest mass and $\mathbf{x}_i$ is the position of particle A_i.

By analogy with equation (188), the luminosity of gravitational 'mass dipole' radiation should be proportional to the second time derivative of **d** . However, the *first* time derivative of **d** is

$$\dot{\mathbf{d}} \;=\; \sum_{A_i} m_i \dot{\mathbf{x}}_i \quad \equiv \quad \mathbf{p} \tag{191}$$

where p is the **total linear momentum** of the system. Since the total momentum is conserved, it follows that the gravitational 'mass dipole' luminosity is zero – i.e **there can be no mass dipole radiation from any source**.

Similarly, the gravitational analogue of the magnetic dipole moment is

$$\mu \;=\; \sum_{A_i} (\mathbf{x}_i) \times (m_i \mathbf{v}_i) \quad \equiv \quad \mathbf{J} \tag{192}$$

where **J** is the **total angular momentum** of the system. Since the total angular momentum is *also* conserved, again it follows that the gravitational analogue of magnetic dipole radiation must have zero luminosity. Hence **there can be no dipole radiation of any sort from a gravitational source**.

The simplest form of gravitational radiation which has non-zero luminosity is, therefore, quadrupolar. We do not consider the mathematical details of quadrupolar radiation any further, save to point out that it can be shown that the quadrupole from a **spherically symmetric mass distribution** is identically zero. This suggests an important result: that, at least up to quadrupole order, **metric perturbations which are spherically symmetric do not produce gravitational radiation**. Thus, if e.g. the collapse of a massive star is spherically symmetric, it will generate *no* gravitational waves.

In fact, it is possible to prove that this result is *also* true for higher order radiation (e.g. octupole etc.), although the proof is very technical and is not discussed further. Interested readers are referred to Chapters 9 and 10 of Schutz '*A First Course in General Relativity*'.

9.2 Example: a binary neutron star system

Finally, we consider the example of the gravitational wave signature of a particular astrophysical system: a binary neutron star.

In general it can be shown (see, e.g. Schutz' textbook) that in the so-called *slow motion approximation* for a weak metric perturbation $h_{\mu\nu} << 1$ then for a source at distance r

$$h_{\mu\nu} = \frac{2G}{c^4 r}\ddot{I}_{\mu\nu} \tag{193}$$

where $I_{\mu\nu}$ is the **reduced quadrupole moment** defined as

$$I_{\mu\nu} = \int \rho(\vec{r}) \left(x_\mu x_\nu - \frac{1}{3}\delta_{\mu\nu} r^2 \right) dV \tag{194}$$

Consider a binary neutron star system consisting of two stars both of Schwarzschild mass M, in a circular orbit of coordinate radius R and orbital frequency f. For

simplicity we define our coordinate system so that the orbital plane of the pulsars lies in the $x-y$ plane, and at coordinate time $t=0$ the two pulsars lie along the $x-$axis. Substituting into equation (194)[4] it is then straightforward to show that

$$I_{xx} = 2MR^2\left[\cos^2(2\pi ft) - \frac{1}{3}\right] \tag{195}$$

$$I_{yy} = 2MR^2\left[\sin^2(2\pi ft) - \frac{1}{3}\right] \tag{196}$$

$$I_{xy} = I_{yx} = 2MR^2\left[\cos(2\pi ft)\sin(2\pi ft)\right] \tag{197}$$

From equations (193) and (195) – (197) it then follows that

$$h_{xx} = -h_{yy} = h\cos\left(4\pi ft\right) \tag{198}$$

and

$$h_{xy} = h_{yx} = -h\sin\left(4\pi ft\right) \tag{199}$$

where the amplitude term h is given by

$$h = \frac{32\pi^2 GMR^2 f^2}{c^4 r} \tag{200}$$

We see from equations (198) and (199) that the binary system emits gravitational waves at twice the orbital frequency of the neutron stars.

[4]taking the mass density distribution to be a sum of dirac delta functions – i.e. treating the pulsars as point masses

How large is h for a typical source? Suppose we take M equal to the Chandrasekhar mass, $M \sim 1.4 M_{\rm solar} = 2.78 \times 10^{30}$kg. We can then evaluate the constants in equation (200) and express h in more convenient units as

$$h = 2.3 \times 10^{-28} \ \frac{R^2[\mathrm{km}] f^2[\mathrm{Hz}]}{r[\mathrm{Mpc}]} \tag{201}$$

If we take $R = 20$km, say, $f = 1000$Hz (which is approximately the orbital frequency that Newtonian gravity would predict) and $r = 15$Mpc (corresponding to a binary system in e.g. the Virgo cluster), then we find that $h \sim 6 \times 10^{-21}$.

Thus we see that the signal produced by a typical gravitational wave source places extreme demands upon detector technology. In the lectures which follow we will explore how these technological challenges are being met and overcome.

Appendix 1: Proof that $G^{\mu\nu}_{\ ;\nu} = 0$

The key to proving this result is the Bianchi identities, which state that

$$R_{\alpha\beta\mu\nu;\lambda} + R_{\alpha\beta\lambda\mu;\nu} + R_{\alpha\beta\nu\lambda;\mu} = 0$$

Hence, our first step will be to prove that the Bianchi identities are true. The left hand side of the above equation is a $(0,5)$ tensor, so if we can show that its components are zero at an arbitrary point on the manifold in a given coordinate system, then they must be zero in all coordinate systems. We choose a LIF at arbitrary point, P and set up a coordinate system in which locally the Christoffel symbols are identically zero. From the definition of the Riemann Christoffel tensor

$$R^{\mu}_{\ \beta\gamma\delta} = \Gamma^{\sigma}_{\beta\gamma}\Gamma^{\mu}_{\sigma\delta} - \Gamma^{\sigma}_{\beta\delta}\Gamma^{\mu}_{\sigma\gamma} + \Gamma^{\mu}_{\beta\gamma,\delta} - \Gamma^{\mu}_{\beta\delta,\gamma}$$

Now, since $g_{\alpha\mu;\lambda} = 0$, we can write

$$R_{\alpha\beta\gamma\delta;\lambda} = (g_{\alpha\mu}R^{\mu}_{\ \beta\gamma\delta})_{;\lambda} = g_{\alpha\mu}R^{\mu}_{\ \beta\gamma\delta;\lambda}$$

Now all the Christoffel symbols are zero at P in our chosen coordinate system, so from the above two equations (changing covariant back to partial derivatives, which are interchangeable at P)

$$R_{\alpha\beta\gamma\delta;\lambda} = g_{\alpha\mu}(\Gamma^{\mu}_{\beta\gamma,\delta\lambda} - \Gamma^{\mu}_{\beta\delta,\gamma\lambda})$$

Substituting for the Christoffel symbols using

$$\Gamma^{\sigma}_{\alpha\beta} = g^{\sigma\nu}(g_{\nu\alpha,\beta} + g_{\nu\beta,\alpha} - g_{\alpha\beta,\nu})$$

and also using the fact that in our LIF $g_{\alpha\beta,\gamma} = g^{\alpha\beta}_{\ \ ,\gamma} = 0$ one obtains

$$R_{\alpha\beta\gamma\delta;\lambda} = \frac{1}{2}(g_{\alpha\gamma,\beta\delta\lambda} + g_{\alpha\delta,\beta\gamma\lambda} - g_{\beta\gamma,\alpha\delta\lambda} - g_{\beta\delta,\alpha\gamma\lambda})$$

Writing out the corresponding expressions for the other two terms on the left hand side of the Bianchi identities and adding gives the required result, i.e.

$$R_{\alpha\beta\gamma\delta;\lambda} + R_{\alpha\beta\lambda\gamma;\delta} + R_{\alpha\beta\delta\lambda;\gamma} = 0$$

in geodesic coordinates at P. Hence the Bianchi identities must hold in all coordinate systems because of their tensorial nature.

Now, from the symmetry properties of the Riemann Christoffel tensor, we have

$$R_{\alpha\beta\lambda\mu;\nu} = -R_{\alpha\beta\mu\lambda;\nu}$$

so that the Bianchi identities can be re-written as

$$R_{\alpha\beta\mu\nu;\lambda} - R_{\alpha\beta\mu\lambda;\nu} + R_{\alpha\beta\nu\lambda;\mu} = 0$$

Contracting this equation with $g^{\alpha\mu}$ we obtain

$$g^{\alpha\mu}R_{\alpha\beta\mu\nu;\lambda} - g^{\alpha\mu}R_{\alpha\beta\mu\lambda;\nu} + g^{\alpha\mu}R_{\alpha\beta\nu\lambda;\mu} = 0$$

Using the product rule for covariant differentiation and the fact that $g^{\alpha\mu}_{\ ;\beta} = 0$, we obtain

$$(g^{\alpha\mu}R_{\alpha\beta\mu\nu})_{;\lambda} - (g^{\alpha\mu}R_{\alpha\beta\mu\lambda})_{;\nu} + (g^{\alpha\mu}R_{\alpha\beta\nu\lambda})_{;\mu} = 0$$

This further simplifies to

$$R_{\beta\nu;\lambda} - R_{\beta\lambda;\nu} + R^{\mu}_{\ \beta\nu\lambda;\mu} = 0$$

We can further contract this equation by multiplying by $g^{\beta\nu}$, using the product rule and the fact that $g^{\alpha\mu}_{\ ;\beta} = 0$, to obtain (after contracting the first two terms and writing the third in terms of the fully covariant form of the Riemann Christoffel tensor)

$$R_{;\lambda} - R^{\nu}_{\lambda;\nu} + g^{\beta\nu}g^{\alpha\mu}R_{\alpha\beta\nu\lambda;\mu} = 0$$

Using the fact that

$$R_{\alpha\beta\nu\lambda} = -R_{\beta\alpha\nu\lambda}$$

the third term on the left hand side can therefore be re-written as

$$g^{\beta\nu}g^{\alpha\mu}R_{\alpha\beta\nu\lambda;\mu} = -(g^{\beta\nu}g^{\alpha\mu}R_{\beta\alpha\nu\lambda})_{;\mu} = -(g^{\alpha\mu}R_{\alpha\lambda})_{;\mu} = -R^{\mu}_{\ \lambda;\mu} \equiv -R^{\nu}_{\ \lambda;\nu}$$

Thus, we have

$$R_{;\lambda} - 2R^{\nu}_{\ \lambda;\nu} = 0$$

Multiplying each term by $-\frac{1}{2}g^{\mu\lambda}$ we obtain

$$g^{\mu\lambda}R^{\nu}_{\ \lambda;\nu} - \frac{1}{2}g^{\mu\lambda}R_{;\lambda} = 0$$

Once again using the product rule and the fact that the first covariant derivatives of the metric vanish this yields

$$(g^{\mu\lambda}R^{\nu}{}_{\lambda})_{;\nu} - (\frac{1}{2}g^{\mu\nu}R)_{;\nu} = 0$$

which of course is equivalent to

$$G^{\mu\nu}_{\ ;\nu} = 0$$

Appendix 2: The Schwarzschild solution

The Schwarzschild metric is a solution of Einstein's equations which describes the space-time exterior to a spherically symmetric, static mass, M.

A2.1: Derivation of the Schwarzschild metric

In most astrophysical situations, we can work with the metric tensor in **orthogonal** form. This means that one can identify a coordinate system in which the components, $g_{\alpha\beta}$, of the metric tensor satisfy

$$g_{\alpha\beta} = 0 \quad \text{for all } \alpha \neq \beta$$

We will derive the Schwarzschild metric in orthogonal form, so we begin by stating some general results which are valid for orthogonal metrics.

We can show that the Christoffel symbols take a simple form for an orthogonal metric

$$\begin{aligned}
\Gamma^{\lambda}_{\mu\nu} &= 0 \quad \text{for } \lambda,\ \mu,\ \nu \text{ all different} \\
\Gamma^{\lambda}_{\lambda\mu} &= \Gamma^{\lambda}_{\mu\lambda} = g_{\lambda\lambda,\mu}/2g_{\lambda\lambda} \\
\Gamma^{\lambda}_{\mu\mu} &= -g_{\mu\mu,\lambda}/2g_{\lambda\lambda} \\
\Gamma^{\lambda}_{\lambda\lambda} &= g_{\lambda\lambda,\lambda}/2g_{\lambda\lambda}
\end{aligned}$$

(Note: the summation convention does not apply in these equations).

For affine parameter, p, the geodesic equation can be re-written for an orthogonal metric in the form

$$\frac{d}{dp}\left(g_{\lambda\lambda}\frac{dx^\lambda}{dp}\right) - \frac{1}{2}\frac{\partial g_{\mu\mu}}{\partial x^\lambda}\left(\frac{dx^\mu}{dp}\right)^2 = 0$$

The Schwarzschild solution is also an example of a spherically symmetric static spacetime (which we henceforth refer to as S^4 for short). We can show that the interval for S^4 takes the general form

$$ds^2 = -e^\nu dt^2 + e^\lambda dr^2 + r^2\left(d\theta^2 + \sin^2\theta\, d\phi^2\right)$$

which, of course, has an orthogonal metric. Note that we have introduced the functions $\nu(r)$ and $\lambda(r)$ in place of g_{tt} and g_{rr}. Since the exponential function is strictly positive for all r, this replacement is legitimate provided that $g_{tt} < 0$ and $g_{rr} > 0$ for all points in our spacetime.

The Christoffel symbols for S^4 are given by

$$\begin{aligned}
\Gamma^t_{rt} = \Gamma^t_{tr} &= \tfrac{1}{2}\nu' & \Gamma^\theta_{r\theta} = \Gamma^\theta_{\theta r} &= \tfrac{1}{r}\\
\Gamma^r_{tt} &= \tfrac{1}{2}\nu' e^{\nu-\lambda} & \Gamma^\theta_{\phi\phi} &= -\sin\theta\cos\theta\\
\Gamma^r_{rr} &= \tfrac{1}{2}\lambda' & \Gamma^\phi_{r\phi} = \Gamma^\phi_{\phi r} &= \tfrac{1}{r}\\
\Gamma^r_{\theta\theta} &= -re^{-\lambda} & \Gamma^\phi_{\theta\phi} = \Gamma^\phi_{\phi\theta} &= \cot\theta\\
\Gamma^r_{\phi\phi} &= -re^{-\lambda}\sin^2\theta
\end{aligned}$$

All others zero

Further, we can write the Ricci tensor for S^4 as

$$R_{\lambda\nu} = \Gamma^\tau_{\lambda\nu}\Gamma^\sigma_{\tau\sigma} - \Gamma^\tau_{\lambda\sigma}\Gamma^\sigma_{\tau\nu} + \Gamma^\sigma_{\lambda\nu,\sigma} - \Gamma^\sigma_{\lambda\sigma,\nu}$$

i.e.

$$R_{tt} = \frac{1}{2}e^{\nu-\lambda}\left(\nu'' + \frac{1}{2}\nu'^2 - \frac{1}{2}\nu'\lambda' + \frac{2}{r}\nu'\right)$$

$$R_{rr} = -\frac{1}{2}\left(\nu'' + \frac{1}{2}\nu'^2 - \frac{1}{2}\nu'\lambda' - \frac{2}{r}\lambda'\right)$$

$$R_{\theta\theta} = 1 - e^{-\lambda}\left[1 + \frac{r}{2}\left(\nu' - \lambda'\right)\right]$$

$$R_{\phi\phi} = R_{\theta\theta}\sin^2\theta$$

and all other terms of the Ricci tensor are identically zero.

We are now in a position to derive the **Schwarzschild solution**. If the star is in an isolated region of space, then we can assume that all components of the Ricci tensor exterior to the star are identically zero. Thus

$$e^{\lambda-\nu}R_{tt} + R_{rr} = \frac{\nu' + \lambda'}{r} = 0$$

which in turn implies that

$$\nu + \lambda = \text{constant}$$

At large distances from the star we want the Schwarzschild metric to reduce to SR. Thus, as

$$r \to \infty \ , \quad \nu \to 0 \quad \text{and} \quad \lambda \to 0$$

which implies that

$$\nu + \lambda = 0$$

so that

$$e^{\nu} = e^{-\lambda}$$

This allows us to eliminate ν, giving

$$e^{-\lambda}\left(1 - \lambda' r\right) = 1$$

i.e.

$$\frac{d}{dr}\left(re^{-\lambda}\right) = 1$$

which we can integrate to give

$$e^{\nu} = e^{-\lambda} = 1 + \frac{\alpha}{r}$$

where α is a constant.

To evaluate α, suppose we release a material 'test' particle from rest. Thus, initially

$$\frac{dx^j}{d\tau} = 0 \quad \text{for } j = 1, 2, 3$$

where τ is **proper time**, and

$$\frac{dx^0}{d\tau} \equiv \frac{dt}{d\tau} \neq 0$$

Using the fact that

$$g_{\alpha\beta}\frac{dx^\alpha}{d\tau}\frac{dx^\beta}{d\tau} = -1$$

and after some reduction we see that

$$\frac{dt}{d\tau} = e^{-\nu/2}$$

We now make use of the geodesic differential equation for radial coordinate, r. At the instant when the particle is released this reduces to

$$\frac{d^2r}{d\tau^2} + \Gamma^r_{tt}\left(\frac{dt}{d\tau}\right)^2 = 0$$

After some further substitution we obtain finally

$$\frac{d^2r}{d\tau^2} = \frac{\alpha}{2r^2}$$

In the limit of a weak gravitational field this result must reduce to the prediction of Newtonian gravity, which is

$$\frac{d^2r}{dt^2} = -\frac{GM}{r^2}$$

where M is the mass of the star. If we adopt convenient units such that the gravitational constant, $G = 1$, this means that

$$\alpha = -2M$$

Finally, then, we can write down the invariant interval for the Schwarzschild metric

$$ds^2 = -\left(1 - \frac{2M}{r}\right)dt^2 + \frac{dr^2}{\left(1 - \frac{2M}{r}\right)} + r^2 d\theta^2 + r^2\sin^2\theta d\phi^2$$

A2.2: Geodesics for the Schwarzschild metric

The geodesics for a material 'test' particle in the Schwarzschild metric satisfy, with the proper time, τ, as affine parameter:

$$\frac{d}{d\tau}\left(g_{\lambda\nu}\frac{dx^\nu}{d\tau}\right) - \frac{1}{2}\frac{\partial g_{\mu\nu}}{\partial x^\lambda}\frac{dx^\mu}{d\tau}\frac{dx^\nu}{d\tau} = 0$$

Notice that the Schwarzschild metric coefficients are independent of both t and ϕ; hence if we set $\lambda = 0$ and $\lambda = 3$ then the second term on the left hand side of the geodesic equation vanishes. Given also that the Schwarzschild metric is *orthogonal*, it follows that

$$\frac{d}{d\tau}\left(g_{tt}\frac{dt}{d\tau}\right) = \frac{d}{d\tau}\left(g_{\phi\phi}\frac{d\phi}{d\tau}\right) = 0$$

Integrating this gives us

$$g_{tt}\frac{dt}{d\tau} = \text{ constant}$$

and

$$g_{\phi\phi}\frac{d\phi}{d\tau} = \text{ constant}$$

The geodesic equation for θ (i.e. $\lambda = 2$) is then

$$\frac{d}{d\tau}\left(r^2\frac{d\theta}{d\tau}\right) - \frac{1}{2}\frac{\partial}{\partial\theta}\left(r^2\sin^2\theta\right)\left[\frac{d\phi}{d\tau}\right]^2 = 0$$

which reduces to

$$r^2\frac{d^2\theta}{d\tau^2} + 2r\frac{dr}{d\tau}\frac{d\theta}{d\tau} - r^2\sin\theta\cos\theta\left(\frac{d\phi}{d\tau}\right)^2 = 0$$

This equation has a particular solution $\theta = \pi/2$; adopting this solution is equivalent to choosing the plane of the orbit of our material particle (e.g. a planet) to lie in the equatorial plane of our coordinate system. Making use of $\theta = \pi/2$ to simplify our solution, it follows that

$$\frac{dt}{d\tau} = \frac{k}{1 - \frac{2M}{r}}$$

and

$$\frac{d\phi}{d\tau} = \frac{h}{r^2}$$

where h and k are constants.

We can now obtain the geodesic differential equation for r, using

$$-1 = g_{tt}\left(\frac{dt}{d\tau}\right)^2 + g_{rr}\left(\frac{dr}{d\tau}\right)^2 + g_{\phi\phi}\left(\frac{d\phi}{d\tau}\right)^2$$

which in turn reduces to

$$\left(\frac{dr}{d\tau}\right)^2 = k^2 - 1 - \frac{h^2}{r^2} + \frac{2M}{r}\left(1 + \frac{h^2}{r^2}\right)$$

A2.3: The advance of pericentre in GR

Changing the dependent variable from r to u and the independent variable from τ to ϕ, our radial geodesic equation reduces to

$$h^2\left(\frac{du}{d\phi}\right)^2 = \left(k^2-1\right) - h^2u^2 + 2Mu\left(1+h^2u^2\right)$$

Differentiating, and cancelling the common factor of $\mathrm{d}u/\mathrm{d}\phi$ gives

$$\frac{d^2u}{d\phi^2} = -u + \frac{M}{h^2} + 3Mu^2$$

The effect of GR is to add the extra term $3Mu^2$ on the right hand side. For typical planetary orbits in the Solar System this extra term is tiny compared with the second term; e.g. for the Earth's orbit the ratio

$$\frac{3Mu^2}{M/h^2} \simeq 3\times 10^{-8}$$

Hence, because the extra GR term is very small anyway, we can obtain a very good approximation to the solution by replacing u in the u^2 term on the right hand side by the solution to the *Newtonian* version of this equation. Doing this we obtain

$$\frac{d^2u}{d\phi^2} = -u + \frac{M}{h^2} + 3\frac{M^3}{h^4}\left(1+2e\cos\phi+e^2\cos^2\phi\right)$$

We can write u as the sum of a 'Newtonian' and 'GR' part, so that u_{GR} describes the correction to the Newtonian orbit. Subtracting off the Newtonian solution gives

$$\frac{d^2u_{\mathrm{GR}}}{d\phi^2} = -u_{\mathrm{GR}} + 3\frac{M^3}{h^4}\left(1+2e\cos\phi+e^2\cos^2\phi\right)$$

which we can rewrite as

$$\frac{d^2u_{\mathrm{GR}}}{d\phi^2} + u_{\mathrm{GR}} = 3\frac{M^3}{h^4}\left(1+\frac{e^2}{2}+2e\cos\phi+\frac{e^2}{2}\cos 2\phi\right)$$

The right hand side of this equation takes the form $A + B\cos\phi + C\cos 2\phi$, where A, B and C are constants. It is easy to verify that particular integrals for each of these terms are, respectively

$$u_{\mathrm{GR}} = A$$

$$u_{\rm GR} = \frac{1}{2} B\phi \sin\phi$$
$$u_{\rm GR} = -\frac{1}{3} C \cos 2\phi$$

and the correction to the Newtonian orbit is given by the sum of these three particular integrals. Since each of the constants, A, B and C is of order the tiny constant M^3/h^4, we see that the first and third terms add to the Newtonian solution respectively a completely negligible constant and an equally negligible constant plus a tiny "wiggle".

The second term, on the other hand, is of a different form. Although the constant, B, is negligibly small, the presence of the ϕ means that this term produces a continually increasing – and thus ultimately non-negligible – effect. In fact

$$u = \frac{M}{h^2}\left(1 + e\cos\phi + \frac{3M^2}{h^2} e\phi \sin\phi\right)$$

Now, given that $3M^2/h^2$ is very small, and then using the approximations $\cos\beta \simeq 1$ and $\sin\beta \simeq \beta$ for small angle β, and the cosine addition formula, we can re-cast this last equation as

$$u = \frac{M}{h^2}\left[1 + e\cos\left(1 - \frac{3M^2}{h^2}\right)\phi\right]$$

Comparing this solution with its Newtonian analogue, we see that again the solution is elliptical in form and that u (and hence r) is a periodic function of ϕ. Notice, however, that the period, P, is given by

$$P = \frac{2\pi}{1 - 3M^2/h^2} > 2\pi$$

This means that the values of r trace out an approximate ellipse, but do not begin to repeat until *after* the radius vector has made a complete revolution. In other words the orbit can be regarded as an ellipse that 'precesses', so that the pericentre line advances each orbit by an amount, Δ, given by

$$\Delta = 2\pi\left(1 - \frac{3M^2}{h^2}\right)^{-1} - 2\pi \simeq \frac{6\pi M^2}{h^2} = \frac{6\pi M}{a(1-e^2)}$$

If we apply this equation to the orbit of Mercury, we obtain a perihelion advance which builds up to about 43 seconds of arc per century.

A2.4: Gravitational light deflection in GR

The geodesics for a photon in the Schwarzschild metric may be derived in a similar manner to Appendix 2.2, but we now must introduce a new affine parameter, λ (say), since the proper time for a photon is zero.[5]

For the 't' and 'ϕ' geodesic equations it is straightforward to see that we again obtain equations of the form

$$\frac{dt}{d\lambda} = \frac{k}{1-2M/r}$$
$$\frac{d\phi}{d\lambda} = \frac{h}{r^2}$$

since, for the 'θ' equation, we can again spot the particular solution $\theta = \pi/2$. It obviously then also follows that

$$\frac{d\theta}{d\lambda} = 0$$

We can then obtain

$$\left(\frac{dr}{d\lambda}\right)^2 = k^2 - \frac{h^2}{r^2} + \frac{2Mh^2}{r^3}$$

We now proceed as in Appendix 2.3, replacing the dependent variable, r by $u = 1/r$, and the independent variable λ by ϕ. This leads to

$$\frac{d^2u}{d\phi^2} + u = 3Mu^2$$

If we ignore the term on the right hand side we can see that a particular integral is

$$u = \frac{\cos\phi}{r_{\min}}$$

Following the same approach as in Appendix 2.3, we can obtain a very good approximation to the solution by replacing u on the right hand side by the solution to the corresponding Newtonian equation[6]. This gives the equation

$$\frac{d^2u}{d\phi^2} + u = \frac{3M}{r_{\min}^2}\cos^2\phi = \frac{3M}{2r_{\min}^2}\left(1+\cos 2\phi\right)$$

[5] In fact, the initial choice of affine parameter will not be important, since we will determine the trajectory of the photon with the coordinate ϕ as the independent variable

[6] If we regard photons (as, indeed, modern physics holds true) as particles with zero rest mass, then formally they should be 'immune' to Newton's gravitational force. If, on the other hand, we regard photons as having a negligible but non-zero mass then – even within a purely Newtonian

It is straightforward to verify that a particular integral of this approximation is

$$u = \frac{3M}{2r_{\rm min}^2}\left(1 - \frac{1}{3}\cos 2\phi\right)$$

from which it follows that the general solution is

$$u = \frac{\cos\phi}{r_{\rm min}} + \frac{3M}{2r_{\rm min}^2}\left(1 - \frac{1}{3}\cos 2\phi\right)$$

We can rewrite this, for e.g. the outgoing photon trajectory, as

$$u = \frac{\cos\left(\frac{\pi}{2} + \frac{\Delta\phi}{2}\right)}{r_{\rm min}} + \frac{3M}{2r_{\rm min}^2}\left[1 - \frac{1}{3}\cos\left(\pi + \Delta\phi\right)\right]$$

or

$$u = -\frac{\sin(\Delta\phi/2)}{r_{\rm min}} + \frac{3M}{2r_{\rm min}^2}\left[1 + \frac{1}{3}\cos\Delta\phi\right]$$

which further simplifies, since $\Delta\phi << 1$, to

$$u = -\frac{\Delta\phi}{2r_{\rm min}} + \frac{2M}{r_{\rm min}^2}$$

Setting $u = 0$ (i.e. $r \to \infty$) this finally gives us the General Relativistic result

$$\Delta\phi = \frac{4M}{r_{\rm min}} \equiv \frac{4GM}{c^2 r_{\rm min}} = \frac{2R_{\rm S}}{r_{\rm min}}$$

This is exactly twice the deflection angle predicted by a Newtonian treatment. If we take $r_{\rm min}$ to be the radius of the Sun (which would correspond to a light ray grazing the limb of the Sun from a background star observed during a total solar eclipse) then we find that

$$\Delta\phi = \frac{4 \times 1.5 \times 10^3}{6.95 \times 10^8} = 8.62 \times 10^{-6} \text{ radians} \quad = \quad 1.77 \text{ arcsec}$$

framework – we can calculate the predicted deflection angle as light passes close to a massive object. In fact, this calculation was first carried out in 1801 by Söldner. This is the Newtonian solution we are referring to here.

Appendix 3: Einstein's tensor in the weak field approximation

A3.1: The linearised Riemann Christoffel tensor

In Minkowski spacetime the Christoffel symbols are all identically zero. This reduces the Riemann Christoffel tensor to

$$R_{\alpha\beta\gamma\delta} \;=\; g_{\alpha\mu}\, R^{\mu}_{\beta\gamma\delta} \;=\; g_{\alpha\mu}\Gamma^{\mu}_{\beta\delta,\gamma} \;-\; g_{\alpha\mu}\Gamma^{\mu}_{\beta\gamma,\delta}$$

Substituting for the Christoffel symbols in terms of the metric and its derivatives

$$R_{\alpha\beta\gamma\delta} \;=\; g_{\alpha\mu}\,\frac{g^{\mu\sigma}}{2}(g_{\sigma\beta,\delta\gamma}+g_{\sigma\delta,\beta\gamma}-g_{\beta\delta,\sigma\gamma}) \;-\; g_{\alpha\mu}\,\frac{g^{\mu\sigma}}{2}(g_{\sigma\beta,\gamma\delta}+g_{\sigma\gamma,\beta\delta}-g_{\beta\gamma,\sigma\delta})$$

This reduces to

$$R_{\alpha\beta\gamma\delta} \;=\; \frac{1}{2}(g_{\alpha\delta,\beta\gamma}+g_{\beta\gamma,\alpha\delta}-g_{\alpha\gamma,\beta\delta}-g_{\beta\delta,\alpha\gamma})$$

If $g_{\alpha\beta}=\eta_{\alpha\beta}+h_{\alpha\beta}$ then

$$R_{\alpha\beta\gamma\delta} \;=\; \frac{1}{2}(h_{\alpha\delta,\beta\gamma}+h_{\beta\gamma,\alpha\delta}-h_{\alpha\gamma,\beta\delta}-h_{\beta\delta,\alpha\gamma})$$

A3.2: The linearised Ricci tensor and curvature scalar

Contracting the Riemann Christoffel tensor it then follows that

$$R_{\mu\nu}=R^{\sigma}_{\mu\sigma\nu}=\Gamma^{\sigma}_{\mu\nu,\sigma}-\Gamma^{\sigma}_{\mu\sigma,\nu}$$

To first order this reduces to

$$R_{\mu\nu}=\frac{1}{2}\eta^{\sigma\alpha}(h_{\alpha\nu,\mu\sigma}+h_{\mu\sigma,\alpha\nu}-h_{\mu\nu,\alpha\sigma}-h_{\alpha\sigma,\mu\nu})$$

Since the partial derivatives of $\eta^{\sigma\alpha}$ are zero, we can write this as

$$R_{\mu\nu}=\frac{1}{2}\left[(\eta^{\sigma\alpha}\,h_{\alpha\nu})_{,\mu\sigma}+(\eta^{\sigma\alpha}\,h_{\mu\sigma})_{,\alpha\nu}-\eta^{\sigma\alpha}h_{\mu\nu,\alpha}{}_{,\sigma}-(\eta^{\sigma\alpha}\,h_{\alpha\sigma})_{,\mu\nu}\right]$$

which further reduces to

$$R_{\mu\nu}=\frac{1}{2}\left[(h^{\sigma}_{\nu})_{,\mu\sigma}+\left(h^{\alpha}_{\mu}\right)_{,\nu\alpha}-h_{\mu\nu,\alpha}{}^{,\alpha}-h_{,\mu\nu}\right]$$

Thus the curvature scalar R is given by

$$R=\eta^{\alpha\beta}R_{\alpha\beta}=\frac{1}{2}\eta^{\alpha\beta}\left[\left(h^{\sigma}_{\beta}\right)_{,\alpha\sigma}+(h^{\sigma}_{\alpha})_{,\beta\sigma}-h_{\alpha\beta,\sigma}{}^{,\sigma}-h_{,\alpha\beta}\right]$$

A3.3: The linearised Einstein tensor

Combining our results for the Ricci tensor and curvature scalar we find

$$\begin{aligned} G_{\mu\nu} &= \frac{1}{2}\left[(h^{\sigma}_{\nu})_{,\mu\sigma} + \left(h^{\alpha}_{\mu}\right)_{,\nu\alpha} - h_{\mu\nu,\alpha}{}^{,\alpha} - h_{,\mu\nu}\right] \\ &\quad -\frac{1}{4}\eta_{\mu\nu}\,\eta^{\alpha\beta}\left[\left(h^{\sigma}_{\beta}\right)_{,\alpha\sigma} + (h^{\sigma}_{\alpha})_{,\beta\sigma} - h_{\alpha\beta,\sigma}{}^{,\sigma} - h_{,\alpha\beta}\right] \end{aligned}$$

To see that this expression reduces to equation (108) of Section 6.3.2 it is easiest to work backwards from that equation. We have, from equation (108)

$$\begin{aligned} \text{LHS} &= \frac{1}{2}\left[h_{\mu\alpha,\nu}{}^{,\alpha} + h_{\nu\alpha,\mu}{}^{,\alpha} - h_{\mu\nu,\alpha}{}^{,\alpha} - h_{,\mu\nu} - \eta_{\mu\nu}\left(h_{\alpha\beta}{}^{,\alpha\beta} - h_{,\beta}{}^{,\beta}\right)\right] \\ &= \frac{1}{2}\left[\eta^{\alpha\sigma}\,h_{\mu\alpha,\nu\sigma} + \eta^{\alpha\sigma}\,h_{\nu\alpha,\mu\sigma} - \eta^{\alpha\sigma}\,h_{\mu\nu,\alpha\sigma} - h_{,\mu\nu} - \eta_{\mu\nu}\eta^{\alpha\gamma}\eta^{\beta\sigma}\,h_{\alpha\beta,\gamma\sigma} + \eta_{\mu\nu}\eta^{\beta\alpha}\,h_{,\beta\alpha}\right] \\ &= \frac{1}{2}\left[(\eta^{\alpha\sigma}h_{\mu\alpha})_{,\nu\sigma} + (\eta^{\alpha\sigma}h_{\nu\alpha})_{,\mu\sigma} - h_{\mu\nu,\sigma}{}^{,\sigma} - h_{,\mu\nu} - \eta_{\mu\nu}\eta^{\alpha\gamma}\left(\eta^{\beta\sigma}h_{\alpha\beta}\right)_{,\gamma\sigma} + \eta_{\mu\nu}\eta^{\alpha\beta}h_{,\alpha\beta}\right] \\ &= \frac{1}{2}\left[(h^{\sigma}_{\nu})_{,\mu\sigma} + \left(h^{\sigma}_{\mu}\right)_{,\nu\sigma} - h_{\mu\nu,\sigma}{}^{,\sigma} - h_{,\mu\nu} - \eta_{\mu\nu}\eta^{\alpha\gamma}\,(h^{\sigma}_{\alpha})_{,\gamma\sigma} + \eta_{\mu\nu}\eta^{\alpha\beta}h_{,\alpha\beta}\right] \end{aligned}$$

The first four bracketed terms match the first four terms in the expression for the Einstein tensor given above. If we now consider the remaining four terms in the above expression for the Einstein tensor, then since $\eta^{\alpha\beta} = \eta^{\beta\alpha}$

$$-\frac{1}{4}\eta_{\mu\nu}\eta^{\alpha\beta}\left[\left(h^{\sigma}_{\beta}\right)_{,\alpha\sigma} + (h^{\sigma}_{\alpha})_{,\beta\sigma}\right] = -\frac{1}{2}\eta_{\mu\nu}\eta^{\alpha\beta}\,(h^{\sigma}_{\alpha})_{,\beta\sigma}$$

Also

$$\begin{aligned} \frac{1}{4}\eta_{\mu\nu}\eta^{\alpha\beta}\left[h_{\alpha\beta,\sigma}{}^{,\sigma} + h_{,\alpha\beta}\right] &= \frac{1}{4}\eta_{\mu\nu}\eta^{\alpha\beta}\left[\eta^{\sigma\gamma}h_{\alpha\beta,\sigma\gamma} + h_{,\alpha\beta}\right] \\ &= \frac{1}{4}\eta_{\mu\nu}\eta^{\sigma\gamma}\left(\eta^{\alpha\beta}h_{\alpha\beta}\right)_{,\sigma\gamma} + \frac{1}{4}\eta_{\mu\nu}\eta^{\alpha\beta}h_{,\alpha\beta} \\ &= \frac{1}{2}\eta_{\mu\nu}\eta^{\alpha\beta}h_{,\alpha\beta} \end{aligned}$$

Thus, apart from some permutation of repeated indices, we see that the remaining four terms of our expression for the Einstein tensor match exactly the final two terms of equation (108). This establishes that equation (108) is indeed the correct expression for $G_{\mu\nu}$.

A3.4: Linearised Einstein tensor in barred form

Equation (110) is also easiest to establish in reverse – i.e. we start with equation (110) and show that its terms can be rewritten in a manner that reduces to equation (108). Consider in turn each of the four bracketed terms on the right hand side of equation (110).

$$\overline{h}_{\mu\nu,\alpha}{}^{,\alpha} \;=\; \eta^{\alpha\sigma}\overline{h}_{\mu\nu,\alpha\sigma} \;=\; \eta^{\alpha\sigma}\left[h_{\mu\nu,\alpha\sigma} - \frac{1}{2}\eta_{\nu\mu}\,h_{,\alpha\sigma}\right]$$

$$\eta_{\mu\nu}\,\overline{h}_{\alpha\beta}{}^{,\alpha\beta} \;=\; \eta_{\mu\nu}\,\eta^{\alpha\sigma}\,\eta^{\beta\sigma}\,\overline{h}_{\alpha\beta,\gamma\sigma} \;=\; \eta_{\mu\nu}\,\eta^{\alpha\sigma}\,\eta^{\beta\sigma}\left[h_{\alpha\beta,\gamma\sigma} - \frac{1}{2}\eta_{\alpha\beta}\,h_{,\gamma\sigma}\right]$$

$$\overline{h}_{\mu\alpha,\nu}{}^{,\alpha} \;=\; \eta^{\alpha\sigma}\,\overline{h}_{\mu\alpha,\nu\sigma} \;=\eta^{\alpha\sigma}\left[h_{\mu\alpha,\nu\sigma} - \frac{1}{2}\eta_{\mu\alpha}\,h_{,\nu\sigma}\right]$$

$$\overline{h}_{\nu\alpha,\mu}{}^{,\alpha} \;=\; \eta^{\alpha\sigma}\,\overline{h}_{\nu\alpha,\mu\sigma} \;=\eta^{\alpha\sigma}\left[h_{\nu\alpha,\mu\sigma} - \frac{1}{2}\eta_{\nu\alpha}\,h_{,\mu\sigma}\right]$$

Hence we can write equation (110) as

$$\begin{aligned}
G_{\mu\nu} \;=\;& -\frac{1}{2}\eta^{\alpha\sigma}\,h_{\mu\nu,\alpha\sigma} + \frac{1}{4}\eta^{\alpha\sigma}\,\eta_{\mu\nu}\,h_{,\alpha\sigma} \\
& -\frac{1}{2}\eta_{\mu\nu}\,\eta^{\alpha\gamma}\,\eta^{\beta\sigma}\,h_{\alpha\beta,\gamma\sigma} \;+\; \frac{1}{4}\eta_{\mu\nu}\,\eta^{\alpha\gamma}\,\eta^{\beta\sigma}\,\eta\alpha\beta\,h_{,\gamma\sigma} \\
& +\frac{1}{2}\eta^{\alpha\sigma}\,h_{\mu\alpha,\nu\sigma} \;-\; \frac{1}{4}\eta^{\alpha\sigma}\,\eta_{\mu\alpha}\,h_{,\nu\sigma} \\
& +\frac{1}{2}\eta^{\alpha\sigma}\,h_{\nu\alpha,\mu\sigma} \;-\; \frac{1}{4}\eta^{\alpha\sigma}\,\eta_{\nu\alpha}\,h_{,\mu\sigma} \\
\\
=\;& -\frac{1}{2}\eta^{\alpha\sigma}\,h_{\mu\nu,\alpha\sigma} \;-\; \frac{1}{2}\eta_{\mu\nu}\,\eta^{\alpha\gamma}\,\eta^{\beta\sigma}\,h_{\alpha\beta,\gamma\sigma} \;+\; \frac{1}{2}\eta^{\alpha\sigma}\,h_{\mu\alpha,\nu\sigma} \\
& +\frac{1}{2}\eta^{\alpha\sigma}\,h_{\nu\alpha,\mu\sigma} \;+\; \frac{1}{2}\eta^{\alpha\sigma}\,\eta_{\mu\nu}\,h_{,\alpha\sigma} \;-\; \frac{1}{2}h_{,\mu\nu}
\end{aligned}$$

Comparing with our expression for $G_{\mu\nu}$ in Appendix A2.3, we see that – after changing some repeated indices and using the fact that the Minkowski metric is symmetric – the above expression is identical. This establishes that equation (110) is indeed the correct expression for the $G_{\mu\nu}$ in terms of $\overline{h}_{\mu\nu}$.

Appendix 4: The Lorentz Gauge Condition

First we show that, if $\overline{h}^{\mu\alpha}{}_{,\alpha} = 0$, the final three terms on the right hand side of equation (110) vanish. Consider the bracketed terms in turn

$$\begin{aligned}
\overline{h}_{\alpha\beta}{}^{,\alpha\beta} &= \left(\eta_{\alpha\gamma}\,\eta_{\beta\sigma}\,\overline{h}^{\gamma\sigma}\right)^{,\alpha\beta} \\
&= \left(\eta_{\alpha\gamma}\,\eta_{\beta\sigma}\,\eta^{\alpha\tau}\,\eta^{\beta\epsilon}\,\overline{h}^{\gamma\sigma}{}_{,\tau\epsilon}\right) \\
&= \delta^{\tau}_{\gamma}\,\delta^{\epsilon}_{\sigma}\,\overline{h}^{\gamma\sigma}{}_{,\tau\epsilon} \\
&= \overline{h}^{\gamma\sigma}{}_{,\gamma\sigma} \quad = \quad \left(\overline{h}^{\gamma\sigma}{}_{,\sigma}\right)_{,\gamma} \quad = \quad 0
\end{aligned}$$

$$\begin{aligned}
\overline{h}_{\mu\alpha,\nu}{}^{,\alpha} &= \eta_{\mu\gamma}\,\eta_{\alpha\sigma}\,\left(\overline{h}^{\gamma\sigma}{}_{,\nu}\right)^{,\alpha} \\
&= \eta_{\mu\gamma}\,\eta_{\alpha\sigma}\,\eta^{\alpha\tau}\,\overline{h}^{\gamma\sigma}{}_{,\nu\tau} \\
&= \eta_{\mu\gamma}\,\delta^{\tau}_{\sigma}\,\overline{h}^{\gamma\sigma}{}_{,\nu\tau} \\
&= \eta_{\mu\gamma}\,\overline{h}^{\gamma\sigma}{}_{,\nu\sigma} \quad = \quad \eta_{\mu\gamma}\left(\overline{h}^{\gamma\sigma}{}_{,\sigma}\right)_{,\nu} \quad = \quad 0
\end{aligned}$$

$$\begin{aligned}
\overline{h}_{\nu\alpha,\mu}{}^{,\alpha} &= \eta_{\nu\gamma}\,\eta_{\alpha\sigma}\,\left(\overline{h}^{\gamma\sigma}{}_{,\mu}\right)^{,\alpha} \\
&= \eta_{\nu\gamma}\,\eta_{\alpha\gamma}\,\eta^{\alpha\tau}\,\overline{h}^{\gamma\sigma}{}_{,\mu\tau} \\
&\quad \eta_{\nu\gamma}\,\delta^{\tau}_{\sigma}\,\overline{h}^{\gamma\sigma}{}_{,\mu\tau} \\
&\quad \eta_{\nu\gamma}\,\overline{h}^{\gamma\sigma}{}_{,\mu\sigma} \quad = \quad \eta_{\nu\gamma}\left(\overline{h}^{\gamma\sigma}{}_{,\sigma}\right)_{,\mu} \quad = \quad 0
\end{aligned}$$

So we see that the final three terms do indeed equal zero provided $\overline{h}^{\mu\alpha}{}_{,\alpha} = 0$.

Finally we establish the equation which must be solved in order that the Lorentz gauge condition $\overline{h}^{\mu\alpha}{}_{,\alpha} = 0$ is satisfied.

Suppose we begin with arbitrary metric perturbation components $h^{(\mathrm{old})}_{\mu\nu} \neq 0$. We define

$$h^{(\mathrm{LG})}_{\mu\nu} \;=\; h^{(\mathrm{old})}_{\mu\nu} \;-\; \xi_{\mu,\nu} \;-\; \xi_{\nu,\mu}$$

where the components ξ^μ are to be determined. We can also define

$$\begin{aligned}
\overline{h}^{(\mathrm{LG})}_{\mu\nu} &= h^{(\mathrm{LG})}_{\mu\nu} - \frac{1}{2}\eta_{\mu\nu}\,\eta^{\alpha\beta}\,h^{(\mathrm{LG})}_{\alpha\beta} \\
&= h^{(\mathrm{old})}_{\mu\nu} - \xi_{\mu,\nu} - \xi_{\nu,\mu} - \frac{1}{2}\eta_{\mu\nu}\left[\eta^{\alpha\beta}\left(h^{(\mathrm{old})}_{\alpha\beta} - \xi_{\alpha,\beta} - \xi_{\beta,\alpha}\right)\right] \\
&= h^{(\mathrm{old})}_{\mu\nu} - \frac{1}{2}\eta_{\mu\nu}h^{(\mathrm{old})} - \xi_{\mu,\nu} - \xi_{\nu,\mu} + \eta_{\mu\nu}\,\eta^{\alpha\beta}\,\xi_{\alpha,\beta} \\
&= \overline{h}^{(\mathrm{old})}_{\mu\nu} - \xi_{\mu,\nu} - \xi_{\nu,\mu} + \eta_{\mu\nu}\,\xi^{\beta}{}_{,\beta}
\end{aligned}$$

Now

$$\begin{aligned}
\overline{h}^{(\mathrm{LG})\,\mu\nu} &= \eta^{\mu\alpha}\,\eta^{\nu\beta}\left[\overline{h}^{(\mathrm{old})}_{\alpha\beta} - \xi_{\alpha,\beta} - \xi_{\beta,\alpha} + \eta_{\alpha\beta}\,\xi^{\sigma}{}_{,\sigma}\right] \\
&= \overline{h}^{(\mathrm{old})\,\mu\nu} - \eta^{\mu\alpha}\,\eta^{\nu\beta}\,\xi_{\alpha,\beta} - \eta^{\mu\alpha}\,\eta^{\nu\beta}\,\xi_{\beta,\alpha} + \eta^{\mu\nu}\,\xi^{\sigma}{}_{,\sigma}
\end{aligned}$$

And

$$\overline{h}^{(\mathrm{LG})\,\mu\nu}{}_{,\nu} = \overline{h}^{(\mathrm{old})\,\mu\nu}{}_{,\nu} - \eta^{\nu\beta}\,\xi^{\mu}{}_{,\beta\nu} - \eta^{\mu\alpha}\,\xi^{s}igma_{,\sigma\alpha} + \eta^{\mu\nu}\,\xi^{\sigma}{}_{,\sigma\nu}$$

i.e.

$$\overline{h}^{(\mathrm{LG})\,\mu\nu}{}_{,\nu} = \overline{h}^{(\mathrm{old})\,\mu\nu}{}_{,\nu} - \eta^{\nu\beta}\,\xi^{\mu}{}_{,\nu\beta}$$

So we can ensure that $\overline{h}^{(\mathrm{LG})\,\mu\nu}{}_{,\nu} = 0$ provided we can find gauge components ξ^μ satisfying

$$\overline{h}^{(\mathrm{old})\,\mu\nu}{}_{,\nu} = \eta^{\nu\beta}\,\xi^{\mu}{}_{,\nu\beta} = \left(-\frac{\partial^2}{\partial t^2} + \nabla^2\right)\xi^\mu$$

We can always solve this equation for well-behaved metrics using standard methods for finding particular solutions of second order partial differential equations.

Abstract: An analysis is accomplished of the input power requirement of High-Frequency Gravitational Wave (HFGW) generators. Several techniques are explored using both off-the-shelf and advanced-nanotechnology generator elements. It is concluded that proof-of-concept test, involving *N* off-the-shelf array elements could be of meter to kilometer length and require 25 MW or less power if array elements are in a staggered arrangement. The power and size of an operational nanotechnology HFGW generator or transmitter device can be greatly reduced by the focusing effect of N^2 radiator pairs. Utilization of conventional piezoelectric Film Bulk Acoustic Resonators (FBARs), tailored and scaled for HFGW generation, could provide the initial commercial generation means. The use of the new infrared-energized ring concept of Woods and the use of a double helix array proposed by Baker may even further reduce the power and size requirements of the device to <<20 W and mm in length and width.

Keywords: High-Frequency Gravitational Waves, HFGW, gravitational wave generator, laboratory GW generation

INTRODUCTION

It has been demonstrated theoretically that high frequency relic gravitational waves (HFRGWs) in the high-frequency band of 10 GHz exist having amplitudes on the order of 10^{-30} m/m and that may be detectable by the proposed ultra-high sensitivity Li-Baker Chinese HFGW detector (Li et al., 2008; Baker, Stephenson and Li , 2008). In particular, the recent papers by Leonard Grishchuk (1977a; 1977b; 2007 and Grishchuk and Soloklin, 1991), confirm that relic high-frequency gravitational waves or HFGWs certainly exist and that the origin of these HFGWs is the cosmic background associated with the big bang. The interested reader is invited to visit the site for the 2007 Invitational 2nd HFGW Workshop at: www.earthtech.org/hfgw2/ in order to view these papers. If such a detector has been built and satisfactorily tested by sensing HFRGWs, then the laboratory generation of High-Frequency Gravitational Waves (HFGWs) can be considered. The figure of merit for such gravitational wave (GW) generation (Baker, Stephenson and Li, 2008) is that the amplitude of the GW is proportional to the distance between gravitational-wave radiators (e. g., the orbital major axis of a binary black hole pair), the force change (e. g., the orbital centrifugal-force change), the GW frequency and the number of in-phase element pairs, *N*, involved in the system squared. (Romero and Dehnen, 1981; Dehnen and Romero, 2003, page 6, Eq. (2.24)). As an example, of low-frequency GW generation, for PSR 1913+16, the distance between the GW radiators (binary neutron stars on orbit) is $4.1\text{x}10^{9}$ m, the change in (centrifugal) force is $1.16\text{x}10^{33}$ N, the frequency is 7.2x10-5 s^{-1} or $7.2\text{x}10^{-5}$ Hz and, since there is but one element (one neutron-star pair), it is multiplied by unity. This yields a GW power of $10.1\text{x}10^{24}$ W (very close to the value as obtained using conventional relativistic analyses (Baker, 2000a)). If we assume that the orbital plane of the star pair is normal to the direction to the Earth and that PSR 1913+16 is $9.5\text{x}10^{15}$ m from the Earth, then the GW flux at the Earth is $2.26\text{x}10^{-8}$ Wm^{-2}. The coalescing binary black holes are much closer to each other of course; however their force changes are billions of times greater and their frequencies momentarily higher than PSR 1913+16. This yields larger GW fluxes that may be detected by the

advanced Laser Interferometer Gravitational Observatory (LIGO) and by the proposed Laser Interferometer Space Antenna. (LISA). In the laboratory the aforementioned gravitational force change could not even approach those of the celestial sources so alternative means need to be investigated thus one must turn to other means of GW generation. Analyses have shown (Baker, 2006) that only electromagnetic, rather than gravitational forces can be utilized in the laboratory and that HFGWs can be generated there. Interferometer-based GW detectors as LIGO and LISA are not sensitive to GW frequencies above at most 2 kHz and, therefore, are inadequate for HFGW detection.

LABORATORY GENERATION OF HFGWs OVERVIEW

A number of devices for the laboratory generation of HFGWs have been proposed including the GASER (a gravitational-wave LASER first proposed by Halpren and Laurent (1964), some 40 years ago) discussed by Giorgio Fontana (2003); as well as an actual LASER generator of HFGWs as discussed by Baker, Li and Li (2006). A rather practical laboratory HFGW generator is one utilizing off-the-shelf components such as magnetron energized piezoelectric crystals or Film Bulk Acoustic Resonators or FBARs (Woods and Baker, 2005; Baker, Woods and Li, 2006). Another, more exotic HFGW generator involves the use of nuclear forces (Fontana and Baker, 2006; Fontana and Binder, 2009). The figure of merit is given explicitly by Baker, Stephenson and Li (2008). This figure of merit can be extended by considering other effects. Since in the laboratory the force change could not even approach those of the celestial sources. it would seem that the magnitude of any laboratory generated GWs could be best increased (1) by utilizing electromagnetic forces rather than gravitational, (2) by increasing the distance between the gravitational radiators, (3) by increasing the GW frequency and especially (4) by developing a large number of in-phase system elements. This last effect enters as the square of the number of elements, N , as proved using General Relativity analyses by Dehnen and Romero–Borja's analyses (Romero and Dehnen, 1981; Dehnen and Romero, 2003). Such N^2 dependence also may be the key to successful laboratory generation of GWs, especially High-Frequency Gravitational Waves (HFGWs). In that regard, recent proposal by Woods (Woods and Baker, 2009; Baker and Black, 2009)) propose the use of infrared-energized atomic nuclei, electrons and or molecules, which have a very large N, contained in a stack of waveguide rings (Patents Pending). In what follows we will briefly consider several aspects of laboratory HFGW generation.

The distance between GW radiators may be proportional to the GW wavelength in that it may have a useful GW-generation limit that is less than or equal to a GW wavelength. The wavelength is inversely proportional to the GW frequency. Thus given some value for the proportional constant, say unity or the distance between radiators equal to one GW wavelength, the GW frequency cancels out. As already noted it is important to take advantage of square of the number of in phase elements for useful laboratory HFGW generation. If we slice the elements in one dimension (the dimension along the axis of HFGW generation) in order to increase the number of elements, then the change in force per element will be inversely proportional to the number of elements. For example, if the elements are sliced into one hundred separate pieces, then each piece will have one hundredth of the force of the un-sliced element. Essentially, "f = ma" and it is assumed that the acceleration of the element was the same after the split as before. This result also follows Eq. (8) of Baker, Stephenson and Li (2008a), and if there were 100 splits of an FBAR, then there would be one-hundredth the GW flux resulting from each, but 100 more of them so the net effect according to the N^2 rule would be $(100)^2/100$ or a one-hundred fold increase in HFGW flux The frequency of the split elements may be a higher value -- but the attendant increase in GW power (proportional to the square of the higher frequency) and the decrease in power due to a smaller distance between tracks (assuming that the distance between tracks is one GW wavelength, which would be smaller) would cancel and there would be no net effect on HFGW amplitude. It is concluded, therefore, that the amplitude of the generated HFGWs is proportional to the number of in phase elements, N (not the square). A large number of elements for a given HFGW-generator length can be best realized by reducing the size of the individual elements to submicroscopic size (as discussed in U. S. Patent Number 6,784,591 (Baker 2000b). Let us consider the 1.8×10^8 cell-phone film bulk acoustic resonators or FBARs, 10,000 Microwave-Magnetron, proof-of-concept laboratory HFGW generator. Assuming a 10 μm distance or margin between the 100 μm on a side conventional FBARs, the overall length of the laboratory generator will be 110×10^{-6}m x 1.8×10^8 elements = 19.8 km. The same result, of course, as that found by Baker, Stephenson and Li (2008). It will have a total HFGW power of 0.066 W and for a distance out from the last in-line, in-phase FBAR element of one HFGW wavelength (6.1 cm) it will have a flux of 3.53 Wm^{-2}, yielding a HFGW amplitude there of $A = 4.9 \times 10^{-28}$ m/m. This result differs from the result of Baker, Stephenson and Li

(2008), since they took the distance out as 1.5 HFGW wavelengths (9 cm) not one wavelength or 6.1 cm. Although the frequencies may be different one can extrapolate approximately from the results of Dehnen and Romero–Borja's (2003) analyses in which the angle of the needle-like radiation pattern is inversely proportional to the square root of the product of the distance between the radiators (the width between FBAR bands or tracks) and *N*. The distance for the system discussed here is 6.1 cm and for Dehnen and Romero–Borja's, 2003 system 0.00001 m, for a factor of 6,100 and *N* differs by $1.8x10^{8}/5x10^{7}= 3.6$ for a product of $2.2x10^{4}$ and the inverse of the square root is $6.7x10^{-3}$. Using the result from Dehnen and Romero (2003) (Eq. (4.51)) of a needle half angle of 1.7 degrees we would extrapolate to 0.0115 degrees or very approximately $2x10^{-4}$ radians.

Since we are no longer constrained to the use of rudimentary off-the-shelf components as we were for the proof-of-concept apparatus, we can manipulate the submicroscopic elements. First, we will stagger the FBARs into two bands or tracks of 100 rows each or 110x100μm = 1.1 cm wide bands of FBARs placed a wavelength or 6.1 cm apart. We will stagger the rows, as shown schematically in Fig. 1, by displacing adjacent rows in the bands by 1.1 μm. Thus the overall length will be reduced to 198 m. Second, we can slice the 100 μm length of each FBAR element, along the direction of travel of the HFGW build up, into one-hundred 1 μm wide slices (exhibiting 0.1 μm margins). The power of each of these small slices will be 10^{7} W (10,000 off-the-shelf kilowatt Magnetron energizers) with their power spread over $1.8x10^{8}x100$ FBAR slices or 0.56 mW for each slice. If we assume a 1 mA current, then the voltage across the 1 μm wide slices is 0.56 V for a 560,000 V/m field strength, which should not arc. The staggered row displacements are now reduced to 11 nm. The overall length will be reduced to about 198 cm. Concentrating the 10 MW power to each of these 1.1 cm wide bands may prove to be difficult. Thus, as an example, we will replace the continuous-wave Magnetrons by a pulsed microwave source having one-microsecond-long pulses one second apart. The required average power for each FBAR band will now be 10 W. As a practical nanotechnology limit, we could reduce the slice width by two orders of magnitude to 10 nm. This would also require that the row displacements would be 110 pm (we are now into atomic if not sub-atomic dimensional changes). The overall length could be reduced to about 2 cm or the amplitude of the HFGWs could be increased to $A = 4.9x10^{-26}$. In this latter case the average energizing microwave power applied to each band would need to be increased to 1 kW. A preferred compromise in this apparent nano-technology limit might be to reduce the HFGWs generator's length to about 20 cm and increase the HFGW amplitude A to $4x10^{-27}$ m/m.

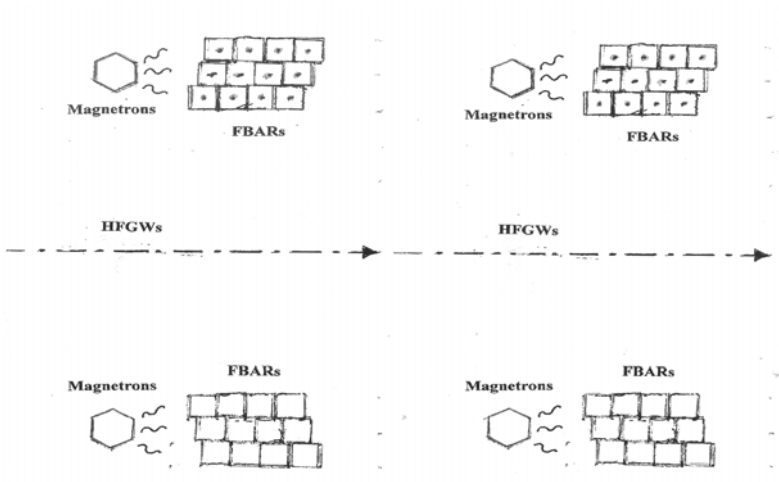

FIGURE 1. Illustration of the Parallel Staggered Tracks of FBARs

LABORATORY-GENERATION HFGW ELEMENT OVERVIEW

The complimentary approach to optimizing a practical HFGW generator is to increase the force produced by each element without increasing the required power, i.e., increasing element efficiency. This was initially done using

the modern light-weight piezoelectric FBARs rather than the heavy 10-gram crystals considered by Dehnen and Romero-Borja that were of 1981 vintage. Their paper on HFGW generation, utilizing conventional general-relativity analyses of a piezoelectric-crystal HFGW generator (Romero and Dehnen, 1981; Dehnen and Romero, 2003), agrees to within half a percent with the approach of Baker, Stephenson and Li (2008), as shown in Baker (2007). Special designs of FBAR-like elements for optimum force-generation efficiency will improve the HFGW generator performance beyond that for the usual cell-phone FBAR designs. Also staggered columns of split FBARs as discussed by Baker (2009) could be placed on double-helix ribbons (Baker and Black, 2009) with the Magnetron energizers conveniently situated on their axes. Another approach to element design is to utilize lasers whose targets are the force-generating elements. This HFGW generator means is initially presented in Baker, Li and Li (2006). Utilization of myriads of nano-scale lasers could generate high-frequency HFGW pulses.

The use of submicroscopic particles for HFGW generation was suggested by Baker (2000b) and was utilized as the basis of an infrared (IR) energized generator by Woods and Baker (2009). There is significant promise for the IR-generated HFGWs (Patents Pending). If you have a standing wave in a waveguide ring and excite it properly, then you have a GW source at its center. Please see Fig. 2 from Woods and Baker (2009). The easiest configuration to analyze requires that two counter-propagating traveling waves be excited inside this waveguide, thus producing a standing optical wave inside the guide. Regions of the guide separated by $\lambda/2$ will oscillate in anti-phase but the resultant HFGW will be in phase, since the produced GW is at doubled frequency. Therefore, this configuration is equivalent to the ring of discrete acoustic resonators (small masses) proposed previously by Woods and Baker (2005) for terrestrial HFGW production. Because the active material vibrates in phase and in opposite pairs and has circular symmetry, all the generated GW will combine in phase at the center of the torus. The GW flux produced at its center is proportional to the N submicroscopic particle pairs in the ring. There is no N^2 build up but there is a N build up. If you have a stack of n rings, which are excited in sequence at light speed as a generated, growing GW passes by, then you have a n^2 build up in GW flux. The IR wavelength is about 2.5×10^{-6}m and the IR waveguide has a cross-sectional area radius of $\lambda/4$ in order for it to be a monomode (lowest order mode) so that the phase doesn't change across the waveguide. Thus the cross-sectional area of each IR ring is $\pi\ (2.5\times10^{-6}\text{m}\ /4)^2 = 1.23\text{x}10^{-12}\text{m}^2$ and its diameter is 1.25×10^{-6} m. The volume of each 100-m radius toroidal ring is $2\pi\ (100)(\ 1.23\text{x}10^{-12}) = 7.7\text{x}10^{-12}\ \text{m}^3$. Woods and Baker (2009) divide the mass density of pentane by its molecular mass and that gives the density of jerkable masses = $6.3\times10^{28}\ \text{m}^{-3}$. Thus the number of masses in a 100-m radius circular wave guide $2N = (6.3\times10^{28})(\ 7.7\text{x}10^{-12}) = 4.85\text{x}10^{17}$ submicroscopic "particles" or potentially jerkable masses. According to Table 1 of Woods and Baker (2009) for pentane $P_i = 4.62\text{x}10^{-16}$ W. Thus the flux for all of the mass pairs in a single ring from Eq. (8) is $(1/2)(2N)(0.01146)\ P_i = 1.29\ \text{Wm}^{-2}$.

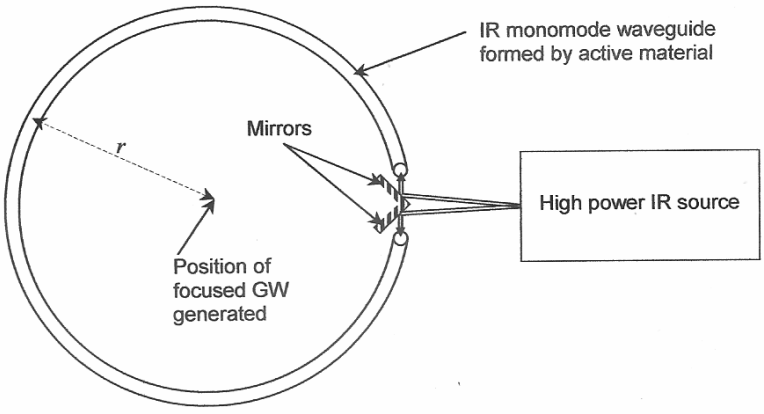

FIGURE 2. Circular Resonator Geometry Using Infra-Red Excitation.

Baker and Black (2009) reduce the ring radius to one meter, but set up 100 rings, concentrically (side by side in the same plane) with an average radius of the one meter. The reduced radius drops the P_i by $(100)^2$ to $4.62\text{x}10^{-20}$, but because of the 100 concentric rings the $N = 4.85\text{x}10^{17}/2$ remains the same. Thus the flux for a single "plate" of concentric rings is $1.29\text{x}10^{-4}\ \text{Wm}^{-2}$. We now stack some 10^6 of these plates on top of one another. Thus a 1.25-m high stack. In this case $n = 10^6$ and we can apply the n^2 law. Thus a HFGW total flux of $1.29\text{x}10^{8}\ \text{Wm}^{-2}$ will be

generated by the stack. Of course (as R. C. Woods has pointed out, Woods and Baker (2009)) we need to be careful how much power is fed to each ring. One possible arrangement is to feed the output of one ring to the input of the next. The problem here is that the source won't have a long enough coherence length, even if the attenuation of the IR doesn't kill the power after a ring or two. To avoid this, from one source the available energizing power, on the order of a MW but possibly reducible to less than 20 W, could be divided equally between all the rings and fed to them up the stack at the speed of light. Thus there is some uncertainty in the IR-ring generator and the FBAR generators would be the best for the proof-of-concept tests and the first practical applications. As computed by Baker and Black (2009) for the stack of rings, the amplitude of the laboratory-generated HFGWs is $A = 1.21 \times 10^{-28}$. Clearly there are a number of opportunities to enhance HFGW generation performance, utilizing special element designs, either by reducing the generator size or increasing the generated HFGW amplitude or both.

.

CONCLUSION

After proving out the Li-Baker detector on relic HFGWs, proof-of-concept tests (involving only off-the-shelf HFGW-array elements) can be accomplished with lengths on the order of 2 km depending upon placement of Magnetrons, FBARs and power lines. The length could be greatly reduced by a factor of 10 to 1000 (due to the N^2 effect for HFGW generated flux) if each track consisted of several close (110μm) parallel -multiple, staggered rows of off-the-shelf FBARs as shown schematically in Fig. 1. (Power proportional to N elements and beam area inversely proportional to N since the pencil beam is narrowed as N increases as shown in Baker and Black (2009)). Such a design would also allow for the power of the Magnetron beam (properly focused) to be more completely absorbed by the FBARs. The power requirement for the 20,000 off-the-shelf Magnetrons on the two linear tracks (not staggered) for the proof-of-concept tests would be about 25 MW, so that a power substation of that size would be required. Power and size of an operational nanotechnology HFGW generator or transmitter utilizing advanced FBARs can be greatly reduced by the focusing effect of N^2 radiator pairs. The use of the IR-rings concept of Woods and Baker (2009) may even further reduce the power and size requirements of the device as a future development. The use of nanotechnology could conceivably result in power and HFGW-generator size of less than 20 watts and only millimeters in length and width.

1 GRAVITATIONAL PLANE WAVES

1.1 Introduction to Gravitational Waves

By analogy to electromagnetism we expect that there should be gravitational waves – moving disturbances in the metric. These should have the following properties:
(a) Gravitational Waves should exist and travel with speed c which is the only Lorentz invariant velocity and is the relation between space and time.
(b) Every from of matter and energy with which we are familiar has the same gravitational effect – positive attraction. i.e. like having all one sign electric charge Thus no dipole radiation only quadrupole and higher order.
(c) Gravitational Waves are very weak. Consider two neutron stars of one solar mass ($M_{NS} = \mathrm{M}_\odot$) and radius $r_{NS} = 6$ km orbiting each other essentially in contact. (This is for example, clearly tidal forces will have a very disruptive effect on the two neutron stars.) The characteristic acceleration at the neutron stars is

$$a = \frac{2G\mathrm{M}_\odot}{(2r_{NS})^2} \simeq 9 \times 10^{11} m/s^2 \simeq 10^{11} g$$

The orbital period for half a rotation (symmetric pattern with identical neutron stars and thus the period of the graviational radiation) is $T/2 = 2\pi/\sqrt{r^3/G\mathrm{M}_\odot} \simeq 10^{-4}$ sec, so that the frequency of the gravitational radiation is about 10 kHz.

Consider a test mass at the Earth one parsec away (1 pc = 3.26 light years). This distance is the distance to the nearest known stars, excepting the Sun, and the test mass will be in the next section our detector. The acceleration $A_\oplus$ from the gravitaional radiation, i.e. proportional to $1/r$ rather than $1/r^2$, is

$$A = \frac{G\,(2m_\odot)\,a}{c^2 r} \simeq 0.09 m/s^2 \simeq 10^{-2} g$$

(d) Detection of gravitational waves is difficult. Consider a resonant frequency pendulum tuned to the gravitational waves. Using the formula for a gravitational pendulum $\omega = \sqrt{g/\ell}$, one finds that to get $f = 10^4$ Hz requires $\ell = 20\mathring{A}$. (24.8A)

However, the wavelength of the gravitational wave is $\lambda_{GW} = c/f \simeq 3x10^5 km/s/10^4/s = 30$ km. Thus a quarter-wavelength long detector would need to

be about 7.5 km. Thus the single pendulum is not a good match to the gravitational wave.

The velocity produced by the gravitational wave on the test mass on Earth is of order $V = A/\omega = A/(2\pi f) \simeq 3 \times 10^{-6}$ m/s. This is a very low velocity and difficult to dectect even with the Mössbauer effect. The amplitude of oscillation is $A/(2\pi f)^2 \simeq 0.5\mathring{A}$.

(e) The generation of gravitational waves is difficult. Just as it is difficult to detect gravitational waves; it is difficult to generate them. We will find that for astrophysical systems the dimensionaless strain h is roughly

$$h \sim \frac{r_{Schwarschild}}{r}\left(\frac{v}{c}\right)^2$$

The power in gravitational waves is proportional to the square of the internal power of the radiating object. The constant of proportionality is equivalent to dividing by a very large power.

$$P = \frac{P_{internal}^2}{P_{cGW}}, \quad \text{where} \quad P_{cGW} = \frac{c^5}{G} = 3.63 \ \times 10^{59}\text{erg/s} = 2 \times 10^5 \text{M}_\odot/s$$

1.2 Properties of Gravitational Waves

There are many similarities between gravitation and electromagnetism. In particular they have similar Poisson Equations relating the field to its sources. For electromagnetism

$$\Box^2 A^\nu = 4\pi J^\nu, \text{ where} \Box^2 A^\nu \equiv \partial_\mu \partial^\mu A^\nu - \partial^\nu \partial_\mu A^\mu = \frac{1}{c^2}\frac{\partial^2 A^\nu}{\partial t^2} - \frac{\partial^2 A^\nu}{\partial x^2} - \frac{\partial^2 A^\nu}{\partial y^2} - \frac{\partial^2 A^\nu}{\partial z^2} \quad (1)$$

where J^ν is the 4-D electric current and the last equality holds for the gauge condition $\partial_\mu A^\mu = 0$ and the usual rectilinear coordinates. For gravity one has (in the weak field limit)

$$\Box^2 \phi^{\mu\nu} = -16\pi G T^{\mu\nu} \quad \text{or} \quad \partial_\lambda \partial^\lambda (h^{\mu\nu} - \frac{1}{2}\eta^{\mu\nu} h) = -16\pi G T^{\mu\nu} \quad (2)$$

where $\kappa = \sqrt{16\pi G} \cong 2.04 \times 10^{-24}$ s (g-cm)$^{-1/2}$ and $T^{\mu\nu}$ the stress-energy tensor. Note the relation between the linearized part of the metric $g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu}$ where $\eta_{\mu\nu}$ is the Minkowski metric tensor and the field variable $\phi^{\mu\nu}$

$$\phi^{\mu\nu} \equiv h^{\mu\nu} - \frac{1}{2}\eta^{\mu\nu} h \quad \rightarrow \quad h^{\mu\nu} = \phi^{\mu\nu} - \frac{1}{2}\eta^{\mu\nu}\phi \quad (3)$$

Such a field is convenient for the gauge condition

$$\partial_\mu \phi^{\mu\nu} = 0 \quad (4)$$

It is no surprise that both Maxwell's and the linearized Einstein equations should have radiation solutions and that both solutions waves move with the speed

of light ($c = 1$ in our notation and is left out of the equation above). It is clear that adding any solution of the form

$$\Box^2 \phi^{\mu\nu} = 0, \quad \text{or, if} \quad \partial_\mu \phi^{\mu\nu} = 0, \quad \partial_\lambda \partial^\lambda \phi^{\mu\nu} = 0 \tag{5}$$

will work.

Try the plane-wave solution

$$\phi^{\mu\nu} = \epsilon^{\mu\nu} cos k_\alpha x^\alpha \tag{6}$$

where $\epsilon^{\mu\nu}$ is a constant tensor, and k_α is a constant vector in the direction of propagation, which are named the polarization tensor and the wavevector, respectively.

(a) Show that this is a solution to equation 5, if

$$k^\alpha k_\alpha = 0, \quad \text{and} \quad \epsilon^{\mu\nu} k^\mu = 0 \tag{7}$$

meaning that $\omega = ck$ where $k = \sqrt{k_x^2 + k_y^2 + k_z^2} = |\mathbf{k}|$ and thus the speed of the gravity wave is the speed of light. Note that this means in the weak field limit there is no dispersion. (The c for your information later. Ignore it for this exercise.)

Now without loss of generality, we can restrict ourself to a plane wave moving in the z-direction $k^\alpha = (\omega, 0, 0, \omega)$ so that

$$\phi^{\mu\nu} = \epsilon^{\mu\nu} cos(\omega t - \omega z) = \epsilon^{\mu\nu} cos(kt - kz) \tag{8}$$

(b) You can either show or take my word for it that equations 7 and the requirement that $h^{\mu\nu}$ and $\phi^{\mu\nu}$ are symmetric means that there only only six possible independent polarizations. Note that there are 16 components to the tensor and symmetry reduces that to 10 independent components. The two relations of equation 7 cut the 10 to 6. (You heard that these correspond to the ± 0, ± 1, and ± 2 helicity modes in class.)

(c) Two of the independent polarization solutions can be

$$\epsilon_\oplus^{\mu\nu} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \tag{9}$$

and

$$\epsilon_\otimes^{\mu\nu} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \tag{10}$$

Show that these are traceless and transverse to the direction of propagation. The claim is that these two are the only one of their set of six that can actually carry energy and momentum. The others can be transformed away by gauge transformations.

We can return to general plane waves

$$\begin{aligned} \phi_{\oplus}^{\mu\nu} &= A_{\oplus}\epsilon_{\oplus}^{\mu\nu} cos k_\alpha x^\alpha \\ \phi_{\otimes}^{\mu\nu} &= A_{\otimes}\epsilon_{\otimes}^{\mu\nu} cos k_\alpha x^\alpha \end{aligned}$$

with energy-momentum tensors

$$\begin{aligned} t_{\oplus}^{\mu\nu} &= A_{\oplus}^2 k^\mu k^\nu sin^2 k_\alpha x^\alpha \\ t_{\otimes}^{\mu\nu} &= A_{\otimes}^2 k^\mu k^\nu sin^2 k_\alpha x^\alpha \end{aligned}$$

The average flux in the direction of propagation is

$$t = \frac{1}{2c}(A_{\oplus}^2 + A_{\otimes}^2)\omega^2 = \rho_{GW}/c \tag{11}$$

and the energy density is related to the flux by c. The stress-energy tensor for waves propagating in the z-direction has for its non-zero components

$$T^{00} = \frac{1}{c}T^{0z} = \frac{1}{c}T^{zz} = c^2 < A_{\oplus}^2 + A_{\otimes}^2 >= \frac{1}{16\pi}\frac{c^2}{G} < h_+^2 + h_\times^2 > \tag{12}$$

1.3 Relative Motion

In class I showed that such gravitational plane waves caused two test particles to oscillate relative to each other. I used the weak field geodesic equation

$$\frac{dp_\mu}{d\tau} = \frac{1}{2}m h_{\alpha\beta,\mu}u^\alpha u^\beta \tag{13}$$

or for a massive particle

$$\frac{du_\mu}{d\tau} = \frac{1}{2}h_{\alpha\beta,\mu}u^\alpha u^\beta \tag{14}$$

to show that a particle at rest $u^\alpha = (1,0,0,0)$ experiences no acceleration and remains at rest. However, two particles that were separated by a distance d in a direction transverse to the direction of propagation and aligned with the $\oplus$ polarization experience a periodic variation in their position to first order

$$\delta l \cong d \times (\frac{1}{2}A_{\oplus} cos\omega t) \tag{15}$$

If a typical strong ($A_{\oplus} \simeq 10^{-18}$) gravity plane wave passes through the earth-moon system ($d \cong 3.84 \times 10^{10}$ cm), what is the variation in the earth-moon distance? If laser ranging to the moon is accurate to 10 cm, can the motion be readily detected?

If the relative distance to a space craft at a distance of 5 astronomical units (7.5×10^{13} cm) can be measured to 1 mm by doppler tracking, can one detect this wave? How accurately must one measure the separation to be able to observe such a wave? Could it be done with laser interferometry?

1.4 Effective tidal Force

A gravitational plane wave causes and apparent deformation of objects. We discussed the appearance of a tube-shaped distribution of matter lying along the direction of propagation of the plane wave. For the two linear polarizations $\oplus$ and $\otimes$ the tube appears alternately squashed in the directions of the polarization axis. Specifically for a plane wave propagating along the z-axis, the $\oplus$ polarization has at a fixed time (for the right phase)

$$\begin{aligned} x(z) &= r(1 - \frac{1}{2}A_{\oplus}\cos\omega z) \\ y(z) &= r(1 - \frac{1}{2}A_{\oplus}\sin\omega z) \end{aligned}$$

The $\otimes$ polarization would look the same but rotated 45°.

For the circular polarizations

$$\begin{aligned} \epsilon^{\mu\nu}_{RH} &= (\epsilon^{\mu\nu}_{\oplus} - i\epsilon^{\mu\nu}_{\otimes})e^{ik_\alpha x^\alpha} \\ \epsilon^{\mu\nu}_{LH} &= (\epsilon^{\mu\nu}_{\oplus} + i\epsilon^{\mu\nu}_{\otimes})e^{ik_\alpha x^\alpha} \end{aligned}$$

the shape is a twisted squashed tube. Waves with the first circular polarization $\epsilon^{\mu\nu}_{RH}$ have positive helicity meaning the angular momentum is parallel to the direction of energy flux. Waves with the second circular polarization $\epsilon^{\mu\nu}_{LH}$ have negative helicity meaning the angular momentum is antiparallel to the direction of energy flux. The angular momentum in the wave is just $2/\omega$ times the energy in the wave.

What is the effective tidal force on the particles in a tubular shape for a gravity wave of amplitude $A_{\oplus} \simeq 10^{-18}$? Hint: Use the equivalence principle and calculate the effective differential acceleration.

$$\frac{d^2x}{dt^2} = -\frac{1}{2}A_{\oplus}x_0\frac{d^2}{dt^2}cos\omega t \tag{16}$$

You can get a similar equation for y. Show that the radial component of the tidal force is

$$f_r = m\ \frac{1}{2}A_{\oplus}r_0\ \omega^2 cos\omega t\ cos2\phi \tag{17}$$

where $r_0^2 = x_0^2 + y_0^2$ is the radial coordinate and ϕ is the azimuthal angle to the polarization axis.

2 Generation of Gravitational Waves

We continue briefly with our analogy to electromagnetism. It is appropriate to note that the relative strength of gravity to electromagnetism for a simple effect such as and atomic transition of energy order $E \sim 1$ eV is $GE^2/e^2 \approx 3 \times 10^{-54}$. Thus we cannot expect to find gravity waves being significant in atomic or individual

particle interactions but will be significantly only as a bulk effect for a large aggregate collection. This (equivalent to the small value of κ) justifies our weak field approximation. This keeps the waves linear and with no dispersion.

The general solution to Poisson equations (1) and (2) are

$$\Box^2 A^\nu = 4\pi J^\nu, \qquad A^\nu(\mathbf{x},t) = \frac{1}{c}\int d^3x' \int dt' \frac{J^\nu(\mathbf{x}',t')}{|\mathbf{x}-\mathbf{x}'|}\delta(t'+|\mathbf{x}-\mathbf{x}'|/c-t) \tag{18}$$

integration over t' replaces $J^\nu(\mathbf{x}',t')$ by $J^\nu(\mathbf{x}',t-|\mathbf{x}-\mathbf{x}'|/c-t)$ and similarly

$$\Box^2 \phi^{\mu\nu} = -16\pi G T^{\mu\nu}, \quad \phi^{\mu\nu} = -\frac{16\pi G}{4\pi}\int d^3x' \frac{T^{\mu\nu}(\mathbf{x}',t-|\mathbf{x}-\mathbf{x}'|/c-t)}{|\mathbf{x}-\mathbf{x}'|} \tag{19}$$

(These were derived from the relation $\nabla^2(1/|\mathbf{x}-\mathbf{x}'|) = -4\pi\delta(\mathbf{x}-\mathbf{x}').$)

In considering radiation one usually divides the situation into various zones when the size of the system radiating is smaller than a wavelength.

Zone	*Conditions*
Near or Static	$d << r << \lambda$
Intermediate	$d << r \sim \lambda$
Far or Radiation Zone	$d << \lambda << r$

(20)

where d is the characteristic size of the radiating system, λ is the wavelength, and r is the distance to the observer.

In the far field region the field scales as $1/r$ and the field is perpendicular to $\mathbf{r}$ as can be seen from the following argument. In the far field zone $kr >> 1$ so that $|\mathbf{x}-\mathbf{x}'| \cong r - \hat{n}\cdot\vec{\mathbf{x}}'$ so that

$$\lim_{kr\to\infty} \vec{\mathbf{A}} \to \frac{e^{ikr}}{cr}\int e^{-ik\hat{n}\cdot\mathbf{x}'}\ \vec{\mathbf{J}}\ d^3x' \cong \frac{e^{ikr}}{cr}\sum_n \frac{(-ik)^n}{n!}\int (\hat{n}\cdot\vec{\mathbf{x}}')^n\ \vec{\mathbf{J}}\ d^3x' \tag{21}$$

where the second part comes from expanding $exp(-ik\hat{n}\cdot\vec{\mathbf{x}}')$ in a Taylor series since we have assumed that $kd << 1$ which implies that $k|x| << 1$.

We expect that quadrupole radiation is the lowest order radiation that gravity can produce since all gravitational charges carry the same sign and the amplitude of the field will be proportional to k^3 and the energy radiated proportional to k^6.

Aside: The general solution

$$\vec{\mathbf{A}} = \frac{4\pi ik}{c}\sum_{l,m} h_l^{(1)}(kr)Y_{lm}(\theta,\phi)\int j_l(kr')Y_{lm}^*(\theta',\phi')\ \vec{\mathbf{J}}\ d^3x' \tag{22}$$

where $h_l^{(1)}(kr)$ are the Hankel functions, $Y_{lm}(\theta,\phi)$ are the spherical harmonics, and $j_l(kr)$ are the Bessel functions.

Making similar approximation for the distance $|\mathbf{x}-\vec{\mathbf{x}}'| \cong r - \hat{n}\cdot\vec{\mathbf{x}}'$ for the gravitational case, one has

$$\phi^{\mu\nu} \cong \frac{16\pi G}{4\pi r}\int d^3x' T^{\mu\nu}(t-r,\mathbf{x}') \tag{23}$$

In the linear approximation, $T^{\mu\nu}$ satisfies the gauge condition

$$\partial_\nu T^{\mu\nu} = 0 \tag{24}$$

which implies

$$\frac{\partial}{\partial t}T^{k0} = -\partial_l T^{kl} \quad \text{and} \quad \frac{\partial}{\partial t}T^{00} = -\partial_l T^{0l}. \tag{25}$$

We can use the first relationship to get

$$\int T^{kl} d^3x = \frac{1}{2}\frac{\partial}{\partial t}\int (T^{k0}x^l + T^{l0}x^k) d^3x \tag{26}$$

and the second to get

$$\int (T^{k0}x^l + T^{l0}x^k) d^3x = \frac{\partial}{\partial t}\int T^{00}x^k x^l d^3x \tag{27}$$

This can be proven by integrating the right hand side by parts. Combined these give us

$$\int T^{kl} d^3x = \frac{1}{2}\frac{\partial^2}{\partial t^2}\int T^{00}x^k x^l d^3x. \tag{28}$$

This indicates that the integral over the stress-energy can be expressed in terms of derivatives of T^{00}. This is simply conservation of energy and momentum.

Putting this back into equation (23) we have

$$\phi^{\mu\nu} \cong -\frac{16\pi G}{4\pi r}\int T^{\mu\nu}(t-r, \mathbf{x}') = -\frac{16\pi G}{8\pi r}\frac{\partial^2}{\partial t^2}\int T^{00}(t-r, \mathbf{x}') d^3x' \tag{29}$$

We will make two other approximations in addition to the weak field and the far zone in our treatment; (1) the gravitational effects are relatively small so that we can replace T^{00} by ρ and (2) we will neglect special relativistic corrections ($v/c << 1$). Note that these approximations mean that we will be in the weak field limit in that the dimensionless strain

$$h \sim \frac{r_{schwarzschild}}{r}\frac{v^2}{c^2} \tag{30}$$

Thus for non-relativistic matter one has

$$\phi^{kl} \cong -\frac{16\pi G}{8\pi r}\frac{\partial^2}{\partial t^2}\int \rho(t-r, \mathbf{x}') d^3x' \tag{31}$$

This integral can be expressed in terms of the quadrupole moment tensor.

$$Q^{kl} = \int (x^k x^l - \frac{1}{3}r^2\delta^l_k)\rho(t-r, \mathbf{x}') d^3x \tag{32}$$

so that

$$\phi^{kl} \cong -\frac{16\pi G}{8\pi r}\{\frac{\partial^2}{\partial t^2}Q^{kl} + \delta^l_k\frac{\partial^2}{\partial t^2}\int r'^3\rho(t-r, \mathbf{x}') d^3x'\} \tag{33}$$

For the calculation of energy flux, the term proportional to δ^l_k can be omitted because that part of the wave carries no energy as it has the wrong polarization.

$$\phi^{kl} \cong -\frac{16\pi G}{8\pi r}\frac{\partial^2}{\partial t^2}Q^{kl} = -\frac{16\pi G}{8\pi r}\ddot{Q}^{kl} \tag{34}$$

This is the lowest order term for gravitational radiation and is clearly quadrupolar as asserted earlier. There can be higher order terms; however, in general one expects them to be significantly smaller than the quadrupole contribution.

It can be shown that the energy radiated per unit solid angle is

$$-\frac{d^2E}{dtd\Omega} = \frac{dPower}{d\Omega} = (\frac{16\pi G}{8\pi r})^2[\frac{1}{2}\dddot{Q}^{kl}\dddot{Q}^{kl} - \dddot{Q}^{kl}\dddot{Q}^{km}n^l n^m + \frac{1}{4}\dddot{Q}^{kl}\dddot{Q}^{mr}n^k n^l n^m n^r] \tag{35}$$

This angular distribution is quite complicated except in very symmetric cases. However, we can integrate over all solid angles to find the total power radiated

$$-\frac{dE}{dt} = \frac{G}{5c^5}\dddot{Q}^{kl}\dddot{Q}^{kl} \tag{36}$$

Now we have a general set of equations we can use to treat the case of various cosmologically and astrophysically interesting objects. We expect gravitational radiation to fall into one of three classes:

Sources of Gravitational Radiation

Type	Source	Characteristic Frequency
Periodic	orbiting and oscillating objects	$10^{-7} - 10^2$ Hz and $10^2 - 10^5$ Hz
Burst	Collisions, Supernova & infall/collapse	$10^{-1} - 10^4$ Hz
Stochastic	CGR, Inflation, Phase Transitions	all

We treat these in the next subsections.

2.1 Order of Magnitude Estimates

We estimated the size of the dimensionless strain produced by a mass

$$h \sim \frac{R_{schwarzschild}}{R}\frac{v^2}{c^2} \tag{37}$$

Now we can estimate the quadrupole moment and its third derivative to estimate the power loss.

$$\dddot{Q}^{lk} \sim \frac{GMR^2}{t_c^3} \sim \frac{GMv^3}{R} \tag{38}$$

where M, R, t_c, and v are the characteristic mass, size, time scale, and velocity of the source. Using our formula for the power radiated

$$-\frac{dE}{dt} = \frac{G}{5c^5}\dddot{Q}^{kl}\dddot{Q}^{kl} \sim \frac{G}{c^5}(\frac{M}{R})^2 v^6 \sim L_{cGW}(\frac{R_{Schwarzschild}}{R})^2(\frac{v}{c})^6 \tag{39}$$

where

$$L_{cGW} \equiv \frac{c^5}{G} = 3.63 \times 10^{59} \text{ erg s}^{-1} = 2.03 \times 10^5 \text{M}_\odot c^2 \text{s}^{-1} \tag{40}$$

If a steel rod of mass 100 tons (10^8 grams) and length 20 meters rotates at its breakup speed (30 radians/sec), what is the approximate radiated power in gravitational waves?

Show that the power in gravity waves for a system with internal power in quadrupole motion $L_{internal} \sim Mv^2/t_c$ is roughly

$$L_{GW} = \frac{L_{internal}^2}{L_{cGW}} \tag{41}$$

Since astrophysical systems are generally gravitationally bound, the virial theorem tells us

$$\text{Kinetic Energy} \sim \frac{MR^2}{t_c^2} \sim |\text{Potential Energy}| \sim \frac{GM^2}{R}. \tag{42}$$

So the characteristic time scale is

$$t_c \sim \sqrt{\frac{R^3}{GM}} \tag{43}$$

so that

$$L_{GW} \sim L_{cGW}(\frac{R_{Schwarzschild}}{R})^5 \tag{44}$$

and the gravitational wave energy radiated by a nonspherical self-gravitating system in a characteristic time is roughly

$$\Delta E \sim L_{GW} t_c \sim Mc^2(\frac{R_{Schwarzschild}}{R})^{7/2}. \tag{45}$$

Thus the gravitational wave emission efficiency is then

$$\Delta E \equiv \epsilon Mc^2, \quad \epsilon \sim (\frac{R_{Schwarzschild}}{R})^{7/2}. \tag{46}$$

Now we can estimate the order of magnitude for dimensionless strain of astrophysical objects at distance r

$$h \sim \epsilon^{2/7}\frac{R_{schwarzschild}}{r} \sim 3 \times 10^{-18}(\frac{\epsilon}{0.1})^{2/7}\frac{(M/\text{M}_\odot)}{(r/10kpc)}. \tag{47}$$

(10 kpc is roughly the distance to our Galactic center.)

3 Periodic Gravitational Waves

We consider here gravitational waves produced by sources whose density changes periodically.

3.1 Emission by a Vibrating Quadrupole

According to the equations above any system of masses with a time-dependent quadrupole moment whose third derivative $\dddot{Q}^{kl} \neq 0$ is not zero will radiate power in gravitational waves. Consider two equal masses connected by a spring - a linear oscillating quadrupole. This is a simplification of problems of interest but will give a scale for estimating situations of interest. We can use the result that a system of spherical masses has the same quadrupole moment as a system of point masses located at the centers of the spherical masses. We align the masses on the z-axis a distance b from the origin with oscillation amplitude a so that their positions are:

$$z = \pm(b + asin\omega t), \quad \text{and} \quad z^2 = b^2 + 2absin\omega t + a^2 sin^2\omega t \tag{48}$$

One can easily show that the quadrupole moment is

$$Q^{kl} = \frac{1}{3}\begin{bmatrix} -2mz^2 & 0 & 0 \\ 0 & -2mz^2 & 0 \\ 0 & 0 & 4mz^2 \end{bmatrix} = \frac{1}{3}(1+2\frac{a}{b}sin\omega t+(\frac{a}{b})^2 sin^2\omega t)\begin{bmatrix} -2mb^2 & 0 & 0 \\ 0 & -2mb^2 & 0 \\ 0 & 0 & 4mb^2 \end{bmatrix} \tag{49}$$

Thus to first order in a/b (so that we only get radiation at frequency ω) this gives

$$\phi^{kl} \cong \frac{16\pi G}{8\pi r}\frac{2a}{3b}\omega^2 sin\omega(t-r)Q(a=0)^{kl} \tag{50}$$

One can use the formula above to work out the angular distribution which comes to a simple pattern.

$$-\frac{d^2E}{dtd\Omega} = (\frac{16\pi G}{8\pi})^2[2mab\omega^3 cos\omega(t-r)]^2 \sin^4\theta \tag{51}$$

where θ is the usual polar angle. Note that this is similar to EM dipole radiation which depends on $\sin^2\theta$. The total emitted power is

$$-\frac{dE}{dt} = \frac{G}{5c^5}\dddot{Q}^{kl}\dddot{Q}^{kl} = \frac{32G}{15c^5}[mab\omega^3 \cos\omega(t-r)]^2 \tag{52}$$

and averaging over a cycle yields

$$-\frac{dE}{dt} = \frac{G}{5c^5}\dddot{Q}^{kl}\dddot{Q}^{kl} = \frac{16G}{15c^5}[mab]^2\omega^6. \tag{53}$$

The damping rate γ_{GW} of the oscillator due to gravity waves is defined as

$$\gamma_{GW} \equiv -\frac{1}{E}\frac{dE}{dt}. \tag{54}$$

Since each mass has kinetic energy of $\frac{1}{2}m\omega^2 a^2$, the damping rate for this oscillator is

$$\gamma_{GW} \equiv -\frac{1}{E}\frac{dE}{dt} = \frac{32G}{15c^5}mb^2\omega^4 \tag{55}$$

and the time for the energy to be damped to $1/e$ is $1/\gamma_{GW}$. Now this is a simple case but it allows us to make order of magnitude estimates for some more realistic astrophysical systems.

3.1.1 Oscillating Neutron Star

A neutron star could be formed asymmetrically or it might be impacted by infalling material such as an asteroid. Suppose that the neutron star has a mass of $m_{ns} = 0.7\mathrm{M}_\odot$, and radius $R_{ns} = 10$ km and that it is initially deformed on one axis so that $\delta R/R \sim 0.1$. It will oscillate on that axis as a nearly incompressible fluid. These parameters give the neutron star an approximate density of $\rho \sim 10^{14}$ gm/cm^{-3}. (Note, I have not checked to see that these are fully consistent with our formula - the Oppenheimer-Volkoff equation or the stiffer equation of state. If I or one of you have time, then we can fix it in the solution hand out.)

How much power is radiated in gravitational waves and what is the damping time? Is this likely to be the most efficient damping mechanism?

Hint: It is easy to show that the oscillation frequency is roughly $\omega \sim \sqrt{G\rho} \sim 3 \times 10^3$ Hz for an incompressible fluid. Use the relation that $v = \sqrt{\partial P/\partial\rho} \sim \sqrt{P/\rho}$ and $P = Gm^2/R^4$ and that $\omega \approx v/R$. Define the vibration energy as

$$E_{vib} = \frac{1}{2}m_{ns}(\delta R)^2\omega^2 \sim (\frac{\delta R}{R})^2 \times 10^{53} \text{ ergs} \tag{56}$$

3.1.2 White Dwarf, Sun, & Earth Oscillations

Gravitational radiation emitted by quadrupole vibrations might be important in the case of novas. Nova outbursts occur on white-dwarf stars in binary systems, where accretion from a companion star gradually accumulates nuclear fuel on the white dwarf surface until the fuel reaches a critical mass and explodes. Among other things, the explosion initiates vibrations in the body of the white dwarf, at characteristic frequencies of 0.01 to 1 Hz. The energy released in a nova explosion is typically 10^{45} ergs, of which as much as 10% goes into the vibrational motion of the star and is subsequently radiated in the form of gravitational waves.

What if the neutron star considered above was a white dwarf instead? How much power would be radiated from a 10% deformation and what would be the

characteristic decay time through the emission of gravitational radiation? Does this follow the order of magnitude scaling laws from earlier and the numbers in the paragraph above? Are gravity waves likely to be important to the dynamics of solar oscillations and earth oscillations? Make a table of system (neutron star, white dwarf, sun, earth) of the form

Table 1
Vibration GW Damping

Object	Mass	R	R_{BH}/R	GW Power	Damping Time
Neutron Star	0.7 $M_\odot$	10 km			
White Dwarf	0.7 $M_\odot$	10^4 km			
Sun ($M_\odot$, $R_\odot$)	1.99×10^{33} g	6.96×10^{10} cm	4.48×10^{-6}		
Earth	5.98×10^{27} g	6.38×10^{8} cm	1.4×10^{-8}		

Note that one might consider using the excitation of vibration modes in the earth as a gravitational wave detector. The confusion background comes from earthquakes, volcanos and mankind.

3.2 Emission by a Rotating Quadrupole

Another periodic source of gravitational waves, which occurs very commonly in astrophysics, is the rotating quadrupole consisting of two masses in orbits around their common center of mass.

As the damping effects of gravitational waves circularizes orbits and it is simpler to calculate, we will consider circular orbits. Since the quadrupole moment repeats when the masses interchange sides in the orbit, the frequency of the emitted gravitational waves is twice the orbital frequency. The angular distribution will be relatively complicated and we skip over it but note that in the direction perpendicular to the orbital plane the gravitational radiation will be circularly polarized while in the plane it will be linearly polarized as in the case of the vibrating quadrupole.

The radiated power of the system is

$$-\frac{dE}{dt} = \frac{32G}{5c^5}\left[\frac{m_1 m_2}{m_1+m_2}\right]^2 R^4\omega^6 = \frac{32G}{5c^5}\mu^2 R^4\omega^6 \tag{57}$$

where R is the separation between the masses m_1 and m_2 and ω is the orbital frequency.

For an astrophysical system, such as a binary star system with circular orbits, gravity holds the masses together and Kepler's third law gives a relationship between the separation R and the orbital period and thus angular frequency:

$$\omega^2 = \frac{G(m_1+m_2)}{R^3} \quad \text{or} \quad P = 0.545\left(\frac{R}{1000\text{ km}}\right)^{3/2}\left(\frac{M_\odot}{m_1+m_2}\right)^{1/2}\text{ sec} \tag{58}$$

so that the radiated power is

$$-\frac{dE}{dt} = \frac{32G^4}{5c^5R^5}(m_1m_2)^2(m_1+m_2). \tag{59}$$

As the binary loses energy by gravitational waves, the distance between the masses decreases at a rate given by

$$\frac{dR}{dt} = -\frac{64G^3}{5c^5R^3}m_1m_2(m_1+m_2) \tag{60}$$

at the same time the orbital frequency increases at a rate given by

$$\frac{d\omega}{dt} = -\frac{3\omega}{2R}\frac{dR}{dt} = \frac{96}{5}[\frac{G(m_1+m_2)}{c^2R^3}]^{3/2}\frac{Gm_1m_2}{c^2R} = \frac{96}{5}\frac{G}{c^5}\omega^3\frac{Gm_1m_2}{R} \tag{61}$$

where we have used the relationship that

$$E = -\frac{Gm_1m_2}{2R} \;\rightarrow\; \frac{dE}{dt} = \frac{Gm_1m_2}{2R^2}\frac{dR}{dt} \tag{62}$$

One can rearrange this to find the change in period $P_b = 2\pi/\omega$ (frequency) of the binary pair.

$$\frac{1}{P_b}\frac{dP_b}{dt} = \frac{3}{2}\frac{1}{R}\frac{dR}{dt} = -\frac{3}{2}\frac{1}{E}\frac{dE}{dt} = -\frac{96}{5}\frac{G^3(m_1+m_2)^2\mu}{c^5R^4} \tag{63}$$

$$= \frac{1}{2.61\times10^7\mathrm{yr}}(\frac{m_1+m_2}{\mathrm{M}_\odot})^{2/3}\frac{\mu}{\mathrm{M}_\odot}(\frac{1\mathrm{hr}}{P_b})^{8/3} \tag{64}$$

Assuming that the expressions above remain valid as $R\rightarrow0$, show that the time $\Delta t_{R\rightarrow0}$ until $R\rightarrow0$

$$\Delta t_{R\rightarrow0} = \frac{5}{256}\frac{c^5}{G^3}\frac{R_{now}^4}{(m_1+m_2)m_1m_2} \cong 1.84(\frac{R}{100\ \mathrm{km}})^4(\frac{m_1+m_2}{\mathrm{M}_\odot})^{-2}(\frac{\mathrm{M}_\odot}{\mu}) \tag{65}$$

and that

$$\frac{\Delta t_{R\rightarrow0}}{P_b} \sim 10^5(\frac{P}{1s})^{5/3} \quad \text{or} \quad \frac{1}{P_b}\frac{dP_b}{dt} \sim (10^5(\frac{P}{1s})^{5/3})^{-1} \tag{66}$$

Now we are in a position to calculate the gravitational radiation power, orbital radius change, and relaxation time for some astrophysical systems.

3.2.1 Jupiter Power

As by far the largest component of the solar system quadrupole, estimate the power emitted by Jupiter in gravitational radiation and the rate of change of its orbit (in cm/year). (Useful numbers for this problem: orbit radius 5.2 AU = 7.8×10^8 km, period of orbit 11.9 years implying $\omega = 1.68\times10^{-8}$ sec^{-1}, mass = 1.9×10^{30} g $\approx 10^{-3}\mathrm{M}_\odot$.

While you are at it, you might want to calculate the rate of change of the earth's orbital radius due to gravity wave emission and compare it to that of other effects you calculated in problem set 5.

3.3 SuperMassive Black Holes

Our current view is that in the center of most galaxies there are supermassive ($10^5 M_\odot$ to $10^8 M_\odot$) black holes. Occassionaly, smaller black holes or supermassive blach holes from the merging of galaxies find themselves in (co-)orbit around the central supermassive black hole. This happens at first because the black holes are so massive and thus sink towards the central of the potential. Later the gravitational radiation they emit causes them to sprial into closer and closer orbits until they eventually merge. One can show that the quadrupole radiation from two inspiraling black holes has the strain of

$$h_\times = 3.6 \times 10^{-22} \frac{1Gpc}{r} \left(\frac{M_1}{10M_\odot}\right) \left(\frac{M_2}{10^6 M_\odot}\right)^{2/3} \left(\frac{f}{0.01Hz}\right)^{2/3}$$

The frequency determines the orbit separation. The time at frequency f until inspiral is

$$T = 1.41 \times 10^6 sec \left(\frac{0.01Hz}{f}\right)^{8/3} \left(\frac{10M_\odot}{M_1}\right) \left(\frac{10^6 M_\odot}{M_2}\right)^{2/3}$$

$$h_{pred} = 3.4\times 10^{-22} \left(\frac{f}{10^{-2}Hz}\right)^{2/3} \left(\frac{M_{BH}}{10^4 M_\odot}\right)^{5/3} \frac{x}{(1+x)^{1/3}} \frac{1}{1-\sqrt{1+z}} \qquad f \sim 10^4 \left(\frac{M_\odot}{M_{BH}}\right) \frac{Hz}{1+z}$$

What is the strain expected at 3 Gpc from two supermassive black holes each with mass about $10^5 M_\odot$ with a frequency $f = 0.01Hz$? Roughly how long before they inspiral to a frequency of $f = 0.03Hz$? Make a rough plot of strain versus frequency with a few characteristic times called out -e.g. 1 year, 1 month, 1 week, 1 day, etc. Use the characteristic times for the proposed LISA (laser interferometer space array) of arond $10^{-4}\ Hz \leq f \leq 10^{-2}\ Hz$.

3.3.1 Rapidly Rotating Deformed Neutron Star

For a slightly deformed, homogeneous neutron star with moment of inertia $I = 2MR^2/5$, mass M, radius R, rotation period P_{ns}, and ellipticity, ϵ, the gravitational wave luminosity is

$$L_{GW} = -\frac{dE}{dt} = \frac{32G}{5c^5} I^2 \epsilon^2 (\frac{2\pi}{P})^6 \tag{67}$$

$$\approx 10^{38}\text{erg s}^{-1} (\frac{I}{4\times 10^{44}\text{g cm}^2})^2 (\frac{P_{ns}}{0.033\text{sec}})^{-6} (\frac{\epsilon}{10^{-3}})^2 \tag{68}$$

and at a time t after its birth since it will slow down

$$L_{GW} \approx 10^{45}\text{erg s}^{-1} (\frac{I}{4\times 10^{44}})^{1/2} (\frac{10^{-3}}{\epsilon}) (\frac{10^6\text{sec}}{t+10^4\text{sec}})^{3/2} \tag{69}$$

3.3.2 Close Binary Stars

Table 2
Interesting Binary Sources of GW

Object	Masses $M_\odot$	Distance (pc)	Frequency 10^{-6} Hz	GW Power ergs/s	Damping Time years	Strain at Earth (10^{-22}
Eclipsing Binaries						
ι Boo	1.0, 0.5	11.7	86			51

PSR2127+11C	1.4, 1.3	10.6	70*			

* Pulsars with elliptical orbits emit significantly at harmonics.
The next section will deal with these three binary pulsars.

There is a whole class of interesting binary star pairs that can be calculated approximately. The most spectacular binary star pair known at the moment is AM CVn (AM Canem Venticorum). Am CVn consists of a blue white dwarf and a low-mass white dwarf in an exceptionally small orbit around each other. Their period is 17.5 minutes! Do you know which star has the bigger radius? (Table 2 tells us that their masses are about 1 and 0.041 $M_\odot$, respectively.) What do you estimate for the ratio of the radii of the lower to higher mass star? Fill out the following table. (See formula in next section to help with the numerical factors.)

3.3.3 Binary Pulsars

There are three known binary pulsars and these and some of their parameters are listed in table 3.

Table 3
Galactic Binary Pulsars

Parameter	PSR 1534+12	PSR 1913+16	PSR 2127+11C
Reference	Wolszczan et al. 1991	Hulse & Taylor 1974	Prince et al. 1991
Flux (400 MHz)	36 mJy	5 mJy	0.6 mJy
Distance	1.1 ± 0.2 kpc	7.3 kpc	10.6 kpc (in M15)
Period P	10.098 hr	7.7519 hr	8.047 hr
eccentricity	0.273677	0.61713	0.68141
$M_1 + M_2$	2.6784 $M_\odot$	2.82837 $M_\odot$	2.71 $M_\odot$
$q = M_1(pulsar)/M_2$	0.97 ± 0.03	1.04	1.0 ± 0.2
$P/(2\dot{P})$	2.5×10^8 yr	1.1×10^8 yr	1.0×10^8 yr
$t_{merge-theory}$	27.3×10^8 yr	3.01×10^8 yr	2.20×10^8 yr
t_{meas}	30×10^8 yr	4.1×10^8 yr	3.20×10^8 yr

Table adapted from Phinney 1991 Ap J 380 L17.

As one can see the eccentricity is significant for these systems. This leads to significant emission at the orbital frequency (as opposed to twice) and in harmonics. The modified energy loss equation according to Peters and Mathews is

$$-\frac{dE}{dt} = L_{GW} = \frac{32G^4}{5c^5a^5}\mu^2(m_1+m_2)^3\ f(\epsilon) \tag{70}$$

$$\approx 3.0 \times 10^{33}\text{erg s}^{-1}(\frac{\mu}{\text{M}_\odot})^2(\frac{m_1+m_2}{\text{M}_\odot})^{4/3}(\frac{P_b}{1\text{hour}})^{-10/3}\ f(\epsilon) \tag{71}$$

where

$$f(\epsilon) = \frac{1 + \frac{73}{24}\epsilon^2 + \frac{37}{96}\epsilon^4}{(1-\epsilon^2)^{7/2}} \tag{72}$$

and a is the semi-major axis.

If the two masses are in an elliptical orbit with eccentricity ϵ then the energy emission in gravity waves rate (to a sign) is

$$L_{GW} = \frac{dE}{dt} = \frac{dE}{dt}|_{\epsilon=0}\ f(\epsilon) \tag{73}$$

and the angular momentum loss rate is

$$\frac{dJ}{dt} = \frac{dJ}{dt}|_{\epsilon=0}\ g(\epsilon) = -\frac{32}{5}\frac{G^{7/2}\mu^2(m_1+m_2)^{3/2}}{a^{7/2}}g(\epsilon) \tag{74}$$

where

$$g(\epsilon) = \frac{1 + \frac{7}{8}\epsilon^2}{(1-\epsilon^2)^2} \tag{75}$$

where these are averaged over the orbit.

Using Kepler's laws we find

$$\frac{1}{P_b}\frac{dP_b}{dt} = \frac{1}{P_b}\frac{dP_b}{dt}|_{\epsilon=0}\ f(\epsilon) = -\frac{96}{5}\frac{G^3(m_1+m_2)\mu}{c^5 a^4}\ f(\epsilon) \tag{76}$$

For an elliptic orbit

$$\epsilon^2 = 1 + \frac{2EJ^2}{G^2\mu^3(m_1+m_2)^2} \tag{77}$$

One can use this relationship to derive an equation for $d\epsilon/dt$ and find that it is negative, so that gravitational radiation tends to circularize an elliptical orbit.

$$\frac{d\epsilon}{dt} = -\frac{304}{15}\frac{G^3\mu\ (m_1+m_2)^2\epsilon}{a^4\ (1-\epsilon^2)^{5/2}}\left(1+\frac{121}{304}\epsilon^2\right) \tag{78}$$

and the semi-major axis a decreases at the rate

$$\frac{da}{dt} = \frac{dR}{dt}|_{\epsilon=0} f(\epsilon) = -\frac{64}{5}\frac{G^3\mu\ (m_1+m_2)^2}{a^3} f(\epsilon) \tag{79}$$

In the Newtonian regime, if we orient the polarization axes along the major and minor axes of the projection of the orbital plane, then the dimensionless strain is

$$h_+ = 2(1+cos^2 i)\ \frac{\mu}{R}[\pi(m_1+m_2)f]^{2/3} cos(2\pi \int \frac{df}{dt}dt\ t) \tag{80}$$

$$h_\times = \pm 4cos^2 i\ \frac{\mu}{R}[\pi(m_1+m_2)f]^{2/3} sin(2\pi \int \frac{df}{dt}dt\ t) \tag{81}$$

3.4 Death Spiral

As the orbital pair loses energy through emitting gravitational waves the orbit becomes more circular, the major axis decreases in size, and the orbital frequency increases. The binary pair will begin a gradual spiral towards each other. The inward motion is slow at first but increases rapidly as the orbit gets smaller. AS the distance gets fairly small the rate gets large and results in a crescendo of gravitational radiation and a death spiral that ends in their coalescence. During the death spiral phase the gravitational radiation frequency will move higher and higher - rapidly in an up glissando. This is a reasonable term since one can easily calculate that the maximum frequency for a binary neutron star is about 1 kHz. It may be up to about 10 times that for optimal black holes.

Let us consider the steps leading up to the end. We will trust our results to the point that Newtonian gravitation is a reasonable approximation. We can use the circular orbit parameters.

One can integrate the rate of change of the orbit radius to find

$$\frac{1}{4}(R^4 - R_0^4) = -\frac{64G}{5c^5} m_1 m_2 (m_1 + m_2)(t - t_0) \tag{82}$$

where the t_0 indicates the starting time of the calculation.

Earlier we derived a formula for the time remaining $\Delta t_{R\to 0}$ until the radius would go to zero, if the equations remained valid. The time remaining went as

$$\Delta t_{R\to 0} = \frac{5}{256}\frac{c^5}{G^3}\frac{R_{now}^4}{(m_1+m_2)^2\mu} = [1 - (\frac{r}{r_0})^4]\frac{r_0}{4}\frac{1}{[-dR/dt|_{t_0}} \tag{83}$$

Thus it is clear that the system spends most of its time at the large distance and much less at small separations.

It is easy to show that the orbital frequency is

$$f_{orbit} = \frac{\omega}{2\pi} = \frac{1}{P_b} = \frac{1}{2\pi}[\frac{5}{256}\frac{c^5}{G^{5/3}\mu(m_1+m_2)^{2/3}}\frac{1}{t_{R\to 0} - t}]^{3/8} \tag{84}$$

where $t_{R\to 0} = t_0 + \Delta t_{R\to 0}$. The gravitational wave frequency will be twice f_{orbit}.

Consider two neutron stars with masses 1.4 $M_\odot$orbiting at 100 km. The intial radiated power is about 6×10^{51} erg/s. The rate of decrease of the orbit radius is $-dR/dt|_{t_0} \sim 7 \times 10^6$cm/s = 70km/s. Clearly to get from 100 km to 20 km is going to take on the order of 1 second. The formula gives 0.36 seconds. Starting from 130 km separation would take about 1 second and 200 km would take about 6 seconds.

At 200 km the orbital frequency is about 50 Hz and the orbital velocity is about 0.1c. By 130 km these are up to 93 Hz and 0.13c and at 100 km this becomes 138 Hz and 0.289c. At 20 km the frequency is 1550 Hz and the orbital speed is 0.32c. Clearly a careful calculation will have to take into account special relativistic effects but our numbers should be accurate to better than 1% at 200 km and better than 10%. We would also have to take into account the spin-orbit coupling due to the frame-dragging of the rotating stars and orbit. This mostly causes a beat in the emitted radiation.

We can estimate the power radiated in gravitational waves in those last few moments.

$$\Delta E = \frac{G}{2} m_1 m_2 [\frac{1}{r_0} - \frac{1}{r}] \tag{85}$$

where the factor of two comes from the gravitational energy splitting between gravitational wave and kinetic energy. With $r_0 = 200$ km and $r = 20$ km one has

$$-\Delta E \simeq 10^{53} \text{ erg} \approx 0.04 M_\odot \tag{86}$$

which means that about 1.5% of the rest mass was radiated. Most of this energy is released in the last states of the coalescence. An extra pulse will be emitted when the neutrons stars collide and the resulting neutron star or black hole

oscillations/vibrations is likely to produce even more. We consider this in the next section.

In the May 1995 Scientific American article by Tvsi Piran that I handed out in class, the author claims that two neutron stars 700 km apart take 15 minutes before collision and and their orbital period shrinks from a fifth of a second to a few milliseconds. Check these numbers and see what mass system one needs for this to be true and are these numbers consistent with the quoted parameters for the three know binary pulsars?

4 Gravitational Wave Bursts

Now we move from periodic (or quasiperiodic) case to the burst case. Any system with a quadrupole whose third derivative is non-zero will radiate.

4.1 Little hits very Big

For illustration we will first consider a small particle falling towards a very large mass. This is just so that we can neglect the motion of the large mass and its radiation. That should make the effects clearer to understand. In the next section we treat this in the fashion of reduced mass. The energy loss can be found by evaluating the quadrupole radiation loss formula and using the quadrupole matrix for a single mass at a distance z on the z axis we found for in the vibrating quadrupole section above.

$$Q^{kl} = \begin{bmatrix} -\frac{1}{3}mz^2 & 0 & 0 \\ 0 & -\frac{1}{3}mz^2 & 0 \\ 0 & 0 & \frac{2}{3}mz^2 \end{bmatrix} \tag{87}$$

Hence,

$$-\frac{dE}{dt} = \frac{G}{5c^5}\dddot{Q}^{kl}\dddot{Q}^{kl} = \frac{2Gm^2}{15c^5}(6\dot{z}\ddot{z} + 2z\dddot{z})^2 \tag{88}$$

Now we need to evaluate the various derivatives of z. Here we consider the case that the small test mass m is falling from rest at a great distance (i.e. infinity) as a result of gravitational attraction to the large stationary mass M. Later you can consider how to treat a more general case of interactions. Conservation of energy gives

$$\frac{1}{2}m\dot{z}^2 = \frac{GmM}{|z|} \tag{89}$$

and Newtonian law of universal interaction and the equivalence principle gives

$$\ddot{z} = \frac{GM}{z^2} \tag{90}$$

Taking the derivative with respect to time

$$\dddot{z} = -\frac{2GM}{z^3}\dot{z} = -\frac{2GM}{|z|^{7/2}}(2GM)^{1/2} \tag{91}$$

Now we can estimate the energy loss by integrating dE along the particle trajectory.

$$\Delta E = -\int_{\infty}^{R} \frac{1}{|z|^{9/2}} 2Gm^2 \; 15c^5 (2GM)^{5/2} dz = -\frac{1}{R^{7/2}} \frac{4Gm^2}{105c^5} (2GM)^{5/2} \tag{92}$$

Clearly the closer the test particle gets the more radiation energy it emits. The question is where to cut off? Clearly, the Schwarzschild radius of the large mass is a hard cut off since none of the gravitational waves would escape.

$$\Delta E_{max} = -\frac{2}{105} mc^2 (\frac{m}{M}) \cong -0.019 mc^2 (\frac{m}{M}) \tag{93}$$

In the next section we will see that this may be as much as roughly a factor of two over more detailed calculations but does neglect the radiation from the oscillations of the system as the masses coalesce.

This is a moderately efficient gravitational wave generator. Consider a one solar mass object falling into a 10 $M_{\odot}$ black hole.

$$\epsilon = \frac{\Delta E}{mc^2} = 0.019 (\frac{m}{M}) = 0.002 \tag{94}$$

In the next section we handle the reduced mass case and get essentially same answer.

4.2 Collision of Two Objects

Consider two point masses m_1 and m_2 falling towards each other under the influence of gravity from rest at infinity. For this case we will assume that the collision is head on and that they move on the x axis. The center of mass is $x = 0$.

$$m_1 x_1 = -m_2 x_2 = \mu x \tag{95}$$

where

$$x \equiv x_1 - x_2, \qquad \mu \equiv \frac{m_1 m_2}{M}, \qquad M = m_1 + m_2 \tag{96}$$

Since

$$m_1 x_1^2 + m_2 x_2^2 = \mu x^2, \tag{97}$$

$$Q_{xx} = \frac{2}{3} \mu x^2, \qquad Q_{yy} = Q_{zz} = -\frac{1}{3} \mu x^2 \tag{98}$$

The equation of motion is

$$\ddot{x} = -\frac{GM}{x^2} \tag{99}$$

and

$$\frac{\dot{x}^2}{2} = \frac{GM}{x}, \tag{100}$$

yielding

$$\ddot{Q}_{xx} = -\frac{4}{3} G\mu M \frac{\dot{x}}{x^2}. \tag{101}$$

Using the formula for radiated power

$$-\frac{dE}{dt} = \frac{G}{5c^5}\left\langle \dddot{Q}_{xx}^2 + \dddot{Q}_{yy}^2 + \dddot{Q}_{zz}^2 \right\rangle = \frac{8}{15}\frac{G}{c^5}\mu^2 M^2 \left\langle \frac{\dot{x}^2}{x^4} \right\rangle. \tag{102}$$

This integral will diverge as $x \to 0$. However, we know that this non-relativistic treatment will fail as we get to the Schwarzschild radius as the gravitational radiation will not escape. If we cut the integral off at $x_{min} = 2GM/c^2$

$$\Delta E = \frac{2}{105}\frac{\mu^2 c^2}{M}. \tag{103}$$

Now we should expect that this is an overestimate as the closer one gets to the Schwarzschild radius the less gravitational wave energy escapes but we also ignored other relativistic effects. The fall of a test particle into Schwarzschild black hole of mass M gives

$$\Delta E = 0.0104\frac{\mu^2 c^2}{M}. \tag{104}$$

This is roughly half of our semi-classical approach. Epply and Smart have calculated the radiation form the head-on collision of two equal-mass Schwarzschild black holes to find

$$\Delta E = 0.001 M c^2 \tag{105}$$

however, there is uncertainty which is at the level of a factor of 2 so it might be in reasonable agreement with the formula above. We can presume that there is more radiation if the collision is not head-on or if there is significant angular momentum in the system.

How would you do this calculation for two particles colliding if in addition to the gravitational attraction, they had significant peculiar velocity? For example, gravitational bremsstrahlung between an electron and proton or two protons in a hot plasma.

The frequency spectrum from a burst of gravitational waves will clearly not be periodic or quasiperiodic. Instead it will be much like EM bremsstrahlung radiation. Modes will be excited from low frequencies right on up to the inverse of the fastest time in collision.

$$\Delta E = \int \frac{dE}{dt} dt = \frac{G}{5c^5}\int \dddot{Q}^{kl}\dddot{Q}^{kl} dt \tag{106}$$

The total energy radiated during the collision is

$$\Delta E = \int \frac{dE}{dt} dt = \frac{G}{5c^5}\int_{-\infty}^{\infty} \dddot{Q}^{kl}\dddot{Q}^{kl} dt \tag{107}$$

$$= \frac{1}{10\pi}\frac{G}{c^5}\int_{-\infty}^{\infty} dt \int_{-\infty}^{\infty} d\omega \int_{-\infty}^{\infty} d\omega' \tilde{Q}^{kl}(\omega)\tilde{Q}^{kl}(\omega') e^{i(\omega-\omega')t} \tag{108}$$

where $\tilde{Q}^{kl}(\omega)$ is the fourier transform of $\ddot{Q}^{kl}$:

$$\tilde{Q}^{kl}(\omega) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \ddot{Q}^{kl} e^{i\omega t} dt, \quad \text{and} \quad \ddot{Q}^{kl} = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \tilde{Q}^{kl}(\omega) e^{-i\omega t} dt, \tag{109}$$

Parseval's theorem gives

$$\frac{dE}{d\omega} = \frac{2}{5} \frac{G}{c^5} |\tilde{Q}^{kl}(\omega)|^2 \tag{110}$$

For this case of two particles coming together under the influence of gravity in the low frequency regime

$$\frac{dE}{d\omega} \rightarrow \frac{2^{11/3}, (\frac{1}{3})^2}{5\pi 3^{7/3}} \frac{G}{c^5} (GM\omega)^{4/3} \mu^2 \quad \text{as} \quad \omega \rightarrow 0 \tag{111}$$

The high frequency cut off corresponds to the time scale at the Schwarzschild horizon. The figure handed out in class shows a representative spectrum of this type.

4.3 GW from Non-Spherical Collapse

One promising source of gravitational radiation is the non-spherical collapse of stellar cores (e.g. supernova). Detailed calculations are clearly very complicated. We consider a highly idealized symmetric case to get an order of magnitude estimate of the effect. Consider the Newtonian collapse of a homogeneous spheroid or ellipsoid.

$$-\frac{dE}{dt} = \frac{2}{375} \frac{GM^2}{c^5} \left\langle (\dddot{a}^2 - \dddot{c}^2)^2 \right\rangle \tag{112}$$

where a and c are the major and minor semi-axes. This collapsing configuration will give out radiation in proportion to the fourth power of the angular momentum.

$$\Delta E \sim (\frac{J}{GM^2/c})^4 Mc^2 \tag{113}$$

so with a lot of angular momentum the efficiency can be significant.

Estimate the efficiency $\epsilon = \Delta E/Mc^2$ in the formation of a remnant with the angular momentum of the Crab pulsar $J \sim 2 \times 10^{47}$ erg s^{-1}and for the pulsar PSR 1937+214 with $J \sim 4 \times 10^{48}$ erg s^{-1}.

5 Chaotic Gravitational Waves

The first set of chaotic gravitational waves that we encountered were the potential Cosmic Gravity Wave Thermal Background which you estimated would have an effective temperature of about 0.9 K. In a moment we will see how this could have come about; however, we should first consider how these might have been erased (stretched to very long wavelengths) and replaced by a new chaotic field by cosmic inflation.

5.1 Gravitons from Inflation

We saw in a previous lecture that inflation, in addition to producing density (scalar) fluctuations, would produce a random, chaotic field of gravitational (tensor) fluctuations. While these are outside the event (particle) horizon they are essentially frozen fluctuations in curvature

$$\delta ln(a) = \frac{\delta\rho}{\rho + P} \tag{114}$$

which Bardeen showed was a gauge invariant quantity. To first order we expect that these curvature fluctuations will be produced with roughly equal amplitude and thus potential fluctuations with dimensionless strain of order

$$(A_{\oplus,\otimes})_k = (h_{+,\times})_k \approx \frac{2}{\sqrt{\pi}} \frac{H_{inflation}}{M_{Planck}} \tag{115}$$

These fluctuations started their existence as part of the universe's wave function and as individual gravitons.

Once the universe is sufficiently old these curvature fluctuations were free to propagate as gravitational waves. That happens when a given graviton mode re-enters the horizon and the tensor metric fluctuations then propagate as gravitons. They also begin to redshift away due to the expansion of the universe.

The energy density of a chaotic field of gravitational waves has an energy density

$$\rho_{graviton} = < \dot{A}_{\oplus}^2 + \dot{A}_{\otimes}^2 > = \frac{\dot{h}_+^2 + \dot{h}_\times^2}{16\pi G} \tag{116}$$

or in power spectrum

$$\rho_{graviton} = \frac{1}{16\pi G} \int [(h_+)_k^2 + (h_\times)_k^2] k dk. \tag{117}$$

This leads us to the estimate of energy density power spectrum

$$k \frac{d\rho_{graviton}}{dk} = \frac{k^2[(h_+)_k^2 + (h_\times)_k^2]}{16\pi G} \tag{118}$$

Thus for the radiation-dominated phase of the universe the change in the energy density at each wavelength is proportional to a^{-2}. .....argument of why as energy per mode/wavelength is originally $\omega^2 A^2$ and it is redshifted away for a longer time inversely proportional to ω, one finds that for modes entering the horizon during radiation dominated phase all have equal energy density per mode (logarithmic interval) in λ .... Thus there is over the range of wavelengths $10^{10} to 10^{26}$ cm an essentially flat energy density or a dimensionless strain falling as $\propto \omega^{-2} \propto \lambda^2$. For longer wavelengths the mode entered during the matter-dominated phase and the energy density rises proportional to λ until one reaches the horizon. thus the

dimensionless strain grows proportional to the wavelength $\propto \omega^{-1} \propto \lambda$. Outside the horizon the dimensionless strain is (constant) equal to the value set by the expansion rate of inflation divided by the Planck mass (to the factor $2/\sqrt{\pi}$. See Figure xx. for an example of the gravitational wave spectrum expected for a sample model of inflation.

We can estimate the present (after expansion) strain of inflation epoch gravitational waves as a function of wavelength

$$h_0 \sim \Omega_\gamma^{1/2} \frac{\lambda_0 H_0}{c} (\frac{H_{inf}}{m_{pl} c^2})^2 \tag{119}$$

Thus a detector operating at a wavelength of $\lambda_0 = 10^3$ km, $H_0 \lambda_0 / c \sim 10^{-20}$. The density in radiation $\Omega_\gamma \sim 10^{-4}$, so $h_0 \sim 10^{-20} (H_{inf}/m_{pl}c^2)^2$.

5.2 Gravitational Waves from Thermal Collisions

We know that gravitational radiation is only emitted when particles actually undergo accelerations. In thermal plasmas, which are common in astrophysics and cosmology, there are thermal collisions - usually coloumb and elastic scattering - frequently. The energy per unit frequency interval emitted as gravitational waves in a collision of particles is

$$\frac{dE}{d\omega} = \frac{G}{2\pi} \sum_{in,out} (-1)^{in/out} m_n m_n \frac{1+\beta_{nm}^2}{(1-\beta_{nm}^2)^{1/2}} ln(\frac{1+\beta_{nm}}{1-\beta_{nm}}) \tag{120}$$

where β_{nm} is the relative velocity between particles n and m. For non-relativistic two-body scattering this reduces to

$$\frac{dE}{d\omega} = \frac{8G}{5\pi} \ \mu^2 \ v^4 \ sin^2\theta \tag{121}$$

where μ is the usual reduced mass, v is the relative velocity, and θ is the scattering angle in the center-of-mass frame.

The gravitational radiation produced by the collisions in a plasma or gas can be obtained by summing the radiated energies per collision, provided the collisions are incoherent (i.e. there is more time between collisions than it takes to radiate so that they do not interfere with each other coherently). This condition is that that we are considering radiation with $\omega_{GW} >> \omega_c$ where ω_c is the collision frequency per particle. In the incoherent regime

$$\frac{dE}{d\omega} = \frac{8G}{5\pi} \ \sum_{a,b} \mu_{ab}^2 n_a n_b \left\langle v_{ab}^2 \int \ \frac{d\sigma_{ab}}{d\Omega} \ sin^2\theta \ d\Omega \right\rangle \tag{122}$$

where n_a and n_b are the number densities of particles of type a and b, $d\sigma_{ab}/d\Omega$ is the center-of-mass-system differential scattering cross-section. The sum runs over all paris of particles and the average is taken over all collisions.

5.2.1 GW from a Plasma

As an example we calculate the gravitational radiation emitted by Coulomb scattering in a plasma. The Rutherford scattering we can retcross-section is

$$\frac{d\sigma_{ab}}{d\Omega} = \frac{q_a^2 q_b^2}{4v_{ab}^4 \mu_{ab}^2 sin^4(\theta/2)} \tag{123}$$

The integral over θ must be cut off at a minimum angle determined by the Debye screening of the Coulomb force at large impact parameters;

$$\int \frac{d\sigma_{ab}}{d\Omega}\ sin^2\theta\ d\Omega = \frac{4\pi q_a^2 q_b^2 ln(1/\theta_{min})}{v_{ab}^4 \mu_{ab}^2} \tag{124}$$

To average over collisions we must find $< v_{ab} >$, as one power is left. For a Maxwell-Boltzmann distribution

$$\langle v_{ab} \rangle = 2(\frac{2kT}{\pi \mu_{ab}})^{1/2} \tag{125}$$

Typically $ln(1/\theta_{min}) \sim 10$. For a plasma of completely ionized hydrogen we must take into account electron-proton and electron-electron collisions. (Why don't we worry about proton-proton and electron-helium plus proton-helium collisions?)

$$\frac{dP}{d\omega} = \frac{64 G n_e^2 e^4}{5c^5}\ (\frac{2kT}{\pi \mu_{ab}})^{1/2}\ (1+\sqrt{2})\ ln(1/\theta_{min}) \tag{126}$$

The electron collision frequency can be estimated as

$$\omega_c \approx \frac{e^4 n_e < v >}{(kT)^2} \approx \frac{e^4 n_e}{(kT)^{3/2} m_e^{1/2}}. \tag{127}$$

5.2.2 GW from the Sun & Stars

Now let us apply this to the hydrogen plasma in the solar or a stellar core. Within a volume of roughly 2×10^{31} cc this plasma has $T \simeq 10^7$ K, $n_e \simeq 3 \times 10^{25}$ cc, and $ln(1/\theta_{min}) \sim 4$. The collision frequency is roughly 10^{15} s^{-1}, which is three orders of magnitude less than the thermal frequency $\omega_{thermal} = kT/\hbar \approx 10^{18}$ s^{-1}, so that an estimate of the total power produced in gravitational radiation can be found by multiplying by $VkT/\hbar$. This gives about 10^8 watts or 100 megawatts.

5.2.3 GW from the Early Universe Plasma

We could do this same calculation for the early universe. What would be power in gravitational radiation produced by thermal collisions of the plasma at the time of nucleosynthesis? (Take a time of 1 sec and $kT = 1$ MeV.) We neglected photons in the plasma calculation above, should we take them into account here? How far back do we have to go in the universe before there is good thermal interaction between the gravitons and other constituents of the universe?

5.2.4 GW from the ElectroWeak Phase Transition

Extra gravitational radiation could be produced during the ElectroWeak Phase Transition (as well as other phase transitions) over the simple plasma conditions due to the traveling domain wall of the phase transition as well as their collisions with each other. ...

5.2.5 GW from Cosmic Strings

Due to the high tension equal to the mass per unit length μ in cosmic strings, they both try to straighten out at the speed of light as well as have oscillations and traveling waves. These lead to the copious production of gravity waves by strings.

We can make a rough order of magnitude estimate of the gravitational radiation from cosmic strings. Most radiation will come from oscillating loops which are formed when a string crosses itself. A loop naturally forms. Loops surviving to epoch given by time t in the radiation era will have a typical size $l \sim G\mu t$ and will produce gravitational waves of frequency $\omega \sim 1/l$ and energy density

$$\rho_{GW-s} = (\dot{M}t)n(l) \simeq \ \mu \ ln(l) \tag{128}$$

where $n(l)$ is the density of loops larger than l. During the radiation dominated era

$$n(l) \sim t^{-3/2} l^{-3/2} \tag{129}$$

and thus

$$\rho_{GW-s} \simeq \frac{(G\mu)^{1/2}}{Gt^2} \tag{130}$$

Since the energy density in relativistic radiations scales as $a^{-4} \propto t^{-2}$ and is essentially the critical density during the radiation dominated error, we have $\rho_\gamma \approx 1/(30Gt^2)$,

$$\Omega_{GW-s} \simeq 30(G\mu)^{1/2}\Omega_\gamma = 6 \times 10^{-7} h^{-2} (G\mu/10^{-6})^{1/2} \tag{131}$$

A more precise calculation (Brandenberger et al. 1986) gives a slightly lower estimate

$$\Omega_{GW-s} = 4 \times 10^{-8} h^{-2} \Omega_0^{-1} (G\mu/10^{-6})^{1/2} \tag{132}$$

Calculate the limit that is set by precision pulsar timing, on the energy density of gravity waves with frequencies of 1/4 yr^{-1}. Five kpc away is PSR 1937+21 discovered by Don Backer which has had a steady 1.6 ms pulse for four years. The time between the main pulse and an interpulse is given as 744.9 plus or minus 1.3 microseconds over those four years. It is part of a group of pulsars whose relative timing is good to about 3 microseconds. Does this come close to the expected signal from GUT cosmic strings? Do more years of observation help?

Hint: Calculate the strain needed to change the timing by 1 microsecond (distance = 5 kpc). Next calculate the energy density for gravitational waves with wave length of 4 light years and compare that to ρ_c to get Ω_{GW}.

6 Anisotropies from Gravitational Waves

What is the typical CBR anisotropy expected from a long wavelength gravity wave in which we are immersed? (Calculate a numerical value that sets the scale for the mean expected rms fluctuation if the energy scale of inflation at current horizon crossing is the GUT scale, first for the quadrupolar term due to the gravity wave in which we currently find ourselves and then for the chaotic field filling the universe. What would we expect for the apparent random velocity dispersion of clusters of galaxies relative to each other due to this chaotic field of gravity waves?

We expect the frequency shift for entering photons to be given the difference in the dimensionless strain at the point of reception and the point of emission.

$$\frac{\Delta T}{T} = z(\theta,\phi) = \frac{1}{2}(h_r - h_e)\ (1 - cos\theta)\ cos2\phi \tag{133}$$

where h_r and h_e are the dimensionless strain at the receiver and emitter respectively and theta is the angle between the line of sight and the direction of propagation of the plane wave $(\hat{\mathbf{n}} \cdot \vec{\mathbf{k}})$ and ϕ is the azimuthal angle around the direction of motion relative to the polarization of the wave.

For a random chaotic field we can estimate the resulting mean square amplitude of temperature or velocity variations as

$$\left\langle z^2 \right\rangle = \left\langle \frac{\Delta T}{T} \right\rangle = \frac{1}{3\pi^3}\ \rho_{GW}\ \omega^{-2} \tag{134}$$

where 5/8 of this is produced by the quadrupole.

Consider the random chaotic field produced by inflation which will have $< A >= 0$ but will have an rms value

$$\left\langle (\frac{\Delta T}{T})^2 \right\rangle = \frac{1}{4}\left\langle \omega h H_0^{-1} \right\rangle^2 \simeq \frac{\omega^2 h^2}{4H_0^2} \approx \frac{8\pi G \rho_{GW}}{H_0^2} \simeq 3\Omega_{GW} \tag{135}$$

THE GENERATION OF GRAVITATIONAL WAVES:

A REVIEW OF COMPUTATIONAL TECNIQUES *†

8. Concluding Remarks

1. INTRODUCTION

1.1 Nature of these lectures

In these lectures I shall review techniques for calculating gravitational-wave generation. My emphasis will be on the techniques themselves, on their realms of validity, and on typical applications of them. Most derivations will be omitted or sketched only briefly, but I shall give references to places where the derivations can be found.

I shall presume that the reader is familiar with general relativity at the level of "track one" of Misner, Thorne, and Wheeler (1973) -- cited henceforth as "MTW." My sign conventions and notation will be the same as in MTW.

1.2 Regions of Spacetime Around a Source

One can characterize a source of gravitational waves, semi-quantitatively, by the following length scales:

$$L \equiv \text{"Size of source"} \equiv \left\{ \begin{array}{l} \text{radius of region inside which} \\ \text{the stress-energy } T^{\alpha\beta} \text{ is contained} \end{array} \right\},$$

$$2M \equiv \text{"Gravitational radius of source"} \equiv \left\{ \begin{array}{l} \text{2 x mass of source in} \\ \text{units where } G = c = 1 \end{array} \right\},$$

$$\lambda\!\!\!^{-} \equiv \text{"reduced wavelength of waves"} \equiv \left\{ \begin{array}{l} 1/2\pi \text{ x characteristic wave-} \\ \text{length of gravitational} \\ \text{waves emitted by source} \end{array} \right\}, \quad (1.2.1)$$

$$\left. \begin{array}{l} r_I \equiv \text{"inner radius of local wave zone"} \\ r_0 \equiv \text{"outer radius of local wave zone"} \end{array} \right\} \text{ (see below).}$$

Corresponding to these length scales, one can divide space around a source into the following regions (See Fig. 1):

Source:	$r \equiv$ radius $\lesssim L$
Strong-field region:	$r \lesssim 10\,M$ if $10\,M \gtrsim L$ typically does not exist if $L \gg 10\,M$
Weak-field near zone:	$L < r$, $10\,M \ll r$, $r \ll \lambda\!\!\!^{-}$ (1.2.2)
Wave generation region:	$r \lesssim r_I$ (includes source, strong-field region, and weak-field near zone)
Local wave zone:	$r_I \lesssim r \lesssim r_0$
Distant wave zone:	$r_0 \lesssim r$.

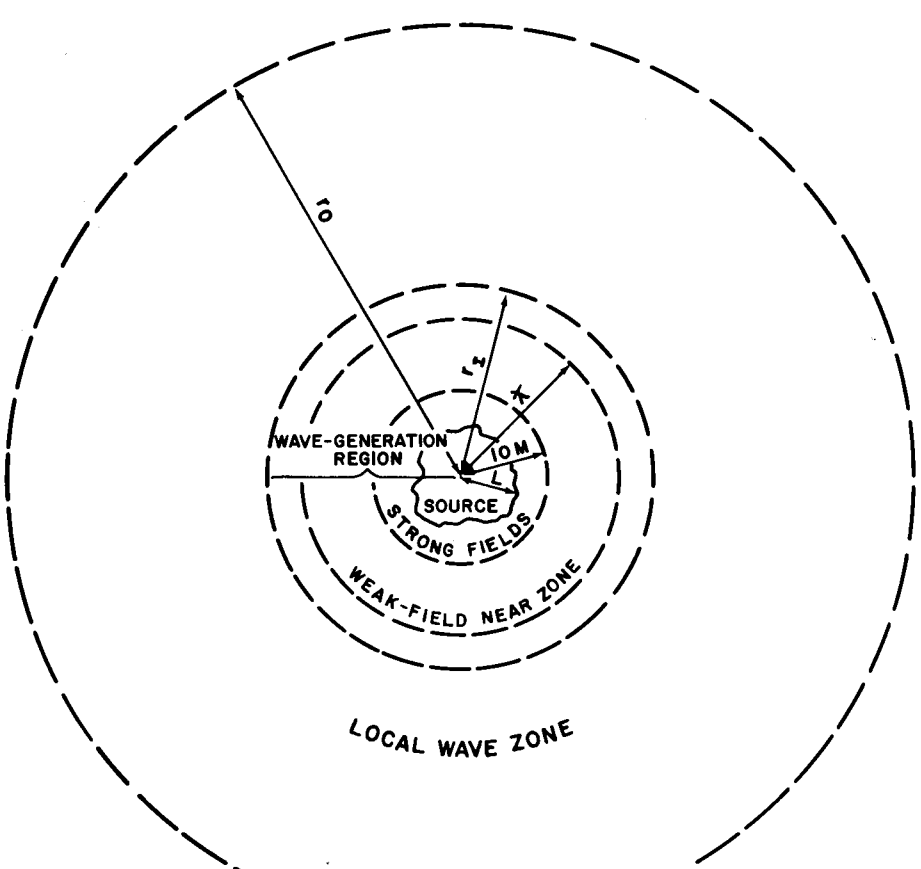

Figure 1. Regions of spacetime surrounding a source.

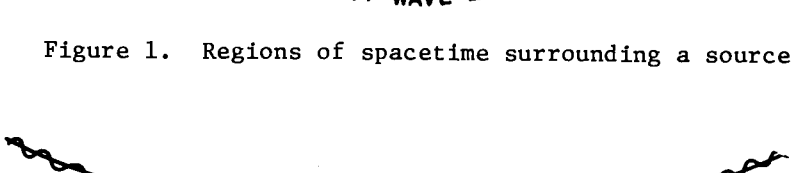

Figure 2. The local wave zone (schematic diagram). The smooth curve depicts the curvature of the background spacetime on which the waves (rippled curve) propagate. Near the source one cannot necessarily split the spacetime geometry into background plus waves; but in the local wave zone one can.

The "local wave zone" is the region in which (i) the source's waves are weak, outgoing ripples on a background spacetime; and (ii) the effects of the background curvature on the wave propagation are totally negligible (see Fig. 2).

The inner edge of the local wave zone r_I is the location at which one or more of the following effects becomes important: (i) the waves cease to be waves and become near-zone field, i.e., r becomes $\lesssim \lambda\!\!\!^{-}$; (ii) the gravitational pull of the source produces a significant redshift, i.e., r becomes $\backsim$ 2M = (Schwarzschild radius of source); (iii) the background curvature produced by the source distorts the wave fronts and backscatters the waves, i.e., $(r^3/M)^{1/2}$ becomes $\lesssim \lambda\!\!\!^{-}$; (iv) the outer limits of the source itself are encountered, i.e., r becomes $\lesssim$ L = (size of source). Thus, the inner edge of the local wave zone is given by

$$r_I = \alpha \times \text{Maximum } \{\lambda\!\!\!^{-},\ 2M,\ (M\lambda\!\!\!^{-}{}^2)^{1/3},\ L\}\ , \qquad (1.2.3)$$

$\alpha \equiv$ (some suitable number large compared to unity).

The outer edge of the local wave zone r_0 is the location at which one or more of the following effects becomes important: (i) a significant phase shift has been produced by the "M/r" gravitational field of the source, i.e., $(M/\lambda\!\!\!^{-}) \cdot \ell n(r/r_I)$ is no longer $<< \pi$; (ii) the background curvature due to nearby masses or due to the external universe perturbs the propagation of the waves, i.e., r is no longer $<< R_B$ = (background radius of curvature). Thus, the outer edge of the local wave zone is given by

$$r_0 = \text{Minimum } \{r_I \cdot \exp(\lambda\!\!\!^{-}/\beta M),\ R_B/\gamma\}, \qquad (1.2.4)$$

$\beta,\gamma \equiv$ (some suitable numbers large compared to unity).

Of course, we require that our large numbers α,β,γ, be adjusted so that the thickness of the local wave zone is very large compared to the reduced wavelength,

$$r_0 - r_I >> \lambda\!\!\!^{-}. \qquad (1.2.5)$$

Throughout these lectures I shall confine attention to sources which possess a local wave zone -- and I shall call such sources "isolated." It seems likely that every source of gravitational waves in the Universe today is "isolated." However, in the very early Universe the background curvature, $1/R_B^2$, was so large that sources might not have been isolated.

In complex situations the location of the local wave zone might not be obvious. Consider, for example, a neutron star passing very near a super-massive black hole. The tidal pull of the hole sets

the neutron star into oscillation, and the star's oscillations produce gravitational waves (Mashoon 1973; Turner 1977). If the hole is large enough, or if the star is far enough from it, there may exist a local wave zone around the star which does not also enclose the entire hole. Of greater interest - because more radiation will be produced - is the case where the star is very near the hole and the hole is small enough ($M_h \lesssim 100 M_\odot$) to produce large-amplitude oscillations, and perhaps even disrupt the star. In this case, before the waves can escape the influence of the star, they get perturbed by the background curvature of the hole. One must then consider the entire star-hole system as the source, and construct a local wave zone that surrounds them both.

The local wave zone acts as a buffer between the wave-generation region $r < r_I$ and the distant wave zone $r > r_0$. The existence of this buffer enables one to separate cleanly the theory of wave generation (applicable for $r < r_0$; treated in §§ 2-6 of these lectures) from the theory of wave propagation (applicable for $r > r_I$; treated in § 7 of these lectures).

1.3 The Gravitational-Wave Field

In the local wave zone where gravity is weak we shall use coordinate systems $(t,x,y,z) \equiv (x^0,x^1,x^2,x^3)$ which are centered on the source and are very nearly Minkowskiian; and we shall sometimes introduce the corresponding spherical coordinates (t,r,θ,ϕ) with

$$x = r\sin\theta\cos\phi\ ,\quad y = r\sin\theta\sin\phi\ ,\quad z = r\cos\theta. \qquad (1.3.1)$$

The components of the metric then differ only slightly from Minkowskii form

$$g_{\alpha\beta} \equiv \eta_{\alpha\beta} + h_{\alpha\beta},\quad \eta_{\alpha\beta} = \mathrm{diag}(-1,1,1,1),\quad |h_{\alpha\beta}| \ll 1. \qquad (1.3.2)$$

Throughout these lectures it will be adequate, in the local wave zone, to treat $h_{\alpha\beta}$ as a linearized field residing in flat space-time. If one knows $h_{\alpha\beta}$ in any such coordinate system (i.e. in any "gauge"), one can compute from it the "gravitational wave field" (§35.4 of MTW)

$$h^{TT}_{jk} \equiv (P_{ja}h_{ab}P_{bk} - 1/2\ P_{jk}P_{ab}h_{ab}). \qquad (1.3.3)$$

Here Latin indices run from 1 to 3; repeated Latin indices must be summed even if they are both "down"; and "TT" means "transverse, traceless part". The projection tensor used in this computation is

$$P_{jk} \equiv \delta_{jk} - n_j n_k\ ;\ n_j \equiv x^j/r. \qquad (1.3.4)$$

The task of wave-generation theory (§§ 2-6) is to determine h^{TT}_{jk} in the local wave zone. Once that has been done, wave-propagation theory (§ 7) can be used to calculate h^{TT}_{jk} in the distant wave zone.

1.4. Formalisms for Calculating Wave Generation

To calculate the generation of gravitational waves one must solve simultaneously the Einstein field equations and the equations of motion of the source. These equations are so complicated that one cannot hope to solve them exactly in any realistic situation. Therefore, one must resort to approximation schemes.

Several different approximation schemes have been devised for handling different types of sources. Most of these approximation schemes have been written in the form of "plug-in-and-grind" formalisms (i.e., computational algorithms). In these lectures I shall describe the following formalisms:

Weak-field formalisms (§2). These formalisms are valid for sources with weak internal gravitational fields ($L \gg 2M$; sources without any strong-field region; cf. Fig. 1). Section 2.1 will present a classification of weak-field formalisms and their realms of validity; and §§2.2-2.7 will present specific weak-field formalisms, each with its own realm of validity. A catalogue of the weak-field formalisms is given in Table 1.

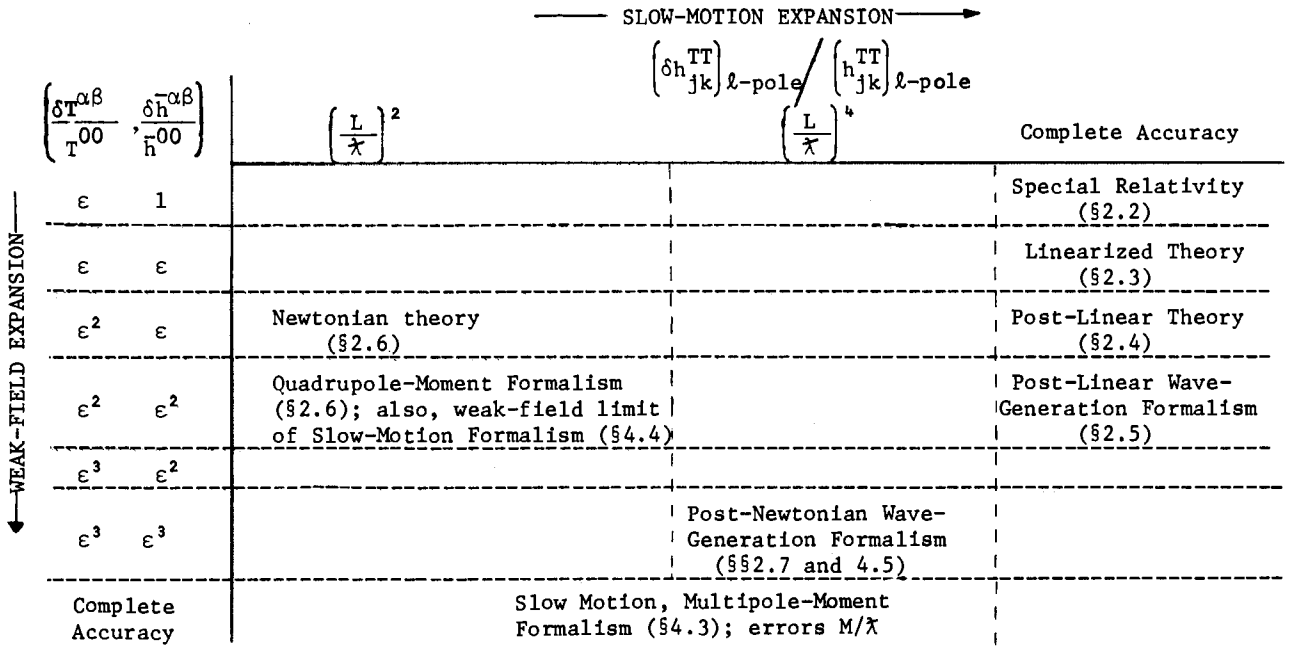
Multipole analysis of the radiation field (§3). The gravitational waves from any source can be resolved into multipole fields, and that multipole resolution yields simple formulas for the energy, linear momentum, and angular momentum carried off by the waves. Section 3 presents such a multipole analysis, restricted to the local wave zone. That analysis can be used fruitfully in conjunction with the wave-generation formulas of §§2,4, and 5.

Slow-motion formalisms (§4). These formalisms are valid for sources with slow internal motions ($L/\lambda\!\!\!^{-} \ll 1$). They make use of near-zone multipole-moment expansions, and consequently they tie in tightly with the multipole analysis of the radiation field (§3). The slow-motion formalisms are catalogued in Table 1 along with the weak-field formalisms.

Small-perturbation formalisms (§5). These formalisms are applicable to sources consisting of small dynamical perturbations of a nonradiative "background" system (e.g., small particles falling into black holes, and small-amplitude pulsations of stars).

TABLE 1

A CATALOGUE OF WEAK-FIELD FORMALISMS AND SLOW-MOTION FORMALISMS



Notation:

δ	means "errors in."
$\bar{h}^{\alpha\beta}$	is the gravitational field (including both nonradiative and radiative parts)
h^{TT}_{jk}	is the radiation field.
ε	is the magnitude of the source's internal gravitational fields.
L	is the source's linear size.
M	is the source's mass.
$\lambda\!\!\!^{-}$	is the reduced wavelength of the gravitational waves.

Formalisms for studying systems with strong internal fields and fast, large-amplitude internal motions (§6). Unfortunately, no analytic formalisms now exist for studying such systems. However one can study their evolution and the waves they emit by numerical solution of the Einstein field equations on a large computer. The necessary numerical techniques are now under development.

2. WEAK-FIELD FORMALISMS

2.1 Classification of Weak-Field Formalisms

Weak-field formalisms are applicable to systems with weak internal gravitational fields.

To compute a characteristic dimensionless strength ε of the internal field of a source, one can analyze the source as though spacetime were flat, using globally Minkowskii coordinates in which the center-of-mass is at rest. In these coordinates one can compute ε from the retarded integral

$$\varepsilon = \underset{\substack{\text{"relevant" values}\\ \text{of the field point}\\ (t,x^j)}}{\text{Maximum over all}} \left\{ \int \frac{T^{00}(t-|\underset{\sim}{x}-\underset{\sim}{x}'|,\ \underset{\sim}{x}')}{|\underset{\sim}{x}-\underset{\sim}{x}'|}\, d^3x' \right\} . \qquad (2.1.1)$$

Here T^{00} is the time-time component of the stress-energy tensor, and the "relevant" field points are those points at which one portion of the source interacts with fields produced by other portions of the source. One need not know ε with high precision; errors as large as a factor 3, say, are perfectly allowable.

For a source consisting of a single coherent body (e.g., a pulsating star) with mass M and linear size L,

$$\varepsilon \backsim M/L. \qquad (2.1.2a)$$

For a source consisting of several lumps, each with mass m and size ℓ, separated by distance $b \gg \ell$,

$\varepsilon \sim m/b$ if one is interested only in waves generated by relative motions of the lumps; (2.1.2b)

$\varepsilon \sim m/\ell$ if one is interested in waves generated by internal motions of the lumps. (2.1.2c)

Weak-field formalisms are valid only for sources that have $\varepsilon \ll 1$.

All weak-field formalisms have roughly the same structure: They utilize a single coordinate system $\{x^\alpha\}$ that covers the entire wave-generation region and local wave zone ($r \lesssim r_0$) and that is as nearly globally Minkowskiian as possible. In this coordinate system they define a "gravitational field" $\bar{h}^{\alpha\beta}$ (second-rank symmetric tensor) by

$$\bar{h}^{\alpha\beta} \equiv -[(-g)^{1/2} g^{\alpha\beta} - \eta^{\alpha\beta}], \tag{2.1.3}$$

where $g^{\alpha\beta}$ are the contravariant components of the metric tensor, where $g \equiv \det||g_{\alpha\beta}||$, and where $\eta^{\alpha\beta}$ are the components of the Minkowskii metric tensor [diag (-1,1,1,1)]. The formalisms then consist of field equations by which the stress-energy tensor $T^{\alpha\beta}$ (associated with matter and non-gravitational fields) generates the gravitational field $\bar{h}^{\alpha\beta}$, and equations of motion by which the gravitational field and internal stresses regulate the time evolution of the stress-energy tensor.

Thorne and Kovacs (1975; cited henceforth as TK) have devised a classification scheme for weak-field wave-generation formalisms--a scheme resembling that by which Havas and Goldberg (1962) classify "point-mass equation-of-motion formalisms." This scheme characterizes wave-generation formalisms by two integers n_T and n_h. These "order indices" tell one the magnitude of the errors made by the formalism--i.e., the amount by which the formalism's predictions should differ from those of exact general relativity theory:[1]

$$|(\text{errors in } T^{\mu\nu})/T^{00}| \sim \varepsilon^{n_T}, \tag{2.1.4a}$$

$$|(\text{errors in } \bar{h}^{\mu\nu})/\bar{h}^{00}| \sim \varepsilon^{n_h}. \tag{2.1.4b}$$

For example, a formalism of order $(n_T, n_h) = (1,1)$ makes fractional errors of order ε in both the stress-energy tensor and the gravitational field, while a formalism of order (2,1) makes fractional errors ε^2 in $T^{\mu\nu}$ and ε in $\bar{h}^{\mu\nu}$.

Errors in $\bar{h}^{\mu\nu}$, when fed into the equation of motion, produce errors in $T^{\mu\nu}$; and similarly, errors in $T^{\mu\nu}$, when fed into the field equations, produce errors in $\bar{h}^{\mu\nu}$. This feeding process places constraints on the order indices (n_T, n_h) of any self-consistent, weak-field wave-generation formalism:

$$n_h = n_T \quad \text{or} \quad n_h = n_T - 1. \tag{2.1.5}$$

[1] Note that all of the $|T^{\mu\nu}|$ are $\lesssim T^{00}$, and consequently all of the $|\bar{h}^{\mu\nu}|$ are $\lesssim \bar{h}^{00}$. This fact dictates the form of equations (2.1.4).

Thus, every weak-field formalism has order indices of the form (n,n-1) or (n,n) for some integer n.

TK devise a scheme for constructing formalisms of any desired order. They also show that any formalism of order (n,n-1) can readily be "strengthened" by augmenting onto it a higher-accuracy field-generation equation. The resulting, augmented formalism will have order (n,n).

In these lectures I shall not describe the general analysis of TK; I shall merely present examples of weak-field formalisms of various orders, and describe the augmentation process which improves their accuracy.

2.2 Special Relativity: A Formalism of Order (1,0)

Special Relativity is characterized by the equations of motion

$$T^{\mu\nu}{}_{,\nu} = 0, \tag{2.2.1}$$

which are oblivious of all gravitational effects. The largest of the individual terms that occur in these equations are of order

$$T^{00}/\ell, \tag{2.2.2}$$

where ℓ is a characteristic length scale inside the source. By contrast, the gravitational forces ignored by these equations of motion are

$$\Gamma^{\mu}{}_{\alpha\nu}T^{\alpha\nu}+\Gamma^{\nu}{}_{\alpha\nu}T^{\mu\alpha}\sim(\bar{h}^{00}/\ell)T^{00}\sim\varepsilon(T^{00}/\ell). \tag{2.2.3}$$

Comparison of the forces ignored (eq. 2.2.3) with the terms included (eq. 2.2.2) shows that special relativity makes fractional errors of order ε in the evolution of the stress-energy--and hence fractional errors of order ε in the stress-energy tensor itself. Evidently, the stress-energy tensor has order index $n_T = 1$.

The gravitational field, by contrast, has order index $n_h=0$, since special relativity is totally oblivious of gravity and therefore makes fractional errors $\delta\bar{h}^{\mu\nu}/\bar{h}^{00}\sim 1 = \varepsilon^0$.

Conclusion: Special relativity (eq. 2.2.1) is a weak-field formalism of order (1,0).

2.3. Linearized Theory: A Formalism of Order (1,1)

One can obtain Linearized Theory from Special Relativity very easily: One leaves unchanged the stress-energy tensor and its equations of motion

$$T^{\mu\nu}{}_{,\nu} = 0, \tag{2.3.1a}$$

but one postulates that this stress-energy generates a gravitational field $\bar{h}^{\mu\nu}$ by the relation

$$\bar{h}^{\mu\nu}(x) = 16\pi \int G(x,x') T^{\mu\nu}(x') d^4x'. \tag{2.3.1b}$$

Here d^4x' is the special relativistic volume element

$$d^4x' \equiv dx^{0'} dx^{1'} dx^{2'} dx^{3'}, \tag{2.3.2}$$

and $G(x,x')$ is the flat-space propagator (Green's function)

$$G(x,x') = \frac{1}{4\pi} \delta_{ret}[1/2(x^\alpha - x^{\alpha'})(x^\beta - x^{\beta'})\eta_{\alpha\beta}], \tag{2.3.3a}$$

$$\delta_{ret} \equiv \begin{cases} \text{Dirac delta function for } x^\alpha \text{ in future of } x^{\alpha'} \\ 0 \qquad\qquad\qquad\qquad \text{for } x^\alpha \text{ in past of } x^{\alpha'}. \end{cases} \tag{2.3.3b}$$

[Notice: (1) in the arguments of $\bar{h}^{\mu\nu}$, G, and $T^{\mu\nu}$ we omit the indices of the coordinates x^α and $x^{\alpha'}$; also (2) by integrating over time, $x^{0'}$, in eq. (2.3.1b) one obtains the expression

$$\bar{h}^{\mu\nu}(x^0, x^j) = 4 \int \frac{T^{\mu\nu}(x^{0'} = x^0 - |\underset{\sim}{x} - \underset{\sim}{x}'|, x^{j'})}{|\underset{\sim}{x} - \underset{\sim}{x}'|} d^3x', \tag{2.3.4}$$

which is familiar from elementary treatises on Linearized Theory; e.g., chapter 18 of MTW.]

The linearized gravitational field (2.3.1b) is a fairly good approximation to the exact general relativistic gravitational field, $\bar{h}^{\alpha\beta} \equiv -[(-g)^{1/2} g^{\alpha\beta} - \eta^{\alpha\beta}]$. It makes fractional errors of order ε. Hence, Linearized Theory has a gravitational order index $n_h = 1$, which is one order "better" than Special Relativity; but its stress-energy order index is the same as that of Special Relativity, $n_T = 1$. The total order of Linearized Theory is $(n_T, n_h) = (1,1)$.

To within the accuracy of Linearized Theory the metric perturbation $h_{\mu\nu}$ is the trace-reversal of $\bar{h}_{\mu\nu}$:

$$h_{\mu\nu} = \bar{h}_{\mu\nu} - 1/2\eta_{\mu\nu} \bar{h}; \quad \bar{h} \equiv \bar{h}_\alpha{}^\alpha. \tag{2.3.5a}$$

(Indices in Linearized Theory are raised and lowered with $\eta_{\mu\nu}$.) Since $h_{\mu\nu}$ and $\bar{h}_{\mu\nu}$ differ only by a trace, the gravitational-wave field in the local wave zone is (cf. eq. 1.3.3)

$$h^{TT}_{jk} = \bar{h}^{TT}_{jk} = P_{ja} P_{kb} \bar{h}_{ab} - 1/2 P_{jk} (P_{ab} \bar{h}_{ab}). \tag{2.3.5b}$$

The fractional errors in this gravitational-wave field are

$$(\text{fractional errors in } \bar{h}^{TT}_{jk}) \equiv \left| \frac{\delta \bar{h}^{TT}_{jk}}{\bar{h}^{TT}_{jk}} \right| = \left| \frac{\delta \bar{h}^{TT}_{jk}}{\bar{h}^{00}} \; \frac{\bar{h}^{00}}{\bar{h}^{TT}_{jk}} \right| \tag{2.3.6}$$

$$\sim \frac{\varepsilon}{|\bar{h}^{TT}_{jk}/\bar{h}^{00}|} \sim \frac{\varepsilon}{|\bar{h}^{TT}_{jk}/Mr^{-1}|} .$$

Here $\bar{h}^{00} \backsim$ (Newtonian potential) $\backsim M/r$ is the largest of the components of the gravitational field; cf. equation (2.1.4b) and footnote 1.

The "rules" for using Linearized Theory to calculate gravitational-wave generation are as follows: (1) Express the special relativistic stress-energy tensor $T^{\mu\nu}$ in terms of the non-gravitational variables of the specific system being analyzed. (2) Solve the special-relativistic equations of motion (2.3.1a) to determine the evolution of the stress-energy tensor. (3) Evaluate the integral (2.3.1b) to determine the first-order gravitational field $\bar{h}^{\mu\nu}$ in the local wave zone. (4) Project out the gravitational-wave field $\bar{h}^{TT}_{jk}$ using equation (2.3.5b). (5) Check, using equation (2.3.6), that the errors in the wave field are acceptably small.

This set of rules shows very clearly the sense in which "Linearized Theory is the theory of order (1,1) obtained by augmenting onto Special Relativity [theory of order (1,0)] field generation equations"; cf. next to last paragraph of § 2.1. In particular, when working in Linearized Theory one at first (Rules 1 and 2) pretends that one is in Special Relativity. Only when one starts evaluating the radiation field (Rules 3 and 4) and its errors (Rule 5) does one depart from Special Relativity.

Recently Press (1977) has transformed the gravitational-wave field (2.3.4) and (2.3.5) of Linearized Theory into the form

$$\bar{h}^{TT}_{jk} = \frac{2}{r}\left\{\frac{d^2}{dt^2}\int [T_{00}+2T_{0p}n_p+T_{pq}n_pn_q]_{ret} x_{j'} x_{k'} \, d^3x'\right\}^{TT}. \tag{2.3.7a}$$

Here "ret" means "evaluated at the retarded time"

$$[T_{00}]_{ret} \equiv T_{00}(t-|\underset{\sim}{x}-\underset{\sim}{x}'|, \underset{\sim}{x}') \tag{2.3.7b}$$

and n_p is the unit radial vector pointing from the source toward the distant observer,

$$n_p \equiv x^p/r \ . \tag{2.3.7c}$$

Press's expression (2.3.7a) is particularly useful for systems in which $|T_{0j}| \ll T_{00}$ and $|T_{jk}| \ll T_{00}$, since then it involves only the second moment of the retarded energy distribution, T_{00ret}. Similar expressions are encountered in the "quadrupole-moment formalism" (eqs. 2.6.4 and 2.6.5 below). However there one requires that the source be confined deep within its own near zone ("slow-motion assumption"), whereas Press's expression requires no such constraint.

Press's expression, appropriately modified, has wider validity than just Linearized Theory: Whenever one has a formalism in which the local-wave-zone field $\bar{h}^{\mu\nu}$ can be written as:

$$\bar{h}^{\mu\nu}(x^0,\underset{\sim}{x})=\frac{4}{r}\int \tau^{\mu\nu}{}_{ret}\, d^3x', \text{ with } \tau^{\mu\nu}{}_{,\nu}=0. \tag{2.3.8}$$

then (as Press emphasizes) expression (2.3.7a) is valid with $T^{\mu\nu}$ replaced by $\tau^{\mu\nu}$ --whatever that animal may be. The weak-field formalisms classified by TK (§2.1 above) all have this property; cf. §II of TK.

2.3.1. A Valid Application of Linearized Theory

Linearized Theory is applicable whenever one can ignore self-gravitational forces inside the source -- i.e., whenever fractional errors

$$\begin{aligned} &|\delta T^{\mu\nu}/T^{00}| \sim \varepsilon \sim (\text{internal gravitational potential}) \\ &|\delta \bar{h}^{TT}_{ij}/\bar{h}^{TT}_{ij}| \sim \frac{\varepsilon}{|\bar{h}^{TT}_{ij}/\bar{h}^{00}|} \end{aligned} \tag{2.3.9}$$

are acceptable. The following is an example of a valid application of Linearized Theory:

A steel bar of mass $M \sim 500$ tons, length $L \sim 20$ meters, and diameter $D \sim 2$ meters generates gravitational waves by rotating end-over-end with angular velocity $\omega \sim 28$ radians per second [Einstein (1918); Eddington (1922); §36.3 of MTW]. (Faster rotation would tear the bar apart.) For such a bar the internal gravitational field is

$$\varepsilon \sim \frac{M}{D} \sim \left(\frac{5\times10^{8}\,g}{2\times10^{2}\,cm}\right)\times\left(\frac{0.7\times10^{-28}\,cm}{g}\right) \sim 2\times10^{-22}. \qquad (2.3.10)$$

The radiation field and the gravitational potential $\bar{h}^{00}$, as calculated from Linearized Theory, turn out to be

$$|\bar{h}^{TT}_{ij}| \sim (ML^2\omega^2/r)\cos[2\omega(t-r) + \text{phase}] \qquad (2.3.11)$$

$$\bar{h}^{00} = 4M/r; \qquad (2.3.12)$$

and the fractional errors in the radiation field (eq. 2.3.6) are thus

$$\left|\frac{\delta\bar{h}^{TT}_{jk}}{\bar{h}^{TT}_{jk}}\right| \sim \frac{\varepsilon}{|\bar{h}^{TT}_{jk}/\bar{h}^{00}|} \sim \frac{\varepsilon}{(\omega L)^2} \qquad (2.3.13)$$

$$\sim \frac{10^{-22}}{[(2\times10^{3}\,cm)(28\,sec^{-1})(3\times10^{10}\,cm/sec)^{-1}]^2} \sim 10^{-11}$$

2.3.2. Invalid Applications of Linearized Theory

For most astrophysical systems internal gravity is important, and Linearized Theory is thus invalid. Examples are as follows:

(1) Gravitational waves from nonradial pulsations of a star. Let the star have mass M and radius R. Then its mean density ρ and its internal gravitational field strength ε are

$$\rho \sim M/R^3, \qquad \varepsilon \sim M/R; \qquad (2.3.14)$$

and its mean pressure [calculated from hydrostatic equilibrium, $dp/dr \sim \rho M/R^2$] is

$$p \sim \rho(M/R) \sim \varepsilon\rho\ . \qquad (2.3.15)$$

Since Linearized Theory makes fractional errors $|\delta T^{\mu\nu}/T^{00}| \sim \varepsilon$, its fractional errors in the pressure are

$$\frac{\delta p}{p} \sim \left|\frac{\delta T^{ij}}{T^{00}}\ \frac{T^{00}}{T^{ij}}\right| \sim \left|\varepsilon\,\frac{\rho}{p}\right| \sim 1. \qquad (2.3.16)$$

Thus, Linearized Theory makes unacceptable errors in the star's internal pressure forces, as well as in its internal gravity.

One should not be surprised to learn that its errors in the gravitational waves due to stellar pulsation are also unacceptably large

$$\left| \frac{\delta \bar{h}^{TT}_{jk}}{\bar{h}^{TT}_{jk}} \right| \gtrsim 1. \qquad (2.3.17)$$

(2) Gravitational waves from a near-encounter between two fast-moving stars. Linearized theory predicts no gravitational interaction between the stars. Therefore, according to Linearized Theory, each star proceeds undisturbed along its straight path through flat space, oblivious of the other star. As a result, no gravitational waves are produced -- an obviously incorrect prediction.

2.4 Post-Linear Theory: A Formalism of Order (2,1)

When analyzing the internal structure and motion of systems with significant self gravity, one needs a formalism which makes fractional errors $|\delta T^{\mu\nu}/T^{00}| \lesssim \varepsilon^2$ ---i.e., which has a stress-energy order index $n_T \geq 2$. The least accurate and least complex such formalism is Post-Linear Theory. It has order $(n_T, n_h) = (2,1)$.

For a derivation of Post-Linear Theory from general relativity theory, see Thorne and Kovács (1975; "TK").

In Post-Linear Theory one describes gravity by a gravitational field ${}_1\bar{h}^{\mu\nu}$, which is a good approximation to the general relativistic field (eq. 2.1.3):

$${}_1\bar{h}^{\mu\nu} = -[\sqrt{-g}\, g^{\mu\nu} - \eta^{\mu\nu}][1 + O(\varepsilon)]. \qquad (2.4.1)$$

Post-Linear Theory, like Special Relativity and Linearized Theory, utilizes the language of flat spacetime. For example, one raises and lowers indices on the gravitational field by means of the flat Lorentz metric $\eta_{\mu\nu}$; and one performs "trace reversals" in the familiar manner of Linearized Theory:

$$ {}_1h^{\mu\nu} = {}_1\bar{h}^{\mu\nu} - 1/2\eta^{\mu\nu}\, {}_1\bar{h}\ ; \quad {}_1\bar{h}^{\mu\nu} = {}_1h^{\mu\nu} - 1/2\eta^{\mu\nu}\, {}_1h; $$

$$ {}_1\bar{h} = -{}_1h = {}_1\bar{h}^{\alpha}_{\alpha} = -{}_1h^{\alpha}_{\alpha} \qquad (2.4.2)$$

(cf. chapter 18 of MTW). The metric of general relativity is approximated by

$$g_{\mu\nu} = \eta_{\mu\nu} + {}_1h_{\mu\nu}\,[1 + O(\varepsilon)]. \qquad (2.4.3)$$

The stress-energy tensor in Post-Linear Theory will typically be expressed in terms of the electromagnetic field $F_{\mu\nu}$, the matter variables (density, pressure, velocity, viscosity,...), and the gravitational field ${}_1\bar{h}^{\mu\nu}$. It must be constructed from these variables in accordance with all the rules of general relativity, to within fractional errors of $O(\epsilon^2)$.

The equations of motion of Post-Linear Theory are formally the same as those of general relativity

$$T^{\mu\nu}{}_{,\nu} + {}_1\Gamma^{\mu}{}_{\alpha\nu}\, T^{\alpha\nu} + {}_1\Gamma^{\nu}{}_{\alpha\nu}\, T^{\mu\alpha} = 0; \qquad (2.4.4a)$$

however, the Christoffel symbols ${}_1\Gamma^{\mu}{}_{\alpha\beta}$ are given by the "first-order approximation"

$${}_1\Gamma^{\mu}{}_{\alpha\beta} = \eta^{\mu\nu}\, {}_1\Gamma_{\nu\alpha\beta} \; ; \; {}_1\Gamma_{\nu\alpha\beta} = ({}_1h_{\nu\alpha,\beta} + {}_1h_{\nu\beta,\alpha} - {}_1h_{\alpha\beta,\nu}). \qquad (2.4.4b)$$

The field equations of Post-Linear Theory are the same as those of Linearized Theory

$${}_1\bar{h}^{\mu\nu,\alpha}{}_{\alpha} = -16\pi\, T^{\mu\nu}; \qquad (2.4.4c)$$

and their solution can be written, using the flat-space propagator (eq. 2.3.3), as

$${}_1\bar{h}^{\mu\nu}(x) = 16\pi \int G(x,x')T^{\mu\nu}(x')d^4x'. \qquad (2.4.5)$$

Notice that Post-Linear Theory differs from Linearized Theory in one crucial, but simple way: It allows the gravitational field ${}_1\bar{h}^{\mu\nu}$ to "push the matter around". [Christoffel symbols have been inserted into the equation of motion; compare eqs. (2.3.1a) and (2.4.4a).] This difference is crucial for astrophysics. It allows Post-Linear Theory to treat accurately the structure and evolution of stars, planets, planetary systems, star clusters, and near stellar encounters -- unless the stars are highly compact (i.e., unless they are neutron stars or black holes). Linearized Theory makes enormous errors on all such systems.

2.5. Post-Linear Wave Generation: A Formalism of Order (2,2)

Despite its fine ability to analyze the internal dynamics of astrophysical systems, Post-Linear Theory does a bad job of predicting their gravitational-wave generation. For wave generation it has no better accuracy than Linearized Theory.

Fortunately, there is a simple way to improve its accuracy. One need only append to it a gravitational field ${}_2\bar{h}^{\mu\nu}$, which is

more accurate than ${}_1\bar{h}^{\mu\nu}$:

$$ {}_2\bar{h}^{\mu\nu} = -[\sqrt{-g}\, g^{\mu\nu} - \eta^{\mu\nu}][1 + 0(\varepsilon^2)]. \qquad (2.5.1) $$

By appending ${}_2\bar{h}^{\mu\nu}$ onto Post-Linear Theory, one boosts its accuracy from order (2,1) to order (2,2). The resulting formalism, called the "Post-Linear Wave-Generation Formalism," bears the same relationship to Post-Linear Theory as Linearized Theory does to Special Relativity.

TK have derived a formula for ${}_2\bar{h}^{\mu\nu}$ in terms of ${}_1\bar{h}^{\mu\nu}$ and $T^{\mu\nu}$. Their formula involves the flat-space propagator

$$ G(x,x') = \frac{1}{4\pi}\, \delta_{ret}[1/2(x^\alpha - x^{\alpha'})(x^\beta - x^{\beta'})\eta_{\alpha\beta}] \qquad (2.5.2a) $$

[eq. (2.3.3)], and also its derivative with respect to the argument of the delta function

$$ G'(x,x') = \frac{1}{4\pi}\, \delta'_{ret}[1/2\,(x^\alpha - x^{\alpha'})(x^\beta - x^{\beta'})\eta_{\alpha\beta}]; \qquad (2.5.2b) $$

$$ \delta'_{ret}(z) \equiv (d/dz)\, \delta_{ret}(z). $$

The TK formula splits ${}_2\bar{h}^{\mu\nu}$ into five pieces

$$ {}_2\bar{h}^{\mu\nu} = {}_2\bar{h}^{\mu\nu}_D + {}_2\bar{h}^{\mu\nu}_F + {}_2\bar{h}^{\mu\nu}_{TL} + {}_2\bar{h}^{\mu\nu}_{TR} + {}_2\bar{h}^{\mu\nu}_W. \qquad (2.5.3) $$

Each piece has a particular physical interpretation. However, one must be careful not to take that interpretation too seriously -- for reasons discussed below. The five pieces are as follows:

Direct field, ${}_2\bar{h}^{\mu\nu}_D$. This field is produced directly by the Post-Linear stress-energy tensor $T^{\mu\nu}$; and it propagates from the source point $x^{\alpha'}$ to the field point x^α by means of the flat-space propagator. In other words, it propagates along the flat-space light cone with parallel-propagation of components and with a "1/r" fall-off of amplitude. The formula for this direct field is

$$ {}_2\bar{h}^{\mu\nu}_D(x) = 16\pi \int G(x,x')T^{\mu\nu}(x')[1 - {}_1\bar{h}(x')]d^4x'. \qquad (2.5.4) $$

This part of ${}_2\bar{h}^{\mu\nu}$ is $\sim M/r$, whereas the other four parts are typically $\lesssim M/r$.

Focussing field, ${}_2\bar{h}^{\mu\nu}_F$. When the gravitational field generated at $x^{\alpha'}$ propagates through regions of nonzero Ricci curvature -- i.e., through matter --, it gets focussed. This focussing increases

the amplitude of ${}_2\bar{h}^{\mu\nu}$, without changing its directionality (i.e., without changing the relative magnitude of its components). The amount of focussing between a source point x^α and a field point x^α is described by the "focussing function"

$$\alpha(x,x') \equiv 1/2\ X^\alpha X^\beta \int_0^1 {}_1R_{\alpha\beta}(x^{\mu'} + \lambda X^\mu)\lambda(1-\lambda)d\lambda, \qquad (2.5.5a)$$

$$X^\alpha \equiv x^\alpha - x^{\alpha'}.$$

Here ${}_1R_{\alpha\beta}(x^{\mu'} + \lambda X^\mu)$ is the first-order Ricci tensor, (calculated from $g_{\alpha\beta} = \eta_{\alpha\beta} + {}_1h_{\alpha\beta}$), evaluated at the event $x^{\mu'} + \lambda X^\mu$, which lies a fraction λ of the way along the straight line between source point and field point. A formula for ${}_1R_{\alpha\beta}$ is

$${}_1R_{\alpha\beta} = -1/2\ {}_1h_{\alpha\beta,\rho}{}^{,\rho} = 8\pi(T_{\alpha\beta} - 1/2\eta_{\alpha\beta}T). \qquad (2.5.5b)$$

For intuition into the focussing function, see Figure 3. In terms of the focussing function α, the flat-space propagator G, and the stress-energy tensor $T^{\mu\nu}$, the focussing field is

$${}_2\bar{h}_F^{\mu\nu}(x) = 16\pi \int \alpha(x,x')G(x,x')T^{\mu\nu}(x')d^4x'. \qquad (2.5.5c)$$

Tail Field, ${}_2\bar{h}_{TL}^{\mu\nu}$. Consider the gravitational field ${}_2\bar{h}^{\mu\nu}$ generated at an event $x^{\alpha'}$. It has a "wave front" that propagates outward, initially spherically and initially along the future light cone of $x^{\alpha'}$. However, focussing produces dimples in the wave front; and dimpling, when analyzed from the viewpoint of Huygens' principle, produces waves that radiate outward from the dimpled region in all directions. (See Figure 4.) The result is a "tail" of the wave field. Let a wave originating at $x^{\alpha'}$ arrive at an event $x^{\alpha''}$, with a dimple in its wave front due to focussing. The amplitude $\beta(x'', x')$ for this dimple to produce a tail is given by

$$\beta(x'',x') = X^{\alpha''} X^{\beta''} \int_0^1 {}_1R_{\alpha\beta}(x^{\mu'} + \lambda X^{\mu''})\lambda^2 d\lambda, \qquad (2.5.6a)$$

$$X^{\alpha''} \equiv x^{\alpha''} - x^{\alpha'}. \qquad (2.5.6b)$$

This amplitude is called the "tail-generating function." The tail which it generates is given by

$$\bar{h}_{TL}^{\mu\nu}(x) = -16\pi \iint_{x'\varepsilon I^-(x)} G(x,x'')\beta(x'',x')G'(x'',x')T^{\mu\nu}(x')d^4x''d^4x'. \qquad (2.5.6c)$$

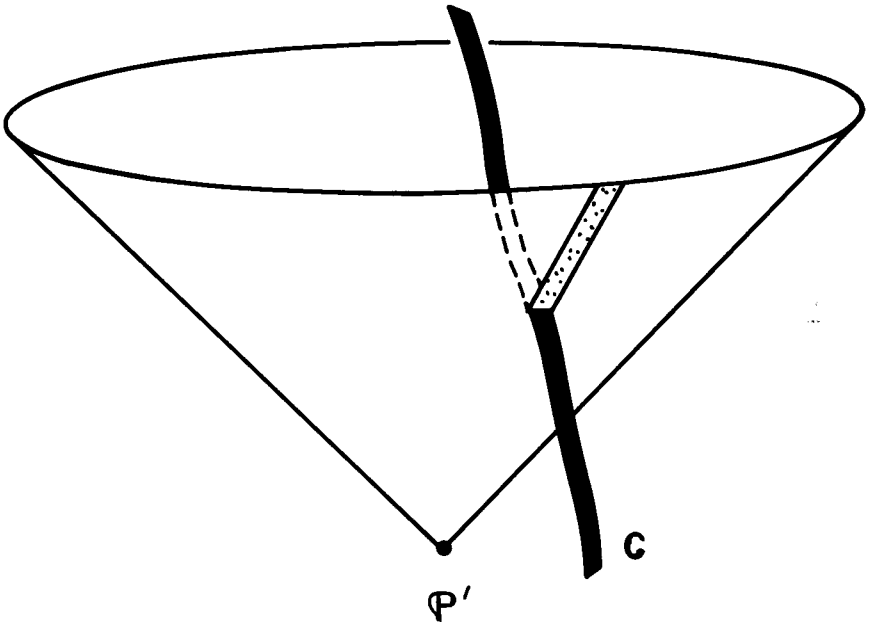


Figure 3. The region of focussing for a gravitational field generated at $\mathcal{P}'$, which propagates through spacetime containing a lump of matter (world tube $\mathcal{C}$). Focussing occurs, and α and $\bar{h}^{\mu\nu}_{\mathrm{F}}$ are nonzero, in the stippled region--i.e., in the region containing rays that have passed through the lump.

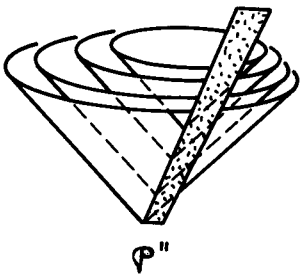

Figure 4. The tail of the gravitational field described in Figure 3. In the region of focussing (stippled region) the tail-generating function β is non-zero. Thus, each point $\mathcal{P}''$ in the stippled region is a source of tail -- and the tail propagates outward from each such $\mathcal{P}''$ along its future light cone.

Here the expression $x' \in I^-(x)$ means that the integration must extend over source points $x^{\alpha'}$ that lie inside but not on the past (flat-space) light cone of x^α.

Transition Field, $_2\bar{h}^{\mu\nu}_{TR}$. The gravitational field $_2\bar{h}^{\mu\nu}$ generated at an event $x^{\alpha'}$ does not really propagate along light cones of the (fictitious) flat space of Post-Linear Theory. Rather, it propagates along light cones of the slightly curved metric $g_{\mu\nu} = \eta_{\mu\nu} + {}_1h_{\mu\nu}$. The result is a time delay relative to flat-space propagation -- a delay measured, for example, in the "Shapiro radar time-delay experiment" (Shapiro 1964; §40.4 of MTW). The direct field (eq. 2.5.4) fails to take this time delay into account. Therefore, one must correct it for the effects of the time delay. The "transition field" $_2\bar{h}^{\mu\nu}_{TR}$ does that correcting. The correction is embodied in a "time-delay function"

$$\gamma(x,x') = \tfrac{1}{2}X^\alpha X^\beta \int_0^1 {}_1h_{\alpha\beta}(x^{\mu'} + \lambda X^\mu)d\lambda, \qquad (2.5.7a)$$

$$X^\mu \equiv x^\mu - x^{\mu'}. \qquad (2.5.7b)$$

For two events x and x' separated by a distance ℓ in the laboratory frame, this time-delay function is

$$\gamma(x,x') = \ell\Delta t_s, \qquad (2.5.7c)$$

where Δt_s is the "Shapiro time delay" (difference between curved-space and flat-space propagation times). In terms of this time-delay function, the transition field is given by[2]

$$\bar{h}^{\mu\nu}_{TR}(x) = 16\pi \int \gamma(x,x')G'(x,x')T^{\mu\nu}(x')d^4x'. \qquad (2.5.7d)$$

The name "transition field" is taken from electromagnetic theory: When a charged particle moves, with uniform velocity, through a medium of variable index of refraction, it radiates. The radiation (called "electromagnetic transition radiation") is caused by variations in the speed of propagation of the particle's Coulomb field.

[2]The expression for $\bar{h}^{\mu\nu}_{TR}$ given by TK differs slightly from eq.(2.5.7d): TK have to "truncate the external time delay" because they do not restrict attention to the local wave zone, wher the external delay is negligible.

The "gravitational transition field" (2.5.7d) has a similar origin: It is caused by variations in the "flat-space" speed of propagation of the particle's direct ("Coulomb") gravitational field.

Whump field, $_2\bar{h}^{\mu\nu}_W$. The gravitational field $_2\bar{h}^{\mu\nu}$ is generated not only by the material stress-energy tensor $T^{\mu\nu}$, but also by "gravitational stresses." For example, when two stars go flying past each other at high speed, their relative gravitational potential energy builds up quickly, then dies out quickly (i.e., goes "whump"), and in doing so it produces a burst of second-order gravitational field. TK call this field the "whump field", not only in the case of stellar fly-by, but also in general. The "gravitational stresses" $W^{\mu\nu}$ which generate it are a certain sum of products of first derivatives of $_1\bar{h}^{\alpha\beta}$; in particular,

$$W^{\mu\nu} \equiv {}_1t^{\mu\nu}_{LL} + (16\pi)^{-1}\, {}_1\bar{h}^{\mu\rho}{}_{,\sigma}\, {}_1\bar{h}^{\nu\sigma}{}_{,\rho} \tag{2.5.8a}$$

where $_1t^{\mu\nu}$ is the "Landau-Lifshitz pseudotensor," accurate up to fractional errors $\sim \varepsilon$:

$$\begin{aligned} {}_1t^{\alpha\beta}_{LL} = (16\pi)^{-1} \Big\{ &\tfrac{1}{2}\eta^{\alpha\beta}\, {}_1\bar{h}_{\lambda\nu,\rho}\, {}_1\bar{h}^{\lambda\rho,\nu} + {}_1\bar{h}^{\alpha}{}_{\lambda,\nu}\, {}_1\bar{h}^{\beta\lambda,\nu} \\ &-({}_1\bar{h}_{\nu\rho}{}^{,\alpha}\, {}_1\bar{h}^{\beta\nu,\rho} + {}_1\bar{h}_{\nu\rho}{}^{,\beta}\, {}_1\bar{h}^{\alpha\nu,\rho}) + \tfrac{1}{2}\, {}_1\bar{h}_{\lambda\nu}{}^{,\alpha}\, {}_1\bar{h}^{\lambda\nu,\beta} \\ &-\tfrac{1}{4}\eta^{\alpha\beta}\, {}_1\bar{h}_{\lambda\nu,\rho}\, {}_1\bar{h}^{\lambda\nu,\rho} - \tfrac{1}{4}\, {}_1\bar{h}^{,\alpha}\, {}_1\bar{h}^{,\beta} + \tfrac{1}{8}\eta^{\alpha\beta}\, {}_1\bar{h}_{,\lambda}\, {}_1\bar{h}^{,\lambda} \Big\}. \end{aligned} \tag{2.5.8b}$$

In terms of these stresses, the whump field is

$$ {}_2\bar{h}^{\mu\nu}_W(x) = 16\pi \int G(x,x')W^{\mu\nu}(x')\,d^4x'. \tag{2.5.8c}$$

The gravitational waves emitted by a Post-Linear source are described by the "tranverse, traceless part" of $_2\bar{h}^{\mu\nu}$, evaluated in the local wave zone

$$h^{TT}_{jk} = \bar{h}^{TT}_{jk} = P_{ja}\, {}_2\bar{h}_{ab}\, P_{bk} - \tfrac{1}{2} P_{jk}(P_{ab}\, {}_2\bar{h}_{ab}). \tag{2.5.9}$$

Here P_{jk} is the usual transverse projection tensor(eq. 1.3.4).

In the local wave zone $_2\bar{h}^{\mu\nu}$ satisfies the flat-space Einstein field equations $_2\bar{h}^{\mu\nu}{}_{,\alpha\beta}\eta^{\alpha\beta} = 0$ and the flat-space "Lorentz gauge condition" $_2\bar{h}^{\mu\nu}{}_{,\nu} = 0$, except for fractional errors of $O(\varepsilon^2)$. As a consequence, the gravitational-wave field h^{TT}_{jk}

transforms, under Lorentz transformations, in the usual manner for a field of spin two and zero rest mass.

Unfortunately, each of the five individual pieces of ${}_2\bar{h}^{\mu\nu}$, by itself, fails to satisfy the gauge condition. As a consequence, the transverse-traceless part of each piece (e.g., $[{}_2\bar{h}^{jk}_{TL}]^{TT}$) fails to transform as a spin-two, zero-rest-mass field. This fact prevents one from attributing a rigorous physical significance to each of the five pieces by itself. The physical interpretations given above are therefore somewhat heuristic. For further discussion, see TK, and also §VIc of Kovács and Thorne (1977a).

Crowley and Thorne (1977; their eq. 37) have derived several potentially useful formulas for the sum of the focussing, tail, and transition fields. An example is:

$$ {}_2\bar{h}^{\mu\nu}_F(x) + {}_2\bar{h}^{\mu\nu}_{TL}(x) + {}_2\bar{h}^{\mu\nu}_{TR}(x) = $$

$$ = -\frac{\partial}{\partial x^\alpha}\int G(x,x')\, {}_1\bar{h}^{\alpha\beta}(x')\frac{\partial}{\partial x^\beta}\, {}_1\bar{h}^{\mu\nu}(x')d^4x'. \qquad (2.5.10) $$

Crowley and Thorne also examine the issue of when one can combine the Post-Linear Wave-Generation Formalism with a point-particle description of gravitating bodies. The answer is non-trivial: Some sets of post-linear formulas are compatible with point-particle descriptions of matter; others are not.

The accuracy of the Post-Linear Wave-Generation Formalism is a slightly delicate issue. Until one looks closely, one expects

$$ (\text{fractional errors in } {}_2\bar{h}^{\mu\nu}) \sim \varepsilon^2; \qquad (2.5.11a) $$

$$ (\text{fractional errors in } {}_2\bar{h}^{TT}_{jk}) \sim \frac{\varepsilon^2}{|\bar{h}^{TT}_{jk}/\bar{h}^{00}|}\ . \qquad (2.5.11b) $$

However, the formalism as expounded above relies on two approximations which can sometimes produce larger errors than (2.5.11): First, it assumes that focussing is small -- i.e., that the focussing function satisfies

[3] See, e.g., §III.B of Eardley, Lee, and Lightman (1974), with the change of notation $\underset{\sim}{e}_{\hat{z}} \to \underset{\sim}{n} = \underset{\sim}{e}_{\hat{r}}$ = (unit radial vector), $\underset{\sim}{e}_{\hat{x}} \to \underset{\sim}{e}_{\hat{\theta}}$ = (unit vector in θ direction), $\underset{\sim}{e}_{\hat{y}} \to \underset{\sim}{e}_{\hat{\varphi}}$ = (unit vector in φ direction), and with specialization to the spin-2 case, $\Psi_2 = \Psi_3 = \Phi_{22} = 0$; and also Thorne (1977d).

$$|\alpha(x,x')| << 1 \text{ for all } x' \text{ inside source and } x \text{ in local wave zone.} \qquad (2.5.12)$$

Second, it assumes that the Shapiro time delays inside the source are short compared to the characteristic timescale for the source's motion -- i.e., that Δt_s (eq. 2.5.7c) and the reduced wavelength of the radiation, $\lambda\!\!\!^{-}$, satisfy

$$\Delta t_s \ll \lambda\!\!\!^{-} . \qquad (2.5.13)$$

These assumptions could be dropped, but only at the cost of making the formalism somewhat more complicated than it already is.

For realistic sources the "short-Shapiro-time-delay" assumption (2.5.13) is generally satisfied. However, one can readily imagine interesting weak-field sources ($\varepsilon << 1$) which violate the "small-focussing assumption." For example, for two stars of mass m and size ℓ separated by a distance $b >> \ell$, the focussing function for rays originating in one star and passing through the other is

$$\alpha \sim (b/\ell)(m/\ell) \sim 10^{-6}\ (b/\ell)(m/M_\odot)(\ell/R_\odot)^{-1} . \qquad (2.5.14)$$

This can be $\gtrsim 1$ for sufficiently large separations b.

The small-focussing and short-Shapiro-time-delay assumption force one to modify the error estimates (2.5.11). The correct error estimates are

$$(\text{fractional errors in } {}_2\bar{h}^{\mu\nu}) \sim \text{maximum } (\varepsilon^2, \varepsilon\alpha, \varepsilon\Delta t_s/\lambda\!\!\!^{-}), \qquad (2.5.15a)$$

$$(\text{fractional errors in } {}_2\bar{h}^{TT}_{jk}) \sim$$

$$\sim \frac{\text{maximum } (\varepsilon^2,\ \varepsilon\alpha,\ \varepsilon\Delta t_s/\lambda\!\!\!^{-})}{|\bar{h}^{TT}_{jk}/\bar{h}^{00}|} . \qquad (2.5.15b)$$

The "rules" for using the Post-Linear Wave-Generation Formalism are as follows: (1) Express the Post-Linear stress-energy tensor $T^{\mu\nu}$ in terms of the nongravitational variables of the specific system being analyzed, and in terms of the first-order gravitational field ${}_1\bar{h}^{\mu\nu}$. Do so in the manner of general relativity, up to fractional errors of $O(\varepsilon^2)$. (2) Solve the coupled Post-Linear equations of motion (2.4.4a) and Post-Linear gravitational field equations (2.4.4c) for the evolution of the source and its

first-order gravitational field ${}_1\bar{h}^{\mu\nu}$. (3) Evaluate the integrals (2.5.3)-(2.5.8) for field points in the local wave zone to determine th five pieces of the second-order gravitational field ${}_2\bar{h}^{\mu\nu}$. Project out the gravitational-wave field $\bar{h}^{TT}_{jk}$ in the local wave zone using equation (1.3.3) (5) Check, using equation (2.5.15b), that the errors in the wave field are acceptably small.

2.5.1. Sample Applications

The Post-Linear Wave-Generation Formalism can be applied, with good accuracy, to most astrophysical systems. For example, it can be applied to the two systems of §2.3.2, in which Linearized Theory was a failure: pulsations of a noncompact star, and near-encounters between fast-moving stars.

Actually, for the stellar pulsation problem -- and for any other problem characterized by slow internal motions (speeds much less than that of light) -- one need not resort to the Post-Linear Formalism in its full complexity. Rather, one can apply a slow-motion variant of the formalism (§2.6 below).

However, for systems with fast motion and weak but significant internal gravity, the Post-Linear Formalism is the simplest formalism that will do the full job. An example is "gravitational Bremsstrahlung radiation" produced in a near-encounter between nearly Newtonian stars ($M/R \ll 1$), which fly past each other with a relative velocity $v \gtrsim 0.1$ x (speed of light). This example is treated in detail by Kovács and Thorne (1977a,b). [Limiting cases and special features of the Bremsstrahlung problem are actually amenable to other techniques, which I do not review in these lectures. These include the Feynman-diagram method (originally designed for quantum gravity problems, but also applicable to classical problems; see Feynman 1963); the method of virtual quanta (Matzner and Nutku 1974); the method of Green's functions for the linearized Schwarzschild metric (a special case of the perturbation methods of §5 below; Peters 1970); and a new colliding-plane-waves tecnique (D'Eath 1977)].

2.6. The Slow-Motion Limit of the Post-Linear Formalism: Newtonian Theory [Order (2,1)] and Quadrupole-Moment Formalism [Order (2,2)]

Most astrophysical systems have not only weak internal gravity, $\varepsilon \ll 1$, but also slow internal motions and weak internal stresses. For such systems the Post-Linear Formalism of §2.4, which has order (2,1), reduces to the Newtonian Theory of Gravity; and the Post-Linear Wave-Generation Formalism of §2.5, which has order (2,2), reduces to the Quadrupole-Moment Wave-Generation Formalism. I shall briefly summarize these formalisms and their realms of validity. For details of the slow-motion transition from the Post-Linear Formalism to these formalisms, see TK. For derivations of these formalisms assuming slow motion from the beginning see, e.g., § 104 of Landau and Lifshitz (1962) or chapter 36 of MTW.

Realm of validity: One can characterize a slow-motion, weak-field system by the following parameters:

$M \equiv$ (mass of system)

$L \equiv$ (size of system)

$\lambda\!\!\!^{-} \equiv$ (characteristic timescale of system) = (reduced wavelength of radiation)

$v \equiv (|T^{0j}|/T^{00})_{max}$ = (maximum internal velocity) (2.6.1)

$S \equiv (|T^{ij}|/T^{00})_{max}$ = (maximum of stress/density)

$\varepsilon \equiv$ (magnitude of internal gravity) $\sim M/L$.

For a static system $\lambda\!\!\!^{-}$ is not zero; rather, it is the characteristic timescale for perturbations against which one hopes the system is stable (e.g., for small-amplitude pulsations, if the system is a static star).

Newtonian Gravitation Theory and the Quadrupole-Moment Formalism require for their validity the following conditions:

Weak gravity: $\varepsilon \ll 1$ (2.6.2a)

Slow motion: $L/\lambda\!\!\!^{-} \ll 1$, which implies $v \ll 1$ (2.6.2b)

Small Stresses: $S^2 \ll 1$, (2.6.2c)

System not near marginal stability:
$$\begin{cases} \omega^2 \equiv (1/\lambda\!\!\!^{-})^2 \gg (M/L)(M/L^3) \\ \omega^2 \equiv (1/\lambda\!\!\!^{-})^2 \gg S^2 (S/L)^2 \end{cases} \quad (2.6.2d)$$

[If the last condition is violated, then post-Newtonian gravitational forces may affect significantly the stability of the system and its motion; cf. Chandrasekhar (1964), or Boxes 24.2 and 26.2 of MTW.]

Newtonian Theory Summarized: Newtonian Theory describes gravity by a scalar gravitational potential U, and describes matter by its mass density ρ, its velocity v_j, and the stress t_{jk} measured in its rest frame. The equations of the theory are: (1) conservation of mass

$$\rho_{,t} + (\rho v_j)_{,j} = 0; \tag{2.6.3a}$$

(2) "Euler" equations of motion

$$\rho(v_{j,t}+v_{j,k}v_k) = \rho U_{,j} - t_{jk,k}; \tag{2.6.3b}$$

(3) gravitational field equation

$$U_{,jj} = -4\pi\rho, \tag{2.6.3c}$$

which has the solution

$$U(\underset{\sim}{x},t) = \int \frac{\rho(\underset{\sim}{x}',t)}{\left|\underset{\sim}{x} - \underset{\sim}{x}'\right|} \, d^3x'. \tag{2.6.3d}$$

For further details see, e.g., §39.7 of MTW.

Quadrupole-Moment Formalism Summarized: To calculate the gravitational waves from a nearly Newtonian system, one can proceed as follows: (1) Specify, by an equation of state, or viscosity, or some other method, the dependence of the stresses t_{jk} on ρ, v_j, and other variables of the system. (2) Solve the Newtonian equations (2.6.3) to determine the structure and evolution of the system. (3) Calculate the gravitational-wave amplitude h^{TT}_{jk} in the local wave zone using the following formula:

$$h^{TT}_{jk} = \frac{2}{r}\left[\ddot{\mathcal{I}}_{jk}(t-r)\right]^{TT}. \tag{2.6.4}$$

Here $\mathcal{I}_{jk}(t)$ is the "reduced quadrupole moment" of the source at time t

$$\mathcal{I}_{jk}(t) = \int \rho(t,\underset{\sim}{x}') \left[x^{j'} x^{k'} - \frac{1}{3}\delta^{jk}(\underset{\sim}{x}')^2\right] d^3x'; \tag{2.6.5}$$

$\ddot{\mathcal{I}}_{jk}$ is the second time derivative of $\mathcal{I}_{jk}$; r is distance from the source to the field point; and "TT" denotes the transverse-

traceless projection process of equation (1.3.3). (4) Verify that the "conditions of validity" (2.6.2) are satisfied.

2.6.1. Sample Applications

The quadrupole-moment formalism has been used more widely in gravitational-wave calculations than any other wave-generation formalism. Examples of its application are: the waves emitted by quadrupole pulsations of a star [see, e.g., Wheeler (1966)]; the waves emitted by orbital motion of a binary star system [see, e.g., Peters and Mathews (1963)]; the gravitational bremsstrahlung radiation from low-velocity near-encounters of two stars [low velocity limit of the problem described in §2.5.1; see, e.g., Ruffini and Wheeler (1971)]; and the "tidal gravitational radiation" produced when a Newtonian star is tidally deformed by passage near a black hole or other star [Mashoon (1973), Turner (1977)].

2.7 The Post-Newtonian Wave-Generation Formalism [Order (3,3)]

For systems with slow, but not extremely slow motions (e.g., $v \sim 0.3$), and weak, but not extremely weak gravity (e.g., $\varepsilon \backsim 0.1$), one needs a gravitational-wave formalism of higher accuracy than the Quadrupole-Moment Formalism. More specifically, one needs a formalism that takes account of Post-Newtonian effects in the structure and evolution of the system.

Epstein and Wagoner (1975) have devised such a formalism. Like all Post-Newtonian formalisms, it is valid only for gravitationally bound, or nearly gravitationally bound systems -- i.e., for systems with

$$v^2 \lesssim \varepsilon, \qquad S^2 \lesssim \varepsilon \tag{2.7.1a}$$

[cf. eq. (2.6.1)]; and it requires moderately weak internal gravity

$$\varepsilon \lesssim 0.1. \tag{2.7.1b}$$

The Epstein-Wagoner "Post-Newtonian Wave-Generation Formalism" has the following structure: (1) First one calculates the structure and evolution of the source using a Post-Newtonian Formalism of order $(n_T, n_h) = (3,2)$ -- e.g., the perfect-fluid Post-Newtonian formalism of Chandrasekhar (1965). (2) Then one evaluates the radiation field in the local wave zone using formulas to be given below (§4.5). [These formulas boost the order of the formalism up to $(n_T, n_h) = (3,3)$.] (3) Finally one verifies that the emitting system satisfies the Post-Newtonian validity conditions (2.7.1).

I delay presenting the Epstein-Wagoner equations until after I have treated multipole-moment formalisms, because Epstein and Wagoner utilize multipole moments in a nontrivial fashion.

2.7.1. Sample Applications

The Epstein-Wagoner formalism is being used in two different ways by the Stanford relativity group: (i) They use it to study deviations from the quadrupole-moment formalism for systems with moderately strong internal gravity or moderately high velocities or both [e.g. for moderately relativistic binary systems, and for stellar flybies at moderately high velocity (gravitational bremsstrahling); see Wagoner and Will (1976)]. (ii) They use it to seek insight into highly relativistic situations [e.g. waves from the collapse of a rotating star to form a black hole; Epstein (1976), Wagoner (1977)], where one can hope for, but is not guaranteed, more reliable results than from the quadrupole-moment formalism.

3. MULTIPOLE-MOMENT ANALYSIS OF THE RADIATION FIELD

3.1. Gravitational-Wave Field

I now wish to turn attention from weak-field formalisms to slow-motion formalisms. But before doing so, I must digress into a topic which is needed as an underpinning for the slow-motion discussion. This topic is the multipole structure of the gravitational-wave field for any isolated source. A number of researchers (not including me) have made major contributions to this subject; see end of §3.3 for references. Recently, I have taken the various contributions, have exhibited the relationships between some of their notations, and have tried to consolidate them into a single formalism in which (to me) the notation looks optimal. The following review of the subject is based on that work (Thorne 1977a--which I shall cite henceforth as TV, since it is Paper V in a series).

Consider the gravitational-wave field h^{TT}_{jk} in the local wave zone of an isolated source. The local wave zone is so constructed [eqs. (1.2.2)-(1.2.5)] that in it one can regard the background on which the waves propagate as completely flat. Consequently, the waves have the radially-propagating, flat-space form

$$h^{TT}_{jk} = r^{-1} A_{jk}(t - r,\theta,\phi) \qquad (3.1.1)$$

where A_{jk} is a symmetric, transverse, traceless amplitude that depends on retarded time $u = t - r$ and on angular location (θ,ϕ) around the source. The fact that A^{TT}_{jk} is symmetric,

transverse, and traceless is embodied in the algebraic relations

$$\text{Symmetry:} \quad A_{jk} = A_{kj}, \tag{3.1.2a}$$

$$\text{Transverse:} \quad A_{jk}n_k = 0, \text{where } \underset{\sim}{n} \equiv \underset{\sim}{x}/r = \text{unit radial vector}, \tag{3.1.2b}$$

$$\text{Traceless:} \quad A_{jj} = 0. \tag{3.1.2c}$$

It is often useful to expand the wave amplitude A_{jk} in spherical harmonics, and to identify the coefficients of the expansion as the multipole moments of the radiation field. In these lectures I shall follow the notation of Sachs (1961), Pirani (1965), MTW (Chap. 36), and TV (Thorne 1977a), which uses symmetric, trace-free tensors to represent spherical harmonics. The formalism of symmetric, trace-free tensors is described briefly in the next section.

3.2. Symmetric, Trace-Free Tensors and Spherical Harmonics

Let $\underline{A}$ be a symmetric, constant (position-independent) tensor of rank ℓ defined in 3-dimensional, flat space. We shall denote its components in a Cartesian coordinate system by $A_{k_1\ldots k_\ell}$, and the components of its completely symmetric part by $A_{(k_1\ldots k_\ell)}$:

$$A_{(k_1\ldots k_\ell)} \equiv \frac{1}{\ell!} \sum_{\pi} A_{k_{\pi(1)}\ldots k_{\pi(\ell)}}. \tag{3.2.1}$$

Here the summation goes over all $\ell!$ permutations, π, of $1\ldots\ell$. We shall denote the trace-free, symmetric part of $\underline{A}$ by the corresponding capital script letter, $\mathcal{A}$:

$$\mathcal{A}_{k_1\ldots k_\ell} = \sum_{n=0}^{[\ell/2]} (-1)^n \frac{\ell!(2\ell-2n-1)!!}{(\ell-2n)!(2\ell-n)!!(2n)!!} \times \tag{3.2.2}$$

$$\times \delta_{(k_1k_2} \cdots \delta_{k_{2n-1}k_{2n}} S_{k_{2n+1}\ldots k_\ell)j_1j_1\cdots j_nj_n}.$$

Here δ_{ab} = (Kronecker delta) are the components of the metric, $[\ell/2]$ means the largest integer less than or equal to $\ell/2$, $S_{k_1\ldots k_\ell} \equiv A_{(k_1\ldots k_\ell)}$, and the "double factorial" $(2n)!!$ is defined by (3.2.8) below.

Consider the set of all symmetric, trace-free tensors of rank ℓ ("STF-ℓ tensors"). The STF-ℓ tensors generate an irreducible representation of the rotation group, of weight ℓ. Hence, there

exists a one-to-one mapping between them and the spherical harmonics of order ℓ. To exhibit that mapping we introduce the unit radial vector $\underset{\sim}{n}$ of our Euclidean space, and we express its Cartesian components in terms of spherical coordinates, θ and ϕ :

$$\underset{\sim}{n}=\underset{\sim}{x}/|\underset{\sim}{x}|, \quad n_1+in_2=\sin\theta\, e^{i\phi}, \quad n_3=\cos\theta. \tag{3.2.3}$$

From the usual expression for the spherical harmonic $Y^{\ell m}(\theta,\phi)$ in terms of $\cos\theta$ and $\sin\theta\, e^{i\phi}$, it is easy to show [see pp. 289-290 of Pirani (1965) or see TV] that

$$Y^{\ell m}(\theta,\phi)=\mathcal{Y}^{\ell m}_{k_1\ldots k_\ell}\, n_{k_1}\ldots n_{k_\ell}. \tag{3.2.4}$$

Here $\mathcal{Y}^{\ell m}_{k_1\ldots k_\ell}$ is the following STF-ℓ tensor

$$\mathcal{Y}^{\ell m}_{k_1\ldots k_\ell} \equiv C^{\ell m} \sum_{j=0}^{[(\ell-m)/2]} a^{\ell m j}(\delta^1_{k_1}+i\delta^2_{k_1})\ldots(\delta^1_{k_m}+i\delta^2_{k_m})\cdot$$

$$\cdot\,\delta^3_{k_{m+1}}\ldots\delta^3_{k_{\ell-2j}}(\delta^{a_1}_{k_{\ell-2j+1}}\delta^{a_1}_{k_{\ell-2j+2}})\ldots(\delta^{a_j}_{k_{\ell-1}}\delta^{a_j}_{k_\ell}) \text{ for } m\geq 0, \tag{3.2.5}$$

$$\mathcal{Y}^{\ell m}_{k_1\ldots k_\ell} \equiv (-1)^m(\mathcal{Y}^{\ell\,-m}_{k_1\ldots k_\ell})^* \quad \text{for} \quad m<0.$$

$$C^{\ell m}\equiv(-1)^m\left[\frac{2\ell+1}{4\pi}\,\frac{(\ell-m)!}{(\ell+m)!}\right]^{1/2}, \quad a^{\ell m j}\equiv\frac{(-1)^j(2\ell-2j)!}{2^\ell j!(\ell-j)!(\ell-m-2j)!}.$$

Here $[(\ell-m)/2]$ means the largest integer less than or equal to $(\ell-m)/2$, and * means complex conjugate.

Henceforth, to simplify notation, when we encounter a sequence of many (say ℓ) indices on a tensor we shall denote it as follows

$$S_{A_\ell} \equiv S_{a_1\ldots a_\ell}. \tag{3.2.6a}$$

Similarly we shall abbreviate the tensor product of ℓ unit radial vectors by

$$N_{B_\ell} \equiv n_{b_1}\ldots n_{b_\ell}. \tag{3.2.6b}$$

In this abbreviated notation equation (3.2.4) says

$$Y^{\ell m}(\theta,\phi) = \mathcal{Y}^{\ell m}_{K_\ell} N_{K_\ell} . \qquad (3.2.4')$$

Thus, capital subscript letters denote sequences of lower-case subscript indices; and the number of indices in a sequence is denoted by a subscript to the capital subscript.

The tensors $\mathcal{Y}^{\ell m}_{K_\ell}$ with $-\ell \le m \le +\ell$ serve two roles: First, they generate the spherical harmonics of order ℓ (eq. 3.2.4'). Second, they form a basis for the $(2\ell+1)$-dimensional vector space of STF-ℓ tensors; i.e., any STF-ℓ tensor $\mathcal{F}$ can be expanded as

$$\mathcal{F}_{K_\ell} = \sum_{m=-\ell}^{\ell} F^{\ell m} \mathcal{Y}^{\ell m}_{K_\ell} . \qquad (3.2.7a)$$

The tensor components $\mathcal{F}_{K_\ell}$ are real if and only if $F^{\ell -m} = (-1)^m F^{\ell m}$. The expansion (3.2.7a) can be inverted as follows (see, e.g., TV)

$$F^{\ell m} = 4\pi \frac{\ell!}{(2\ell+1)!!} \mathcal{F}_{K_\ell} \mathcal{Y}^{\ell m}_{K_\ell} \qquad (3.2.7b)$$

where the "double factorial" is defined by

$$n!! \equiv n(n-2)(n-4)\ldots(2 \text{ or } 1). \qquad (3.2.8)$$

In practical calculations one can use spherical harmonics and STF-ℓ tensors interchangeably: Consider any sphere centered on the coordinate origin, and on that sphere consider any scalar function $f(\theta,\phi)$. One can expand $f(\theta,\phi)$ in spherical harmonics with complex-number expansion coefficients

$$f(\theta,\phi) = \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} F^{\ell m} Y^{\ell m}(\theta,\phi); \qquad (3.2.9a)$$

alternatively, one can expand it in powers of the unit radial vector $\underset{\sim}{n}$, with coefficients that are STF-ℓ tensors

$$f(\theta,\phi) = \sum_{\ell=0}^{\infty} \mathcal{F}_{K_\ell} N_{K_\ell} . \qquad (3.2.9b)$$

The expansion coefficients of the two schemes are related by equations (3.2.7a,b).

Similar expansions can be made for vector fields and tensor fields. The resulting formalism, which relates vector and tensor spherical harmonics to STF-ℓ tensors, is presented in TV.

3.3. Multipole Expansion of Gravitational-Wave Field

The vacuum Einstein field equations permit the gravitational-wave amplitude A_{ij} (eq. 3.1.1) to be any symmetric, transverse, traceless function of retarded time $t-r$ and angle. One can show [see, e.g., TV] that this fact allows A_{ij} to be expanded in a multipole series of the form

$$h_{ij}^{TT} = r^{-1}A_{ij}$$

$$= \left[\sum_{\ell=2}^{\infty} (4/\ell!) r^{-1} \, {}^{(\ell)}\mathcal{I}_{ijA_{\ell-2}}(t-r)\, N_{A_{\ell-2}} \right. \qquad (3.3.1)$$

$$\left. + \sum_{\ell=2}^{\infty} [8\ell/(\ell+1)!] r^{-1} \varepsilon_{pq(i} \, {}^{(\ell)}\mathcal{S}_{j)pA_{\ell-2}}(t-r) n_q N_{A_{\ell-2}} \right]^{TT}.$$

Here the normalizations (factors of 4, 8, ℓ, etc.) have been chosen to make equations (4.4.3) look simple; ε_{abc} is the Levi-Civita tensor; parentheses around tensor indices denote symmetrization; ${}^{(\ell)}\mathcal{I}_{A_\ell}(t-r)$ and ${}^{(\ell)}\mathcal{S}_{A_\ell}(t-r)$ are the trace-free, symmetric coefficients of the expansion evaluated at retarded time $t-r$; a prefix superscript in parentheses, e.g., ${}^{(k)}\mathcal{S}(u)$, means that the quality is to be differentiated k times with respect to its argument u

$${}^{(k)}\mathcal{S}(u) \equiv d^k\mathcal{S}/du^k; \qquad (3.3.2)$$

and TT means that the transverse, traceless part is to be taken (eq. 1.3.3).

The coefficients ${}^{(\ell)}\mathcal{I}_{A_\ell}$ and ${}^{(\ell)}\mathcal{S}_{A_\ell}$ of the spherical harmonic expansions--integrated ℓ times (superscript ℓ removed)--are called the "mass" and "current" moments of the radiation field:

$$\mathcal{I}_{ab} \equiv \text{(mass quadrupole moment)}, \quad \mathcal{S}_{ab} \equiv \text{(current quadrupole moment)},$$

$$\mathcal{I}_{abc} \equiv \text{(mass octupole moment)}, \quad \mathcal{S}_{abc} \equiv \text{(current octupole moment)}, \qquad (3.3.3)$$

$\mathcal{I}_{A_\ell} \equiv$ (mass ℓ-pole moment), $\mathcal{S}_{A_\ell} \equiv$ (current ℓ-pole moment).

They are trace-free, symmetric tensors which depend on retarded time.

Notice that the mass quadrupole part of the radiation field (3.3.1) has a form familiar from the "Quadrupole Moment Formalism"

$$(h^{TT}_{jk})_{\text{mass quadrupole}} = 2r^{-1}\,\ddot{\mathcal{I}}^{TT}_{jk} \qquad (3.3.4)$$

[cf. eq. (2.6.4)] . Also notice that the mass-multipole moments produce a radiation field with "electric-type parity" (also called "even-type parity"), $\pi = (-1)^\ell$; while the current-multipole moments produce a radiation field with "magnetic-type" ("odd-type") parity, $\pi = (-1)^{\ell+1}$

If the radiation field is known, one can project out its multipole moments using the following integrals over a sphere of constant (t-r):

$$^{(\ell)}\mathcal{I}_{B_\ell} = \left[\begin{array}{l}\text{Symmetric, trace-}\\ \text{free part of}\end{array}\right]\left\{\frac{\ell(\ell-1)(2\ell+1)!!}{2(\ell+1)(\ell+2)}\,\frac{r}{4\pi}\int h^{TT}_{b_1b_2}\,n_{b_3}\cdots n_{b_\ell}\,d\Omega\right\}, \qquad (3.3.5a)$$

$$^{(\ell)}\mathcal{S}_{B_\ell} = \left[\begin{array}{l}\text{Symmetric, trace-}\\ \text{free part of}\end{array}\right]\left\{\frac{(\ell-1)(2\ell+1)!!}{4(\ell+2)}\,\frac{r}{4\pi}\int \varepsilon_{b_1jk}\,n_j\,h^{TT}_{kb_2}\,n_{b_3}\cdots n_{b_\ell}\,d\Omega\right\} \qquad (3.3.5b)$$

Multipole expansions of a generic radiation field have been given in various notations by Sachs (1961), Pirani (1965), Mathews (1962), Janis and Newman (1965), Bonnor and Rotenberg (1966), and Campbell and Morgan (1971). I like the above STF notation -- which is due to Sachs (1961), and Pirani (1965)-- because it ties in nicely with the theory of slow-motion sources (see below) and with the standard form of the quadrupole-moment formalism. Elsewhere (TV) I exhibit the relationship between the above STF expansions and expositions that use other conventions for spherical harmonics.

3.4. Multipole Expansion of Energy, Momentum, and Angular Momentum in Waves

The energy and linear momentum carried off by the radiation field (3.3.1) are most easily evaluated using the Isaacson (1968) stress-energy tensor for gravitational waves

$$T^{GW}_{\alpha\beta} = (1/32\pi)\left\langle h^{TT}_{jk,\alpha}\,h^{TT}_{jk,\beta}\right\rangle \qquad (3.4.1)$$

(cf. MTW, §§35.7 and 35.15). Here the brackets, $\langle\ \rangle$, denote an average over several wavelengths. The power radiated into a unit solid angle about the radial, $\underset{\sim}{n}$, direction is

$$(dE/d\Omega dt) \equiv -r^2 n_j T^{GW}_{j0} = +r^2\ T^{GW}_{00}\ ; \tag{3.4.2}$$

and the total power radiated is the integral of this power over a sphere lying in the local wave zone:

$$dE/dt = \int (dE/d\Omega dt) d\Omega. \tag{3.4.3}$$

By inserting the gravitational-wave field (3.3.1) into equations (3.4.1)-(3.4.3) and integrating one obtains (see TV)

$$\frac{dE}{dt} = \sum_{\ell=2}^{\infty} \frac{(\ell+1)(\ell+2)}{(\ell-1)\ell} \frac{1}{\ell!(2\ell+1)!!} \left\langle {}^{(\ell+1)}\mathcal{I}_{A_\ell}\ {}^{(\ell+1)}\mathcal{I}_{A_\ell} \right\rangle \tag{3.4.4}$$

$$+ \sum_{\ell=2}^{\infty} \frac{4\ell(\ell+2)}{(\ell-1)} \frac{1}{(\ell+1)!(2\ell+1)!!} \left\langle {}^{(\ell+1)}\mathcal{S}_{A_\ell}\ {}^{(\ell+1)}\mathcal{S}_{A_\ell} \right\rangle .$$

The waves carry linear momentum out radially--and, as with any locally plane-fronted radiation field, the magnitude of their momentum flux is the same as that of their energy flux:

$$(dP_j/d\Omega dt) \equiv r^2\ n_k\ T^{GW}_{kj} = r^2\ n_j T^{GW}_{00} = n_j\ (dE/d\Omega dt) \tag{3.4.5}$$

(cf. eq. 35.77j of MTW). The total linear momentum carried off by the waves,

$$dP_j/dt = \int (dP_j/d\Omega dt) d\Omega, \tag{3.4.6}$$

can be evaluated by inserting the wave field (3.3.1) into the above equations and integrating:

$$\frac{dP_j}{dt} = \sum_{\ell=2}^{\infty} \left\{ \frac{2(\ell+2)(\ell+3)}{\ell(\ell+1)!(2\ell+3)!!} \left\langle {}^{(\ell+2)}\mathcal{I}_{jA_\ell}\ {}^{(\ell+1)}\mathcal{I}_{A_\ell} \right\rangle + \right.$$

$$+ \frac{8(\ell+3)}{(\ell+1)!(2\ell+3)!!} \left\langle {}^{(\ell+2)}\mathcal{S}_{jA_\ell}\ {}^{(\ell+1)}\mathcal{S}_{A_\ell} \right\rangle + \tag{3.4.7}$$

$$\left. + \frac{8(\ell+2)}{(\ell-1)(\ell+1)!(2\ell+1)!!} \left\langle \varepsilon_{jpq}\ {}^{(\ell+1)}\mathcal{I}_{pA_{\ell-1}}\ {}^{(\ell+1)}\mathcal{S}_{qA_{\ell-1}} \right\rangle \right\}.$$

Note, that, whereas the energy radiated (eq. 3.4.4) involves a beating of each multipole moment against itself, the linear momentum radiated (eq. 3.4.7) involves a beating of "adjacent" multipole moments.

The dependence of the wave amplitude, h^{TT}_{ij}, on angle causes its wave fronts to be not quite precisely spherical--and thereby enables the waves to carry off angular momentum. One might hope that the angular momentum loss could be calculated by integrating $\epsilon_{jab}\, x_a\, T^{GW}_{b0}$ over a sphere surrounding the source. Unfortunately, such a procedure fails--for this reason: the averaging process that underlies equation (3.4.1) for $T^{GW}_{\alpha\beta}$ treats as zero the "tiny corrections" which die out as $1/r^3$. However, it is precisely the $1/r^3$ part that carries off the angular momentum. I was vaguely aware of this fact when writing the relevant sections of MTW, but was not sufficiently certain to spell it out explicitly. Subsequently Bryce DeWitt (1971) derived a simple, correct expression for the flux of angular momentum:

$$\frac{dS_j}{dt} = \frac{1}{16\pi}\int \epsilon_{jpq}\, x_p \left\langle \left(h^{TT}_{qa}\, {}^{(1)}h^{TT}_{ab}\right)_{,b} - \frac{1}{2} h^{TT}_{ab,q}\, {}^{(1)}h^{TT}_{ab} \right\rangle r^2\, d\Omega. \tag{3.4.8}$$

A word of interpretation is needed. This equation is correct only if the integral is evaluated in the asymptotic rest frame of the source. (Similarly for all previous formulae in this section.) As the source's linear momentum changes (eq. 3.4.7), its asymptotic rest frame gradually changes; and one must gradually change the reference frame in which one evaluates (3.4.8) (and all previous integrals).

Return to equation (3.4.8). By inserting the wave field (3.3.1) and integrating, one obtains

$$\frac{dS_j}{dt} = \sum_{\ell=2}^{\infty} \frac{(\ell+1)(\ell+2)}{(\ell-1)\ell!\,(2\ell+1)!!} \left\langle \epsilon_{jpq}\, {}^{(\ell)}\mathcal{I}_{pA_{\ell-1}}\, {}^{(\ell+1)}\mathcal{I}_{qA_{\ell-1}} \right\rangle \tag{3.4.9}$$

$$+\sum_{\ell=2}^{\infty} \frac{4\ell^2(\ell+2)}{(\ell-1)(\ell+1)!(2\ell+1)!!} \left\langle \epsilon_{jpq}\, {}^{(\ell)}\mathcal{S}_{pA_{\ell-1}}\, {}^{(\ell+1)}\mathcal{S}_{qA_{\ell-1}} \right\rangle.$$

Notice that this angular momentum radiated, like the energy radiated (eq. 3.4.4), involves a beating of each multipole with itself.

3.5. Discussion of the Multipole Formalism

Of what use are the above formulas? I view them as tools to to be used in studying the generation of gravitational waves from explicit sources. Given a source, one identifies the local wave zone. Using any technique one can dream up (and this is the tough part of the analysis!), one calculates the time-changing multipole moments of the source. One then plugs into the above formulas to get the radiation field and the rate it carries off energy, momentum, and intrinsic angular momentum.

As an alternative application, one can calculate the radiation field of a given source (the tough task; above formulas not necessarily useful); one can use equations (3.3.5) to resolve it into multipole pieces; and one can then use the other formulas above to read off the energy, momentum, and angular momentum radiated.

Once the radiation field h_{ij}^{TT} is known in the local wave zone, one can propagate it on outwards to Earth using the propagation equation of the geometric-optics formalism (§7 below). For typical situations the wave form (3.3.1) will remain highly accurate all the way to Earth, except for uninteresting phase shifts caused by the waves' self energy and by various masses present in the Universe, and except for changes in the weakest of the multipole fields caused by nonlinear beating together of stronger multipole fields.

4. SLOW-MOTION FORMALISMS

4.1. Overview

Turn attention now from weak-field systems (§2) and arbitrary systems (§3) to slow-motion systems--i.e., systems for which

$$\lambda\!\!\!^{-} \equiv (\text{reduced wavelength of radiation}) >> L \equiv (\text{size of source}). \quad (4.1.1)$$

Thorne (1977b--cited henceforth as TVI) has derived a slow-motion multipole-moment formalism for calculating gravitational-wave generation by such systems. This slow-motion formalism generalizes the quadrupole-moment formalism of §2.6 to include all multipole moments, and to encompass sources with arbitrarily strong internal gravity; cf. Table 1.

The slow-motion formalism takes, as its starting point, a multipole analysis of the external gravitational field of a stationary source. That stationary multipole analysis is described in §4.2; and the slow-motion wave-generation formalism built on it is described in §4.3. Then, in §4.4 the weak-field limit of

the slow-motion formalism is described. Throughout § 4 we shall use subscripted coordinate indices: $x_\alpha \equiv x^\alpha$.

4.2. Multipole Moments of a Stationary Source

Consider a stationary system residing in asymptotically flat spacetime and surrounded by vacuum. It is well known[4] that the vacuum geometry of spacetime surrounding such a stationary system is uniquely determined by two families of time-independent multipole moments: the mass moments, and the current moments. The object of this section is to give a definition of these moments (i.e., a set of conventions for them) that will tie in simply with radiation theory. More specifically, if the stationary source is set into very slow motion (§4.3 below), its moments as defined here (§4.2) will be identical to those which characterize the emitted radiation (§3 above).

4.2.1. ACMC-N Coordinate Systems

As a tool in defining the moments of a stationary source, we introduce a special class of coordinate systems: A coordinate system will be called "asymptotically Cartesian and mass centered to order N" ("ACMC-N") if and only if its metric coefficients have the following form. Expand them in inverse powers of "radius"

$$r \equiv [(x_1)^2 + (x_2)^2 + (x_3)^2]^{1/2} \quad . \tag{4.2.1}$$

The coefficients must be time-independent (so the Killing vector is $\partial/\partial x_0$); the leading term must be the Minkowskii metric; and the remaining terms must have the form

$$g_{\alpha\beta} = \eta_{\alpha\beta} + \frac{A^0_{\alpha\beta}\,(\underset{\sim}{n})}{r} + \frac{A^1_{\alpha\beta}\,(\underset{\sim}{n})}{r^2} + \ldots + \frac{A^{N+1}_{\alpha\beta}(\underset{\sim}{n})}{r^{N+2}} + [\text{terms that die out faster than } 1/r^{N+2}], \tag{4.2.2}$$

where

$$\underset{\sim}{n} = \underset{\sim}{x}/r = (x_j/r)\,(\partial/\partial x_j). \tag{4.2.3}$$

Expand each of the coefficients $A^P_{\alpha\beta}\,(\underset{\sim}{n})$ in spherical harmonics.

[4] See, e.g., van der Burg (1968), Geroch (1970), Clarke and Sciama (1971).

$A^0_{\alpha\beta}$ and A^1_{00} must involve only harmonics of order 0.

A^1_{0j} and A^1_{jk} must involve only harmonics of order 0 and 1.

(4.2.4)

$A^2_{\alpha\beta}$ must involve only harmonics of order 0,1, and 2.

$A^3_{\alpha\beta}$ must involve only harmonics of order 0,1,2, and 3

.

.

.

(4.2.4 con'd)

$A^N_{\alpha\beta}$ must involve only harmonics of order 0,1,...,N.

Note the absence of a dipole in A^1_{00}; that is what makes the coordinates "mass centered".

That such a coordinate system always exists is proved in TVI by showing that "deDonder coordinates," with appropriate specialization of the gauge, are ACMC-∞.

4.2.2. Multipole Moments

Given an ACMC-N coordinate system, we define the multipole moments of order $\ell \leq N+1$ in the following manner: The ℓ-order part of the $1/r^{\ell+1}$ piece of g_{00} is the mass ℓ-pole moment; and the ℓ-order, "odd-type parity" part of the $1/r^{\ell+1}$ piece of g_{0j} is the current ℓ-pole moment. More specifically,

$$A^{\ell}_{00} = [2(2\ell-1)!!/\ell!]\, \mathcal{I}_{A_\ell}\, N_{A_\ell} + (\text{parts of order} < \ell) \qquad (4.2.5a)$$

$$A^{\ell}_{0j} = [-4\ell(2\ell-1)!!/(\ell+1)!]\, \varepsilon_{jpq}\, \mathcal{S}_{pA_{\ell-1}}\, n_q N_{A_{\ell-1}} \qquad (4.2.5b)$$

$$+ (\text{"even-type" parts of order } \ell) + (\text{parts of order} < \ell)$$

(4.2.5b)

where $\mathcal{I}_{A_\ell}$ is the ℓ-pole mass moment, and $\mathcal{S}_{A_\ell}$ is the ℓ-pole current moment.

In TVI the self-consistency of this definition is proved; i.e., it is shown that every ACMC-N coordinate system gives the same result for the moments of order $\ell \leq N + 1$.

This definition of multipole moments is far less elegant than definitions given by other researchers.[4] However, the other definitions lead to moments which fail to tie in nicely with radiation theory. My moments must be nonlinear, algebraic functions of the moments defined elsewhere,[4] but I have not attempted to exhibit that relationship explicitly.

The above definition of multipole moments is embodied in the following formula for the metric coefficient of an ACMC-N coordinate system:

$$g_{00} = -1 + \frac{2\mathcal{I}}{r} + \frac{(0\text{-pole})}{r^2} + \frac{1}{r^3}\left[3\mathcal{I}_{ab}n_a n_b + (1\text{ pole}) + (0\text{ pole})\right.$$

$$+\ldots+\frac{1}{r^{\ell+1}}\left[\frac{2(2\ell-1)!!}{\ell!}\mathcal{I}_{A_\ell}N_{A_\ell} + (\ell\text{-1 pole})+\ldots+(0\text{ pole})\right]$$

$$+\ldots+\frac{1}{r^{N+1}}\left[\frac{2(2N-1)!!}{N!}\mathcal{I}_{A_N}N_{A_N} + (N\text{-1 pole})+\ldots+(0\text{ pole})\right]$$

$$\left.+\frac{1}{r^{N+2}}\left[\frac{2(2N+1)!!}{(N+1)!}\mathcal{I}_{A_{N+1}}N_{A_{N+1}} + (\text{poles with } \ell \neq N+1)\right]\right.$$

$$+\left[\text{terms that die out faster than } 1/r^{N+2}\right]. \qquad (4.2.6a)$$

$$g_{0j} = -\frac{1}{r^2}\left[2\varepsilon_{jpq}\mathcal{S}_p n_q + \left(\begin{array}{l}1\text{ pole part with}\\ \text{parity } \pi = -\end{array}\right) + (0\text{ pole})\right]$$

$$-\ldots-\frac{1}{r^{\ell+1}}\left[\frac{4\ell(2\ell-1)!!}{(\ell+1)!}\varepsilon_{jpq}\mathcal{S}_{pA_{\ell-1}}n_q N_{A_{\ell-1}} +\right.$$

$$\left.+\left(\begin{array}{l}\ell\text{ pole part with}\\ \text{parity } \pi = (-1)^\ell\end{array}\right) + (\ell\text{-1 pole}) + \ldots + (0\text{ pole})\right]$$

$$-\ldots-\frac{1}{r^{N+1}}\left[\frac{4N(2N-1)!!}{(N+1)!}\varepsilon_{jpq}\mathcal{S}_{pA_{N-1}}n_q N_{A_{N-1}} +\right.$$

$$\left.+\left(\begin{array}{l}N\text{ pole part with}\\ \text{parity } \pi = (-1)^N\end{array}\right) + (N\text{-1 pole}) + \ldots + (0\text{ pole})\right] +$$

$$- \frac{1}{r^{N+2}} \left[\frac{4(N+1)(2N+1)!!}{(N+2)!} \varepsilon_{jpq} \mathcal{S}_{pA_N} n_q N_{A_N} + \left\{ \begin{matrix} \text{N+1 pole part with} \\ \text{parity } \pi = (-1)^{N+1} \end{matrix} \right\} \right.$$

$$\left. + \text{(parts with } \ell \neq N+1) \right]$$

$$+ [\text{terms that die out faster than } 1/r^{N+2}] \quad . \qquad (4.2.6b)$$

$$g_{jk} = \delta_{jk} + \frac{\text{(0 pole)}}{r} + \frac{1}{r^2} [\text{(1 pole)} + \text{(0 pole)}] + \ldots$$

$$+ \frac{1}{r^{\ell+1}} [\text{(ℓ pole)} + \ldots + \text{(0 pole)}] + \frac{1}{r^{N+1}} [\text{(N pole)}$$

$$+ \ldots + \text{(0 pole)}] + \frac{1}{r^{N+2}} \left[\begin{matrix} \text{any angular} \\ \text{dependence} \end{matrix} \right]$$

$$+ [\text{terms that die out faster than } 1/r^{N+2}]. \qquad (4.2.6c)$$

4.2.3. Example: The Kerr Metric

As an example, consider the Kerr metric (external field of a stationary black hole). In Boyer-Lindquist coordinates, made quasi-Cartesian by defining

$$x_1 = r \sin\theta \cos\phi, \quad x_2 = r \sin\theta \sin\phi, \quad x_3 = r \cos\theta,$$

the nonzero metric coefficients are (cf. page 877 of MTW)

$$g_{00} = - \frac{r^2 + a^2 \cos^2\theta - 2Mr}{r^2 + a^2 \cos^2\theta} = -1 + \frac{2M}{r} - \frac{2Ma^2 \cos^2\theta}{r^3} + 0\left(\frac{1}{r^5}\right),$$

$$g_{0j} = - \frac{2\varepsilon_{jpq} J_p n_q}{r^2 + a^2 \cos^2\theta} = - \frac{2\varepsilon_{jpq} J_p n_q}{r^2} + 0\left(\frac{1}{r^4}\right), \qquad (4.2.7)$$

$$g_{jk} = \delta_{jk} + \frac{2M}{r} n_j n_k + \frac{1}{r^2} [\text{(0 pole)} + \text{(2 pole)}] + 0\left(\frac{1}{r^3}\right),$$

where

$$\underset{\sim}{J} \equiv Ma(\partial/\partial x_3). \qquad (4.2.8)$$

The presence of a quadrupole $1/r^2$ term in g_{jk} prevents this coordinate system from being ACMC-1; it is only ACMC-0. Hence, from the metric coefficients we can read off only the moments of order 0 and 1:

$\mathcal{I}$ ≡ (mass monopole moment; i.e., total mass-energy) = M;

$\mathcal{I}_a$ ≡ (mass dipole moment) = 0 [guaranteed to vanish because coordinates are mass centered];

$\underset{\sim}{\mathcal{S}}$ ≡ (current dipole moment; i.e., total angular momentum)

$$= Ma(\partial/\partial x_3) \quad . \qquad (4.2.9)$$

In order to deduce the higher-order moments one must perform a coordinate transformation that gets rid of the offending quadrupole term in g_{jk}. Such a transformation is exhibited in TVI.

4.3. The Slow-Motion, Multipole-Moment Formalism For Strong-Field Sources

Turn attention now from stationary sources to the slow-motion, multipole-moment formalism.

Consider a specific (but arbitrary) slow-motion, isolated system. If the system were not changing at all ($\lambda = \infty$), the metric everywhere outside the source would be stationary -- i.e., it would be describable by the stationary multipole-moment formalism of § 4.2. We can pass from that stationary metric to the true metric by gradually turning on the time dependence of the system's multipole moments -- i.e., by gradually letting λ decrease from infinity. Mathematically this is achieved by expanding the metric simultaneously in the two small dimensionless parameters R/r and R/λ, where R is the length scale that characterizes the weak-field, near-zone metric:

$$R \equiv \underset{\ell=1,2,\ldots}{\text{Maximum}} \left\{ \left| \frac{\mathcal{I}_{A_\ell}}{M} \right|^{1/\ell}, \left| \frac{\mathcal{S}_{A_\ell}}{M} \right|^{1/\ell} \right\} \qquad (4.3.1)$$

See TVI for details. For typical (not highly spherical) sources, R will be approximately equal to the size of the source L.

At zero order in R/λ, the R/r expansion of the metric must be formally identical to the general stationary expansion of § 4.2. But the time dependence of that "zero-order solution" will

generate corrections or order $(R/\lambda\!\!\!^{-})$, $(R/\lambda\!\!\!^{-})^2$, ... In TVI it is shown that those corrections are determined uniquely by the (time dependent) multipole moments, plus the demand that the near-zone metric match onto outoing waves. TVI also performs the match onto outgoing waves in the local wave zone, with the following result: The matching requires that the moments $\mathcal{I}_{A_\ell}$, $\mathcal{S}_{A_\ell}$ that appear in the zero-order [i.e., $(R/\lambda\!\!\!^{-})^0$] near-zone solutions [eqs. (4.2.6)] be identical to the moments that appear in the radiation field [eq. (3.3.1)] -- except for differences that are typically negligible:

$$|\delta\mathcal{I}_{A_\ell}| \lesssim MR^\ell(M/\lambda\!\!\!^{-}),\quad |\delta\mathcal{S}_{A_\ell}| \lesssim MR^\ell(M/\lambda\!\!\!^{-}). \qquad (4.3.2a)$$

For the most strongly radiating moment $\mathcal{M}_{A_\ell}$ (usually the mass quadrupole moment $\mathcal{I}_{A_2}$) the disagreement is

$$|\delta\mathcal{M}_{A_\ell}| \lesssim |\mathcal{M}_{A_\ell}|(M/\lambda\!\!\!^{-}). \qquad (4.3.2b)$$

This result leads to the following slow-motion formalism for calculating the generation of gravitational waves:
(1) Analyze the structure and evolution of the system in any convenient coordinates and by any fairly accurate approximation scheme. (2) From that analysis obtain an approximation to the external gravitational field which, at any instant, satisfies (to some degree of accuracy) the time-independent, vacuum Einstein field equations. (3) By transforming that external field to an ACMC coordinate system, read off its dominant multipole moments (the moments with the largest values of ${}^{(\ell)}\mathcal{I}_{A_\ell}$ or ${}^{(\ell)}\mathcal{S}_{A_\ell}$). (4) Plug those dominant moments into the gravitational-wave formulae of §3.

One attractive approximation scheme for use in steps (1) and (2) is the "instantaneous-gravity" approximation. In this scheme one sets to zero all time derivatives of the metric (but) not of the matter variables) when solving the Einstein field equations. This has the effect of removing all dynamical freedom from the gravitational field and making gravitational interactions within the source instantaneous rather than retarded. One automatically obtains an external gravitational field which satisfies the time-independent vacuum field equations; and, unless one has made a foolish choice of coordinates, the moments which one computes from that external field should contain errors no larger than $L/\lambda\!\!\!^{-}$. The radiation field computed from those moments will then have fractional errors $L/\lambda\!\!\!^{-}$ and $M/\lambda\!\!\!^{-}$. (Here L is the size of the source).

Typically the ℓ-pole mass and current moments will have magnitudes

$$\mathcal{I}_{A_\ell} \sim ML^\ell \ , \quad \mathcal{S}_{A_\ell} \sim M(L/\lambda\!\!\!^{-})L^\ell \ . \tag{4.3.3}$$

In this case their contributions to the radiation field [eq.(3.3.1)] will be

$$(h^{TT}_{jk})_{\text{mass } \ell\text{-pole}} \sim (M/r)\ (L/\lambda\!\!\!^{-})^\ell, \tag{4.3.4a}$$

$$(h^{TT}_{jk})_{\text{current } \ell\text{-pole}} \sim (M/r)\ (L/\lambda\!\!\!^{-})^{\ell+1} \ ; \tag{4.3.4b}$$

Since $L/\lambda\!\!\!^{-} \ll 1$ (slow-motion assumption), mass quadrupole radiation is usually far larger than the other multipoles. The current quadrupole field and mass octupole field are normally a factor $L/\lambda\!\!\!^{-}$ smaller. It is this fact which allows one to compute only the lowest few multipole moments when applying the slow-motion formalism.

In special cases (e.g., torsional oscillations of a neutron star) the mass quadrupole moment will vanish, or will be far smaller than its normal value. Then the current quadrupole or mass octupole radiation may dominate -- unless they, too, are abnormally small, allowing higher moments to make themselves felt.

Notice that, if one is interested in the linear momentum radiated by the source (eq. 3.4.7), one must compute not just the lowest significant multipole moment, but also the moments "adjacent" to it. Linear momentum is carried off only through the interference of adjacent multipole fields with each other.

4.3.1. A Sample Application

As a typical application of the slow-motion, multipole-moment formalism, consider a slowly rotating neutron star which is not quite axially symmetric. Ipser (1971) has formulated a general relativistic analysis of the interior of such a star, using the Regge-Wheeler (1957) formalism for small, strong-field deviations from spherical symmetry. Ipser's analysis shows how internal stresses, supported by the crystal structure of the star's mantle, maintain the star's deformation. It also gives formulas for the star's near-zone multipole moments in terms of the star's internal structure. By inserting those near-zone multipole moments into the slow-motion wave-generation formalism, one obtains the gravitational-wave field $\bar{h}^{TT}_{jk}$ produced by the star's rotation, and also the energy and angular momentum radiated. (Ipser computed the gravitational-wave field from his near-zone multipole moments by brute force, and discovered the then surprising result that it had the same form as in weak-field, slow-motion theory. That discovery was the original motivation for my constructing the above formalism.)

4.4 Weak-Field Limit of the Slow-Motion Formalism

For a slow-motion source ($L/\lambda\bar{}<<1$) with weak internal fields ($\varepsilon << 1$) and weak internal stresses ($S^2 << 1$), one can use Newtonian theory to analyze the interior region; cf. §2.6. Using Newtonian theory, one can express the multipole moments

$$\mathcal{I}_{A_\ell} \text{ and } \mathcal{S}_{A_\ell}$$

in terms of volume integrals over the source [see, eg., TV for detailed proof].

The multipole volume integrals must be performed in a mass-centered Cartesian coordinate system--i.e., in Cartesian coordinates with

$$\mathcal{I}_j(t) \equiv \int \rho(\underset{\sim}{x},t)\, x_j\, d^3x = 0. \tag{4.4.1}$$

[Note that such a coordinate system is automatically the rest frame of the source, since the time-derivative of equation (4.4.1) can be put in the form

$$\begin{aligned} 0 = d\,\mathcal{I}_j(t)/dt &= \int [\partial\rho(\underset{\sim}{x},t)/\partial t]\, x_j\, d^3x \\ &= \int \rho(\underset{\sim}{x},t)\, v_j d^3x = \text{(momentum of source)}. \end{aligned} \tag{4.4.2}$$

The third equality follows from the equation of mass conservation (2.6.3a) and an integration by parts.]

In a mass-centered Cartesian coordinate system, the volume integrals for $\mathcal{I}_{A_\ell}$ and $\mathcal{S}_{A_\ell}$ are

$$\mathcal{I}_{A_\ell} = \text{Symmetric trace-free part of } I_{A_\ell}, \tag{4.4.3a}$$

$$I_{A_\ell} = \begin{pmatrix}\ell\text{'th moment of}\\ \text{mass distribution}\end{pmatrix} = \int \rho x_{a_1} \cdots x_{a_\ell}\, d^3x; \tag{4.4.3b}$$

$$\mathcal{S}_{A_\ell} = \text{Symmetric trace-free part of } S_{A_\ell}, \tag{4.4.4b}$$

$$S_{A_\ell} = \begin{pmatrix}\ell\text{-1 moment of angular}\\ \text{momentum distribution}\end{pmatrix} \tag{4.4.4b}$$

$$= \int (\varepsilon_{a_1 jk} x_j \rho\, v_k)\, x_{a_2} \cdots x_{a_\ell}\, d^3x.$$

The "symmetric, trace-free part" can be computed from equations (3.2.1) and (3.2.2).

The volume integrals (4.4.3) and (4.4.4) are not precisely equal to the exact near-zone multipole moments of the source, of course. They contain errors of post-Newtonian order (cf. eq. 2.6.1):

$$(\delta \mathcal{I}_{A_\ell}) \text{ due to weak-field assumption} \sim ML^\ell[\varepsilon+(L/\lambda\!\!\!^{-})^2+S^2], \tag{4.4.5a}$$

$$(\delta \mathcal{S}_{A_\ell}) \text{ due to weak-field assumption} \sim M(L/\lambda\!\!\!^{-})L^\ell[\varepsilon+(L/\lambda\!\!\!^{-})^2+S^2]. \tag{4.4.5b}$$

These errors are in addition to the amounts (eqs. 4.3.2) by which the wave-zone multipole moments fail to agree with the near-zone multipole moments.

The weak-field limit of the slow-motion wave-generation formalism can be summarized by the following set of rules: (1) Use the Newtonian theory of gravity to analyze the structure and evolution of the source. (2) Calculate the lowest few multipole moments by evaluating expressions (4.4.3) and (4.4.4) in the mass-centered, Cartesian coordinates. (3) Insert those multipole moments into the local-wave-zone formulas of §3. Those formulas will then describe the lowest few multipoles of the radiation field. (4) Check that the radiation field is larger than the errors inherent (a) in the matching of near zone onto local wave zone (eqs. 4.3.2. with R = L), and (b) in the weak-field assumption

$$(\delta h^{TT}_{jk})_{\text{mass } \ell\text{-pole, errors}} \sim (M/r)\ (L/\lambda\!\!\!^{-})^\ell[\varepsilon+(L/\lambda\!\!\!^{-})^2+S^2], \tag{4.4.6a}$$

$$(\delta h^{TT}_{jk})_{\text{current } \ell\text{-pole, errors}} \sim (M/r)(L/\lambda\!\!\!^{-})^{\ell+1}[\varepsilon+(L/\lambda\!\!\!^{-})^2+S^2]. \tag{4.4.6b}$$

This weak-field, slow-motion formalism dates back to Einstein (1918), for the mass quadrupole part. The mass octupole and current quadrupole parts were first derived (so far as I know) by Papapetrou (1962, 1971); and the full formalism (in different notations from this) was first derived by Mathews (1962); see also Campbell and Morgan (1971). The earliest versions of the formalism assumed gravity so weak that one had to use Linearized Theory rather than Newtonian Theory in analyzing the source ("no self-gravity"). However, it was soon realized that a modest amount of self-gravity causes no problems in the formalism.

4.5 Post-Newtonian Multipole Formalism

We now return to the Epstein-Wagoner (1975) Post-Newtonian Wave-Generation Formalism, which was described qualitatively in §2.7. In this formalism Epstein and Wagoner find it most convenient to analyze the structure and motion of their source using a different Post-Newtonian gauge from that of Chandrasekhar (1965). Like Chandrasekhar, they describe the matter of their source by perfect-fluid thermodynamic variables measured in its local rest frame

$$\rho_o = \text{mass density}, \quad P = \text{pressure}, \quad \Pi = \text{specific internal energy}; \tag{4.5.1a}$$

and by the coordinate velocity of the fluid

$$v_j \equiv \frac{dx^j}{dt} . \tag{4.5.1b}$$

The internal gravity of the source they describe by the potentials U, V_j, Ψ, and χ which satisfy

$$U_{,jj} = -4\pi\rho_o, \quad V_{j,kk} = -4\pi\rho_o v_j,$$

$$\Psi_{,jj} = -4\pi\rho_o(v^2+U+\tfrac{1}{2}\Pi + \tfrac{3}{2}P/\rho_o), \quad \chi_{,jj} = -2U, \tag{4.5.2}$$

and which are related to the post-Newtonian metric by

$$g_{00} = -1+2U-2U^2+4\Psi-\chi_{,00}+O(\varepsilon^6) \tag{4.5.3a}$$

$$g_{0j} = -4V_j+O(\varepsilon^5) \tag{4.5.3b}$$

$$g_{jk} = 2U\delta_{jk}+O(\varepsilon^4) \tag{4.5.3c}$$

[In the Post-Newtonian formalism one assumes $\varepsilon \sim S^2 \sim (L/\lambda\!\!\!^{-})^2$.] The equations governing the evolution of the source in the Epstein-Wagoner gauge are the equation of mass conservation

$$[\rho_o(1+\tfrac{1}{2}\underset{\sim}{v}^2+3U)]_{,0}+[\rho_o(1+\tfrac{1}{2}\underset{\sim}{v}^2+3U)v_j]_{,j}=0, \tag{4.5.4a}$$

the equation of state

$$P=P(\rho_o,\Pi), \tag{4.5.4b}$$

the adiabatic equation of energy conservation

$$\rho_o\, d\Pi/dt + Pv_{j,j}=0, \quad d/dt \equiv \partial/\partial t + v_j\, \partial/\partial x_j, \tag{4.5.4c}$$

and the Euler equations of motion

$$\rho_o dv_i/dt - \rho_o U_{,i} + P_{,i} - (\Pi + \underset{\sim}{v}^2 + 4U + P/\rho_o)P_{,i}$$

$$+ (3\rho_o U_{,0} + P_{,0} + 4\rho_o v_j U_{,j})v_i + (4U - \underset{\sim}{v}^2)\rho_o U_{,i} - 4\rho_o V_{i,0}$$

$$+ 4\rho_o v_k (V_{k,i} - V_{i,k}) + \rho_o (\tfrac{1}{2}\chi_{,00i} - 2\Psi_{,i}) = 0 .$$

After one has computed the structure and evolution of the source using these equations, one can then compute the multipole moments which govern the radiation field. For typical sources -- to which Epstein and Wagoner restrict their attention -- the multipole components of the radiation field have the magnitudes (4.3.4). The mass quadrupole dominates with magnitude $(M/r)(L/\lambda\!\!\!^{-})^2$ and the post-Newtonian formalism is able to compute it with a fractional error $\sim \varepsilon^2 \sim (L/\lambda\!\!\!^{-})^4$. If one wishes to compute the other multipole contributions to similar absolute accuracy, then one must have fractional errors no larger than the following in the various multipole moments (cf. eq. 4.3.4):

$$\mathcal{I}_{A_2} : (L/\lambda\!\!\!^{-})^4, \quad \mathcal{I}_{A_3} : (L/\lambda\!\!\!^{-})^3, \quad \mathcal{I}_{A_4} : (L/\lambda\!\!\!^{-})^2, \quad \mathcal{I}_{A_5} : (L/\lambda\!\!\!^{-}),$$

$$\mathcal{S}_{A_2} : (L/\lambda\!\!\!^{-})^3 \quad \mathcal{S}_{A_3} : (L/\lambda\!\!\!^{-})^2 \quad \mathcal{S}_{A_4} : (L/\lambda\!\!\!^{-}). \qquad (4.5.5)$$

Up to this accuracy the multipole moments can be expressed in the following form:

$$(\mathcal{I}_{jk},\ \mathcal{I}_{ijk},\ \mathcal{S}_{jk}) = \text{Symmetric trace-free parts of } (I_{jk},\ I_{ijk},\ S_{jk}),$$

$$I_{jk} = \int\left[\tau_{00}x_j x_k + \frac{11}{21}\tau_{jk}r^2 + \frac{4}{21}\tau_{pp}x_j x_k - \frac{4}{7}x_p\tau_{pj}x_k\right]d^3x,$$

$$I_{ijk} = \int\left[\tau_{00}x_i x_j x_k + x_i\tau_{jk}r^2 + \frac{1}{3}\tau_{pp}x_i x_j x_k - x_p\tau_{pi}x_j x_k\right]d^3x, \qquad (4.5.6)$$

$$S_{ij} = \int\left[x_i\varepsilon_{jpq}x_p\tau^0{}_q - \frac{3}{28}\varepsilon_{ipq}x_p r^2\partial_t\tau_{qj} + \frac{1}{28}x_i\varepsilon_{jpq}x_p\partial_t\tau_{qs}x_s\right]d^3x,$$

$(\mathcal{S}_{ijk},\ \mathcal{I}_{ijk\ell})$ equal the Newtonian expressions (4.4.3), (4.4.4).

Here, the "effective energy density". τ_{00}, "effective momentum density" $\tau^0{}_j$, and "effective stress" τ_{jk} are

$$\tau_{00} = \rho_o(1 + \Pi + \underset{\sim}{v}^2 + 4U) - \frac{3}{8\pi}U_{,j}U_{,j} \qquad (4.5.7a)$$

$$\tau^0{}_j = \rho_o(1+\Pi+v^2+4U)v_j + Pv_j + \frac{3}{4\pi}U_{,0}U_{,j} + \frac{1}{2\pi}U_{,k}V_{k,j}$$

$$- \frac{1}{2\pi}V_k U_{,kj} - 2\rho_o V_j , \qquad (4.5.7b)$$

$$\tau_{jk} = \rho_o v_j v_k - \frac{1}{4\pi}U_{,j}U_{,k} - \frac{1}{2\pi}UU_{,jk}$$

$$+ \delta_{jk}(P + \frac{3}{8\pi}U_{,i}U_{,i} - 2\rho_o U). \qquad (4.5.7c)$$

Epstein and Wagoner use a different notation than ours for the multipole moments. The above formulas for the moments (eqs. 4.5.6) are derived in TV.

5. PERTURBATION FORMALISMS

Thus far I have described two large classes of wave-generation formalisms: weak-field formalisms (§2) and slow-motion formalisms (§4). Now I turn attention to a third large class: Perturbation formalisms.

The fundamental assumption underlying all perturbation formalisms is this: that the entire wave-generation region of space-time can be treated as a small perturbation which radiates, superimposed on a nonradiative but strongly curved "background" Examples are: (1) Small-amplitude pulsations of fully relativistic stars. Here the background is an unperturbed, equilibrium stellar model; and the perturbation is the pulsation. (2)Slow rotation of a slightly nonspherical neutron star (pulsar). Here the background is a nonrotating, spherical star; and the perturbation is both the deformation and the rotation. (3) Motion of a small object in the gravitational field of a black hole. Here the background is the Kerr metric of the black hole; and the small perturbation is the stress-energy tensor of the object, plus the gravitational field it produces.

There are a variety of different perturbation formalisms, each designed to handle a specific type of problem. Some applications make use of several formalisms combined together--and many applications combine a perturbation formalism for the wave-generation region with a multipole analysis of the radiation field (i.e., with a variant of the formalism described in §3).

In a recent review article (§II.C of Thorne 1977c) I have described most of the perturbation formalisms with which I am familiar. Rather than repeat that material here, I simply refer the reader to it.

6. WAVE GENERATION BY SOURCES WITH STRONG INTERNAL FIELDS AND FAST, LARGE-AMPLITUDE MOTIONS

The strongest sources of gravitational waves in the Universe should be sources with strong internal fields ($\varepsilon \sim 1$) and fast ($v \sim L/\lambda\!\!\!^{-} \sim 1$), large-amplitude internal motions. Examples are the highly nonspherical collapse of a star to form a black hole (or naked singularity, or whatever it does form), and a collision between two black holes. Unfortunately, such sources have eluded all efforts at analytic analysis.[5] There exists no formalism today by which one can calculate the waves they generate. Obviously, an accurate analysis of such systems is the most important and most difficult task lying ahead of us in the theory of gravitational-wave generation.

Fortunately great progress has been made on this task recently by Bryce DeWitt, Larry Smarr, Kenneth Eppley, and others (see Smarr 1977 for a review). Abandoning all hope of a truly analytic analysis, they turn to massive electronic computers as their key tool. Their method is elegant numerical solution of the full, nonlinear Einstein field equations. By now they have encountered and surmounted a number of serious numerical problems. The resulting numerical methods are nearly good enough to give reliable results for strong-field, high-speed, large-amplitude sources--and we can expect true reliability within another year or two. This, when it is achieved, will be very useful in planning gravitational-wave-detection efforts.

[5] An exception is the special situation of a collision between two black holes with relative velocity very nearly the speed of light [$\gamma=(1-v^2)^{-1/2} \gg 1$], for which D'Eath (1977) has formulated a remarkable "colliding-plane-wave" approximation that yields the dominant features of this radiation.

7. PROPAGATION OF WAVES TO EARTH

7.1. The Geometric-Optics Formalism

Once the gravitational-wave field h^{TT}_{jk} is known in the local wave zone, one can then propagate it out through the surrounding Universe to Earth, using the vacuum Einstein field equations. In nearly all situations one can use the geometric-optics approximation to the Einstein equations (e.g. Exercise 35.15 of MTW). In this section I describe the geometric optics formalism in a language different from, but equivalent to MTW.

This formalism, which is valid for $r \gg r_I$ (wave zone), describes spacetime by a background metric $g^{(B)}_{\mu\nu}$ through which the waves propagate. The waves are described by a gravitational-wave field $\psi_{\mu\nu}$ which reduces to

$$\psi_{jk} = h^{TT}_{jk}\,,\quad \psi_{j0} = 0,\quad \psi_{00} = 0 \quad \text{in local wave zone and in asymptotic rest frame of source.} \tag{7.1.1}$$

In an appropriate coordinate system (gauge) the full metric of spacetime is

$$g_{\mu\nu} = g^{(B)}_{\mu\nu} + \psi_{\mu\nu} + 0\,(\psi^2). \tag{7.1.2}$$

The waves are distinguished from the background by the very small length scale λ on which they vary

$$\lambda \equiv \begin{bmatrix}\text{length scale of}\\ \text{variations in } \psi_{\mu\nu}\end{bmatrix} \ll \mathcal{R}_B \equiv \begin{bmatrix}\text{radius of curvature}\\ \text{of background spacetime}\end{bmatrix}. \tag{7.1.3}$$

The geometric optics formalism remains valid so long as the propagating waves do not encounter regions of extremely strong curvature--i.e. regions where $\mathcal{R}_B \lesssim \lambda$.

In applying the geometric optics formalism to a specific problem, one proceeds as follows: (i) In the local wave zone and in the asymptotic rest frame of the source one describes the background metric by the line element

$$ds^2 = -dt^2 + dr^2 + r^2(d\theta^2 + \sin^2\theta d\phi^2) + O(M/r)dx^\alpha dx^\beta, \tag{7.1.4}$$

with the source located at the origin. (ii) One constructs null geodesics of $g^{(B)}_{\mu\nu}$ extending radially away from the source. Near the source each geodesic has the form

$$t - r = \tau_e = \text{const.},\quad \theta = \text{const.},\quad \phi = \text{const.} \quad \text{in local wave zone.} \tag{7.1.5}$$

These geodesics are called "rays." The gravitational waves propagate along them. (iii) Each ray is labeled by the proper time ("emission time" or "retarded time") τ_e at which it intersects the source; and by this ray labeling τ_e becomes a scalar field extending through all spacetime. (iv) Each ray has an affine parameter ζ, a world line $\mathcal{P}(\zeta)$ with coordinates $x^\alpha(\zeta)$, and a tangent vector ("propagation vector")

$$\vec{k} = d/d\zeta, \qquad k^\alpha = dx^\alpha/d\zeta. \tag{7.1.6}$$

Of course, since $\mathcal{P}(\zeta)$ is a null geodesic, $\vec{k}$ must satisfy

$$\vec{k}^2 \equiv k_\alpha k^\alpha = 0, \qquad k_{\alpha|\beta} k^\beta = 0. \tag{7.1.7}$$

Here and below a slash denotes covariant derivative with respect to the background metric. (v) One normalizes the affine parameter of each ray so that near the source

$$\zeta = r = \left\{\begin{array}{l}\text{proper distance from source}\\ \text{as measured in asymptotic}\\ \text{rest frame; eq.(7.1.4)}\end{array}\right\} \quad \text{in local wave zone.} \tag{7.1.8a}$$

As a result

$$k^0 = 1, \qquad \underset{\sim}{k} = \underset{\sim}{n} = \left\{\begin{array}{l}\text{unit radial vector}\\ \text{pointing away from}\\ \text{source}\end{array}\right\} \quad \begin{array}{l}\text{in source's asymptotic}\\ \text{rest frame and local}\\ \text{wave zone.}\end{array} \tag{7.1.8b}$$

(vi) From the above definitions and constructions one can show that throughout spacetime the gradient of the retarded time is equal to the propagation vector, except for sign

$$\vec{k} = -\vec{\nabla}\tau_e; \qquad k_\alpha = -\tau_{e,\alpha}. \tag{7.1.9}$$

(vii) In the local wave zone one imposes the starting conditions (7.1.1) on the gravitational-wave field $\psi_{\alpha\beta}$. Note that because h^{TT}_{jk} is transverse and traceless, $\psi_{\alpha\beta}$ is initially trace-free and orthogonal to the propagation vector

$$\psi \equiv \psi^\alpha_\alpha \equiv \psi_{\alpha\beta}\, g^{\alpha\beta}_{(B)} = 0, \quad \psi_{\alpha\beta} k^\beta = 0. \tag{7.1.10}$$

These properties are preserved as the waves propagate (cf. eq. 7.1.12 below). (viii) Initially, and after it has propagated, $\psi_{\alpha\beta}$ is a rapidly varying function of retarded time τ_e and in addition is a slowly varying function of location along surfaces of constant τ_e:

$$\psi_{\alpha\beta} = \psi_{\alpha\beta}\ (\tau_e; x^0, x^1, x^2, x^3), \tag{7.1.11a}$$

$$\dot{\psi}_{\alpha\beta} \equiv \frac{\partial \psi_{\alpha\beta}}{\partial \tau_e} = O\left[\frac{\psi_{\alpha\beta}}{\lambda}\right], \qquad \ddot{\psi}_{\alpha\beta} \equiv \frac{\partial^2 \psi_{\alpha\beta}}{\partial \tau_e^2} = O\left[\frac{\psi_{\alpha\beta}}{\lambda^2}\right] \tag{7.1.11b}$$

$$\left\{\frac{\partial \psi_{\alpha\beta}}{\partial x^\mu}\right\}_{\tau_e} = O\left[\frac{\psi_{\alpha\beta}}{\zeta} + \frac{\psi_{\alpha\beta}}{\mathcal{R}_B}\right], \tag{7.1.11c}$$

$$\psi_{\alpha\beta|\gamma} = \dot{\psi}_{\alpha\beta} k_\gamma + O\left[\frac{\psi_{\alpha\beta}}{\zeta} + \frac{\psi_{\alpha\beta}}{\mathcal{R}_B}\right]. \tag{7.1.11d}$$

Here the slash ($\psi_{\alpha\beta|\gamma}$) denotes covariant derivative with respect to the background metric, and O[X] means "of order X." (ix) $\psi_{\alpha\beta}$ propagates along the rays in accordance with the propagation equation

$$\psi_{\alpha\beta|\mu} k^\mu = -\frac{1}{2} k^\mu{}_{|\mu} \psi_{\alpha\beta}. \tag{7.1.12}$$

(x) One uses equation (7.1.12) to propagate the initial, local-wave-zone field out through the Universe to Earth.

Because, in an appropriate gauge, $\psi_{\alpha\beta}$ is the metric perturbation associated with the waves (eq. 7.1.2), one can use the usual formulas (Chapters 35 and 37 of MTW) to calculate from $\psi_{\alpha\beta}$ whatever properties of the waves one wishes. For example, one can use equations (35.62a,e)of MTW to compute the contribution of the waves to the Riemann curvature tensor of spacetime. By virtue of equations (7.1.11) that contribution is

$$R^{(GW)}_{\alpha\beta\gamma\delta} = \frac{1}{2}\left(\ddot{\psi}_{\alpha\delta} k_\beta k_\gamma + \ddot{\psi}_{\beta\gamma} k_\alpha k_\delta - \ddot{\psi}_{\beta\delta} k_\alpha k_\gamma - \ddot{\psi}_{\alpha\gamma} k_\beta k_\delta\right) + \text{fractional errors of } O[\lambda/\zeta + \lambda/\mathcal{R}_B]. \tag{7.1.13}$$

Similarly, one can use equation (35.70) of MTW to compute the Isaacson (1968) stress-energy tensor associated with the waves. It reduces to

$$T^{(GW)}_{\alpha\beta} = \frac{1}{32\pi} \langle \dot{\psi}_{\mu\nu} \dot{\psi}^{\mu\nu} \rangle k_\alpha k_\beta, \tag{7.1.14}$$

where $\langle\ \rangle$ means"average over several wavelengths of the waves."

The gravitational-wave field is not fully measurable. Only that part which contributes to the Riemann curvature tensor is measurable; the remainder can be changed at will by gauge transformations (infinitesimal coordinate transformations). The form of the generic gauge transformation which preserves all the above equations is

$$\psi_{\mu\nu}^{NEW} = \psi_{\mu\nu}^{OLD} + \Phi_\mu k_\nu + \Phi_\nu k_\mu \ , \qquad (7.1.15a)$$

where Φ_μ is a vector field which has the same variability properties as $\psi_{\alpha\beta}$ [eqs. 7.1.11], which is orthogonal to the propagation vector

$$\Phi_\mu k^\mu = 0, \qquad (7.1.15b)$$

and which satisfies the propagation equation

$$\Phi_{\mu|\alpha} k^\alpha = -\frac{1}{2} k^\alpha \Phi_{\mu|\alpha} \ . \qquad (7.1.15c)$$

An arbitrary observer with 4-velocity $\vec{u}$, at an arbitrary event in spacetime, may find it convenient to make $\psi_{\mu\nu}$ "spatial, transverse, and traceless" in his own rest frame. He can accomplish this by a gauge transformation of the above form with

$$\Phi_\mu = -\frac{u^\alpha \psi_{\alpha\mu}}{u^\gamma k_\gamma} + \frac{u^\alpha \psi_{\alpha\beta} u^\beta}{2(u^\gamma k_\gamma)^2} k_\mu \ . \qquad (7.1.16a)$$

The resulting ("NEW"; "Transverse Traceless") gravitational-wave field $\psi_{\mu\nu}^{TT}$ is related to the original ("OLD") one $\psi_{\mu\nu}$ by

$$\psi_{xx}^{TT} = \psi_{xx} = -\psi_{yy} = -\psi_{yy}^{TT}; \quad \psi_{xy}^{TT} = \psi_{xy} = \psi_{yx}^{TT} \ ; \quad \text{all other } \psi_{\alpha\beta}^{TT} = 0$$

in local rest frame of observer, with Minkowskii coordinates so oriented that $\vec{k} = k^0(\vec{e}_0 + \vec{e}_z)$. (7.1.16b)

In other words, this gauge transformation simply throws away all parts of $\psi_{\alpha\beta}$ except those that are purely spatial and are transverse to the propagation direction; and in the process it preserves the tracelessness of $\psi_{\alpha\beta}$.

7.2 Example of Propagation

As an example of the above formalism, consider a gravitational wave emitted by the gravitational collapse of a 10^6 solar-mass star at a time when the universe was only a few million years old.

Idealize the background metric, through which the waves propagate toward Earth, as a perfectly smooth Friedmann metric (MTW chapter 29)

$$ds^2 = g^{(B)}_{\mu\nu} dx^\mu dx^\nu = a^2[-d\eta^2 + d\chi^2 + \Sigma^2(d\theta^2 + \sin^2\theta d\phi^2)] \quad (7.2.1a)$$

$$a = a(\eta), \quad \Sigma = \begin{cases} \sin\chi & \text{if universe is "closed"} \\ \chi & \text{if universe is "flat"} \\ \sinh\chi & \text{if universe is "open"} \end{cases} ; \quad (7.2.1b)$$

and at each event in the universe introduce the orthonormal frame ("local proper rest frame of universe")

$$\vec{e}_{\hat{\eta}} = \frac{1}{a}\frac{\partial}{\partial\eta}, \quad \vec{e}_{\hat{\chi}} = \frac{1}{a}\frac{\partial}{\partial\chi}, \quad \vec{e}_{\hat{\theta}} = \frac{1}{a\Sigma}\frac{\partial}{\partial\theta}, \quad e_{\hat{\phi}} = \frac{1}{a\Sigma\sin\theta}\frac{\partial}{\partial\phi} . \quad (7.2.1c)$$

Place the supermassive star (source) at the origin of the Friedmann spatial coordinate system, $\chi_s = 0$; and let it emit its gravitational waves during an interval of time $\eta_s \le \eta \le \eta_s + \Delta\eta$. The duration of the burst [$\Delta\tau_e = a(\eta_s)\Delta\eta$ = (a few seconds)] will be very short compared to the age of the universe at the time of emission; and hence "a" will change negligibly during the emission

$$a_s \equiv a(\eta_s) >>> (da/d\eta)_s \, \Delta\eta . \quad (7.2.2)$$

The rays, along which the waves propagate, are null geodesics emanating from the star's world line ($\chi_s = 0$, $\eta_s \le \eta \le \eta_s + \Delta\eta$). By solving the geodesic equation in the Friedmann metric one obtains the following equations for the ray originating at ($\chi = 0$, $\eta = \eta_s + \tau_e/a_s$) and propagating in the (θ_e, ϕ_e) direction:

$$\chi = \eta - (\eta_s + \tau_e/a_s), \quad \theta = \theta_e, \quad \phi = \phi_e , \quad (7.2.3a)$$

$$k^\eta = k^\chi = \frac{d\eta}{d\zeta} = \frac{d\chi}{d\zeta} = \frac{a_s}{a^2}, \quad k^\theta = k^\phi = 0. \quad (7.2.3b)$$

Note that the "physical components" of the propagation vector (components in the local proper rest frame of the universe [7.2.1c]) are

$$k^{\hat{\theta}} = k^{\hat{\phi}} = 0, \quad k^{\hat{\eta}} = k^{\hat{\chi}} = (a_s/a) \text{ at general event} \quad (7.2.4)$$

$$= 1 \text{ at source.}$$

The source's retarded time, expressed as a function of Friedmann coordinates, is

$$\tau_e = a_s\,(\eta - \eta_s - \chi); \tag{7.2.5}$$

cf. equation (7.2.3a). The gradient of τ_e is the negative of the propagation vector, as required by equation (7.1.9).

In the asymptotic rest frame of the source ($\chi \ll 1$; $\eta_s \lesssim \eta \lesssim \eta_s + \Delta\eta$) the Minkowskii radial and time coordinates are related to Friedmann coordinates and to retarded time by

$$r = a_s\chi, \quad t = a_s(\eta-\eta_s); \quad \tau_e = t-r; \tag{7.2.6a}$$

and the line element is

$$ds^2 = -dt^2 + dr^2 + r^2\,(d\theta^2 + \sin^2\theta\, d\phi^2) \tag{7.2.6b}$$

$$+ O(M/r)\, dx^\alpha\, dx^\beta \leftarrow \text{contributions from gravity of source}$$

$$+ O(r^2/a^2 + t\, d\,\ell n\, a/dt) dx^\alpha dx^\beta \leftarrow \text{cosmological corrections.}$$

The gravitational waves, expressed in a gauge that is "TT" with respect to this asymptotic rest frame, have as their only nonzero components

$$\psi_{\hat\theta\hat\theta} = -\psi_{\hat\phi\hat\phi} \equiv \frac{1}{r}\, A_+(\tau_e,\theta,\phi) \qquad \text{in local wave zone.} \tag{7.2.7}$$

$$\psi_{\hat\theta\hat\phi} = \psi_{\hat\phi\hat\theta} \equiv \frac{1}{r}\, A_x(\tau_e,\theta,\phi)$$

The quantities A_+ and A_x are amplitudes for the two orthogonal polarization states "+" and "x". They are rapidly varying functions of retarded time $\tau_e = t-r$, and slowly varying functions of θ and ϕ :

$$\dot A \equiv \frac{\partial A}{\partial \tau_e} \sim \frac{A}{\lambda\!\!\!^{-}}, \qquad \frac{1}{r}\frac{\partial A}{\partial\theta} \sim \frac{A}{r}, \qquad \frac{1}{r\sin\theta}\frac{\partial A}{\partial\phi} \sim \frac{A}{r} \tag{7.2.8}$$

[cf. eq. (7.1.11) and note that in the asymptotic rest frame ζ = (affine parameter) = r].

The gravitational-wave field (7.2.7) propagates out into the Friedmann universe by means of the geometric-optics propagation equation (7.1.12). By solving this equation one discovers that

$$a\Sigma\psi_{\hat{\alpha}\hat{\beta}} = \text{constant along each ray,} \tag{7.2.9}$$

where Σ is the cosmological circumference function defined in equation (7.2.1b). Consequently (cf. eqs. [7.2.1b], [7.2.6a], [7.2.7], and [7.2.5]) the gravitational-wave field at an arbitrary event (η,χ,θ,ϕ) in spacetime is

$$\psi_{\hat{\theta}\hat{\theta}} = -\psi_{\hat{\phi}\hat{\phi}} = \frac{1}{a\Sigma} A_+[a_s(\eta-\eta_s-\chi),\theta,\phi] \tag{7.2.10a}$$

$$\psi_{\hat{\theta}\hat{\phi}} = \psi_{\hat{\phi}\hat{\theta}} = \frac{1}{a\Sigma} A_x[a_s(\eta-\eta_s-\chi),\theta,\phi]. \tag{7.2.10b}$$

Because the source is far from Earth, when these waves reach Earth they look plane waves. An observer on Earth can interpret them in terms of a local Minkowskii coordinate system with basis vectors

$$\frac{\partial}{\partial t} \equiv \vec{e}_0 = \vec{e}_{\hat{\eta}}, \quad \frac{\partial}{\partial z} \equiv \vec{e}_z = e_{\hat{\chi}}, \quad \frac{\partial}{\partial x} \equiv \vec{e}_x = \vec{e}_{\hat{\theta}}, \quad \frac{\partial}{\partial y} \equiv \vec{e}_y = \vec{e}_{\hat{\phi}}. \tag{7.2.11a}$$

If the location of Earth today is $(\eta_o, \chi_o, \theta_o, \phi_o)$, then the observer's Minkowskii coordinates and the global Friedmann coordinates near Earth are related by

$$t=a_o(\eta-\eta_o),\ z=a_o(\chi-\chi_o),\ x=a_o\Sigma_o(\theta-\theta_o),\ y=a_o\Sigma_o\sin\theta_o(\phi-\phi_o). \tag{7.2.11b}$$

The observer on Earth describes the universe's cosmological structure in terms of a Hubble expansion rate H_o and a deceleration parameter q_o; and he describes the source of the waves as having a cosmological redshift Z_s, which is related to the expansion factor by

$$1 + Z_s = a_o/a_s. \tag{7.2.12}$$

The equations of Friedmann cosmology permit one to express $a_o\Sigma_o \equiv$ (circumference of a circle that passes through Earth and is centered on the source at redshift Z_s)$/2\pi$ in terms of H_o, q_o, and Z_s:

$$a_o\Sigma_o \equiv R = \frac{H_o^{-1}}{q_o^2(1+Z_s)}\left[1-q_o+q_oZ_s-(1-q_o)(2q_oZ_s+1)^{1/2}\right]; \tag{7.2.13}$$

cf. eq. (29.33) of MTW. By combining equations (7.2.10) -(7.2.13) one obtains the following expressions for the gravitational-wave field that sweeps past Earth:

$$\psi_{xx} = -\psi_{yy} = \frac{1}{R}A_+\left[\frac{t-z}{1+Z_s} + \text{const.}, \theta_o,\phi_o\right], \tag{7.2.14a}$$

$$\psi_{xy} = \psi_{yx} = \frac{1}{R}A_x\left[\frac{t-z}{1+Z_s} + \text{const.},\theta_o,\phi_o\right], \tag{7.2.14b}$$

all other $\psi_{\mu\nu}$ vanish.

Notice that the time dependence, $A[(t-z)/(1+Z_s)+\text{const.}, \theta_o,\phi_o]$, of the waves as they sweep past Earth is identical to the time dependence of the emitted waves as measured by the source, $A[\tau_e,\theta_o,\phi_o]$, except for a redshift of $1+Z_s$ -- the same redshift as one sees in electromagnetic spectral lines. Notice also that for very large redshifts, $Z_s >>1$, the amplitude of the waves is independent of redshift:

$$\psi \sim \frac{A}{R} = \frac{A}{H_oq_o} \quad \text{for} \quad Z_s >> 1 \quad \text{and} \quad Z_s >> 1/q_o. \tag{7.2.15}$$

8. CONCLUDING REMARKS

Although it may appear from these lectures that the theory of gravitational-wave generation is a highly sophisticated and complex subject, one should not let this blind one to its gross inadequacies.

The strongest sources of gravitational waves in the universe--and the most promising sources for ultimate detection -- are those with strong internal gravity and fast large-amplitude internal motions. For them the only reliable technique of analysis is massive computer calculations (§6). All the fancy analytic tools of these lectures are helpless in the face of such sources!

I am indebted to Joseph Weber for his patience, and to Alessandra Exposito and Jim Isenberg for valuable assistance in the preparation of the typed manuscript.

ABSTRACT

The study displays the existence of a gravitational singularity in the universe generating synchronized and extremely low frequency plane TEM (transverse electromagnetic) waves. It is proposed that atomic intrinsic electromagnetic fields create resonance with these plane TEM waves, causing atoms to receive and to re-emit synchronized plane TEM waves. The energy flow of synchronized plane TEM waves, travelling in opposite directions between e.g. two atoms, creates mutual force of attraction, *i.e.* gravity. Consequently, gravity is not an intrinsic atomic feature; however, the result of passive atoms exposed to electromagnetic energy. The study describes how plane TEM waves emitted by the gravitational singularity were measured. The study also displays how gravity from the earth, moon, sun and the gravitational singularity was measured and how gravity was simulated using an electronic device. The present electromagnetic law of gravity is compared with Newtonian geometric law of gravity.

Keywords: Gravity; Gravitation; Poynting Vector; Elementary Particle; Dipole; TEM Waves

1. Introduction

Newton made the geometric description of gravity. Despite elapsed time the theoretical description of gravity remains unsolved.

It's known that the atom contains charge, static electric- and magnetic dipole moment. These fields decrease with the square of the distance and can consequently not create gravity. It seems unlikely that the atom generates alternating electromagnetic fields by itself, and hence electromagnetic energy is often ruled out as the origin of gravity. The prevailing track is to explain gravity with string theory [1,2].

The present study builds on the observation that gravity comprises plane TEM (transverse electromagnetic) waves or energy. The theory of plane TEM waves is well known and hence, it is possible to describe gravity entirely by the laws of electromagnetism. All theory is found in university grade textbooks [3,4]. TEM waves can also be explained by its photon according to the wave-particle duality [5,6]. In the present paper the gravitational energy is described by the plane TEM wave.

The study builds on the observation that the universe contains one generator emitting plane TEM waves. All emitted plane TEM waves are quasi synchronized, facilitated by its extremely low frequency and origin. This generator or gravitational singularity can consist of circulating charge and is called the Gravity Source in the present study.

Electric, **E**, and magnetic, **B**, field vectors are linked in plane TEM waves and in this case they are almost static. An atomic elementary entity that contains a static electric field, $\mathbf{E}_i$, merged with a static magnetic field, $\mathbf{B}_i$, creates resonance with this type of plane TEM waves; it receives plane TEM waves and re-emits them without changing content. It is called MQ (mass quantum) in the present study.

In order to illustrate the simplicity of gravity a grossly simplified universe is described. This simplified universe contains a Gravity Source and only two MQs, MQ_1 and MQ_2. The Gravity Source emits plane TEM waves, TEM_1, to MQ_1. MQ_1 creates resonance, receives and re-emits TEM_1 uniformly in space and where a part is received by MQ_2. MQ_2 creates resonance, receives and re-emits TEM_1 uniformly in space and where a part is received by the Gravity Source. Simultaneously the Gravity Source emits plane TEM waves, TEM_2, to MQ_2, MQ_2 re-emits a part to MQ_1 and MQ_1 re-emits a part to the Gravity Source. Consequently, this simplified universe contains circulating, synchronized plane TEM waves travelling in opposite directions between the Gravity Source, MQ_1 and

MQ_2. According to the laws of electromagnetism, synchronized plane TEM waves travelling in opposite directions create mutual force of attraction, *i.e.* gravity. This model can be scaled up to any number of MQs, e.g. to today's universe.

In the present study the hypothesis is that gravity is electromagnetic energy generated centrally in the universe, distributed within the universe, received and re-emitted by fully passive atoms or MQs (mass quanta) in atoms.

This theory was verified in Section 2. Synchronized, plane TEM waves travelling in opposite direction were mapped on the laws of electromagnetism. It resulted in an equation describing the relation between the number of involved MQs, their distance and the mutual force of attraction. This relationship can be called the electromagnetic law of gravity and which was compared with the Newtonian geometric law of gravity.

Section 3 describes an electronic device that simulated the MQ. This device was used in Section 4 in order to empirically verify the theory in Section 2. Measurements were made according to a method described in [7]. Section 3 also describes an electronic device that contained a static magnetic field merged to an alternating electric field and where the frequency of this field was adjusted to the frequency of plane TEM waves emitted by the Gravity Source. It facilitated measurement of the Gravity Source frequency.

Section 5 covers discussion and where the measured (gravity) TEM wave's characteristics are mapped on the atom's nucleus, traditionally described by the Standard Model [8,9]. It results in a better understanding of the atom. The position of the earth's rotational axis relative to the Galactic Centre [10,11] and the Gravity Source is discussed based on data obtained from WMAP and the Planck mission [12], indicating the huge influence of the Gravity Source on the entire universe.

Conclusions are made in Section 6.

Aim of the study: the aim of the study is to present and to verify a theoretical model of gravity.

2. Theoretical Model of Gravity

Maxwell's equations $\operatorname{curl}\mathbf{H} = \boldsymbol{i} + \partial\mathbf{D}/\partial t$ and $\operatorname{curl}\mathbf{E} = -\partial\mathbf{B}/\partial t$ result in plane TEM (transverse electromagnetic) waves [3]. This is the most common electromagnetic energy in the universe resulting in e.g. radio waves, light and X-rays depending on frequency.

The behavior and characteristics of plane TEM waves is independent of its frequency. The field vectors **E** and **B** or $\mathbf{H}(\mathbf{B} = \mu_0\mathbf{H})$ are linked and perpendicular. The field vector amplitudes relate as $\mathrm{E} = c\mathrm{B}$, where c is the speed of light. The electric and magnetic field vector amplitudes E and B decrease with the distance from the source as 1/r. The Poynting vector **S** describes the TEM energy flow density [4]

$$\mathbf{S} = \mathbf{E} \times \mathbf{H} \tag{1}$$

The energy stored in the magnetic field is just equal to that in the magnetic field. The direction of energy flow is reversed for a wave travelling in the opposite direction because the phase of **E** and **H** is reversed.

Assume that one source, Source 1, radiates plane TEM_1 waves, described by its Poynting vector $\mathbf{S}_1(r)$ at the distance r from Source 1. Source 2 is positioned at the distance r. Source 2 is switched on whereby it radiates plane TEM_2 waves uniformly. In the direction towards Source 1 plane TEM_1 and TEM_2 waves interact because of the force between their synchronized field vectors. This also implies that there is energy transfer from TEM_1 to TEM_2 when TEM_2 propagates towards Source 1. In equilibrium there is energy transfer in both directions, *i.e.* from TEM_1 to TEM_2 vice versa. Note that **E** and **H** are always perpendicular and hence $\mathbf{S} = \mathbf{E} \times \mathbf{H}$ can be replaced by $\mathrm{S} = \mathrm{E} \cdot \mathrm{H}$. Equilibrium is defined by the amount of energy that Source 1 is able to deliver at Source 2, e.g. at the distance r, $\mathrm{S}_1(r)$, and the amount of energy that Source 2 is able to deliver at Source 1, *i.e.* $\mathrm{S}_2(r)$. This results in back reaction force $\mathrm{F}(r)$ proportional to $\mathrm{S}_1(r)$ on Source 1 and $\mathrm{S}_2(r)$ on Source 2, *i.e.* radiation reaction [4], and where γ is a constant. This creates mutual force of attraction $\mathrm{F}(r)$,

$$\mathrm{F}(r) = \gamma \cdot \mathrm{S}_1(r) \cdot \mathrm{S}_2(r) \tag{2}$$

It is now assumed that each source is an MQ (mass quantum, defined below) and where its Poynting vector is $\delta\mathrm{S}(r)$ and where r denotes the distance from the source. **E** and **H** decrease linearly with the distance r implying that $\delta\mathrm{S}(r)$ decreases with the square of the distance; $\delta\mathrm{S}(r) = \delta\mathrm{S}(0)/r^2$. The mutual force of attraction $\delta\mathrm{F}(r)$ between two MQs at distance r is

$$\delta\mathrm{F}(r) = \gamma \cdot \delta\mathrm{S} \cdot \delta\mathrm{S}/r^2. \tag{3}$$

It is now assumed that one MQ acts on p collocated MQs, belonging to the set **P** of all MQs at Source 2, and where each force can be described by $\delta\mathrm{F}(r)$. These MQs are synchronized resulting in the force

$$\sum_{p\in P} \delta\mathrm{F}(r) = \gamma \cdot \delta\mathrm{S} \cdot \sum_{p\in P} \delta\mathrm{S}\,/r^2 = \gamma \cdot (\delta\mathrm{S} \cdot \delta\mathrm{S}) \cdot p/r^2 \tag{4}$$

It is now assumed that n collocated MQs, belonging to the set **N** of all MQs at Source 1, act on p collocated MQs, belonging to the set **P** of all MQs at Source 2, resulting in the total force $\mathrm{F}(r)$,

$$\mathrm{F}(r) = \gamma \cdot \sum_{n\in N} \delta\mathrm{S} \cdot \sum_{p\in P} \delta\mathrm{S}/r^2 = \gamma \cdot (\delta\mathrm{S} \cdot \delta\mathrm{S}) \cdot n \cdot p/r^2 \tag{5}$$

$\delta\mathrm{S} \cdot \delta\mathrm{S}$ is a constant described by the intrinsic characteristics of the MQ, and hence Equation (5) is simpli-

Copyright © 2013 SciRes.

fied into

$$\mathrm{F}(r) = \xi \cdot n \cdot p / r^2 \qquad (6)$$

where ξ is a constant.

In the present study Equation (6) is called the law of gravity between two clusters, at distance r containing n respectively p MQs. Note that the cluster can be few MQs, an atom, a mass or a planet.

The implication of Equation (3) is that an atomic MQ generates gravity quantum and consequently, the present theory applies to quantum gravity.

It is proposed that elementary entities or more precisely mass quanta MQs, in the atomic nucleus, contain intrinsic, combined electric and magnetic fields or electromagnetic dipoles. Every MQ creates resonance and receives Gravity Source plane TEM waves. This results in emitted TEM waves. Two MQs and their emitted TEM waves create mutual force of attraction δF(r). This is illustrated with gravity between the earth and the sun. The earth contains n mass quanta (MQs) creating a force $n \cdot \delta \mathrm{F}(r)$ on every mass quanta (MQ) in the sun. The sun contains p mass quanta (MQs), thus the total force of attraction is $n \cdot p \cdot \delta \mathrm{F}(r)$ and that is equal to Equation (6). The earth's mass m_1 is proportional to the number of MQs on earth, *i.e.* $m_1 \sim n$, and the sun's mass $m_2 \sim p$. Equation (6) is then approximately equal to the Newtonian geometric law of gravity

$$\mathrm{F}_{\mathrm{Gravity}} = \xi \cdot n \cdot p / r^2 \approx \mathrm{F}_{\mathrm{Newton}} = \mathrm{G} \cdot m_1 \cdot m_2 / r^2 \qquad (7)$$

Note that F_G, G and the *constant* decreases with the distance to the Gravity Source.

3. Materials and Methods

All experiments were performed using one or many identical electronic devices called MQ. The MQ created resonance with plane TEM waves; it received and emitted plane TEM waves. Each MQ consisted of two neodymium magnets, with diameter 22 mm, spaced by a thin (0.05 mm) plastic foil. The south pole of one magnet attracted the north pole of the other. This created an internal magnetic field $\mathbf{B}_i$. One magnet was connected to the positive pole of a voltage source U. The other magnet was connected to the negative pole, **Figure 1**. This created an internal electric field $\mathbf{E}_i$, e.g. 10^6 V/m at $U = 50$ V. $\mathbf{B}_i$ and $\mathbf{E}_i$ were merged within the thin space between the magnets and could be described as electromagnetic dipoles. Measurements were performed with the neodymium magnets connected to a 9 V battery, forming a portable MQ, detached from external influence (e.g. AC, ground). This MQ was used in Experiments 5-10.

Experiments 1-4 and 11 were performed with the magnets connected to a low frequency signal generator with output voltage 0.5 mV RMS. Hence, the static electric field was replaced by an alternating electric field. The MQ created resonance at the signal generator frequency; it received and re-emitted plane TEM waves having this frequency. This device, also called MQ, was used in order to measure the frequencies of plane TEM waves originating from the Gravity Source.

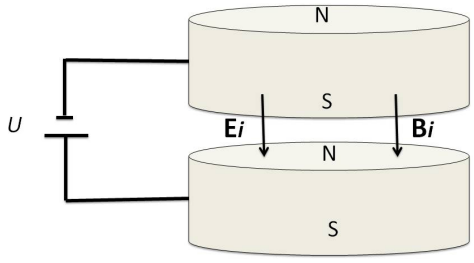

Figure 1. Generating TEM waves. Two neodymium magnets, with a diameter 22 mm, were spaced by a thin (0.05 mm) plastic foil with the south pole of one magnet attached to the north pole of the other. This created an internal magnetic field $\mathbf{B}_i$. One magnet was connected to the positive pole of a voltage source U, and the other magnet to the negative pole. This created an internal electric field $\mathbf{E}_i$, combined with $\mathbf{B}_i$. This device, called MQ received and re-emitted plane TEM waves.

Measurements of plane TEM wave field vector amplitudes were made as described in [7]. That report describes in detail how the position and amplitude of electric and magnetic field vectors were measured using a charge meter. The charge meter is described in detail. Measurements in the present study were made almost identically to those described in [7]. In summary the charge meter contained a probe with charge density ρ. The probe was moved, with constant speed, through the TEM wave electric field vectors **E**. This resulted in an electric body force $\rho\mathbf{E}$ on the probe charge density ρ. This current pulse was amplified and displayed. In this case **E** was field vectors, implying that div**E** was large and resulted in a distinct current pulse. This probe was also moved, with constant speed, through the TEM magnetic field vectors **B**, which resulted in a magnetic body force $\mathbf{J} \times \mathbf{B}$ on current **J** in the probe. In this case **B** was field vectors, implying that div**B** was large and resulted in a distinct current pulse. The measurement method had one important feature. The field vector's physical length was proportional to its amplitude and in the present study between 0.1 - 10 m. It was easy to measure and determine the physical length of the field vectors since div**E** and div**B** were large. Hence, this was an accurate measure of the relative amplitude. Consequently, all results are presented as relative amplitude.

TEM waves propagating in two directions, from Source 1 to Source 2 and from Source 2 to Source 1, were measured in the following way. A permanent magnet with magnetic field $\mathbf{B}_\mathbf{M}$ (1 μT) was inserted within the TEM wave's path, 1 m in front of Source 1. The propa-

Copyright © 2013 SciRes.

gating TEM wave consisted of electric **E** and magnetic **B** field vectors. The magnetic field $\mathbf{B_M}$ created a force on the positive magnetic field vectors $\mathbf{B}^+$ and on the negative magnetic field vectors $\mathbf{B}^-$. According to [3] it made the TEM wave's positive magnetic field vectors $\mathbf{B}^+$ divert the distance d_1 to one side and the negative magnetic field vectors $\mathbf{B}^-$ divert the distance d_2 to the opposite side. TEM waves propagating in one direction (e.g. from Source 1 to Source 2) were influenced so that their field vectors were diverted in the horizontal plane, see **Figure 2**, the electric field vectors **E** where oriented in the horizontal plane and the magnetic field vectors **B** were oriented in the vertical plane. TEM waves propagating in the opposite direction (e.g. from Source 2 to Source 1) were influenced so that their field vectors were diverted in the vertical plane, see **Figure 3**. The electric field vectors **E** where oriented in the vertical plane and the magnetic field vectors **B** were oriented in the horizontal plane. This enabled measurement of the two directions separately. Consequently, TEM waves propagating in opposite directions between two sources were rotated 90 degrees relative to each other. The field vectors propagated in smooth bows distanced by the magnetic field $\mathbf{B_M}$.

Measurements were performed 50 km south of Stockholm, Sweden.

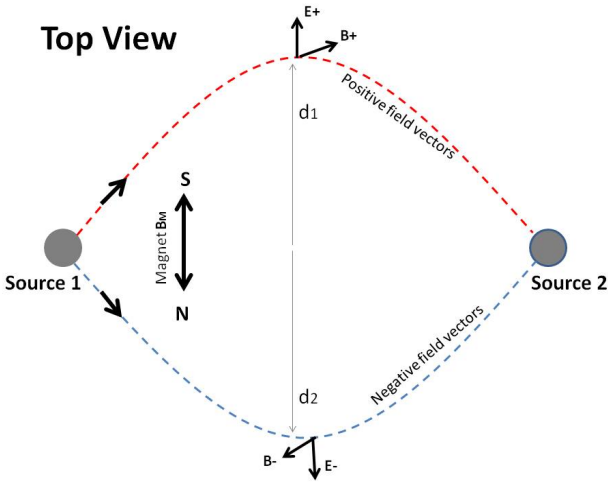

Figure 2. Measuring TEM waves propagating from Source 1. Two MQs, as described in Figure 1, Source 1 and Source 2, were positioned at 10 m distance. Source 1 was connected to a 9 V battery and Source 2 was also connected to a 9 V battery. This resulted in TEM waves propagating between the two sources. A permanent magnet $\mathbf{B_M}$ was inserted within the flow of TEM waves, 1 m in front of Source 1. TEM waves propagating from Source 1 to Source 2 were diverted in the horizontal plane. This resulted in that positive field vectors $\mathbf{E}^+$ and $\mathbf{B}^+$ were diverted the distance d_1 in the horizontal plane. The negative field vectors $\mathbf{E}^-$ and $\mathbf{B}^-$ were diverted the distance d_2 to the opposite side in the horizontal plane. This enabled separate measurement of TEM waves propagating from Source 1 to Source 2, respectively from Source 2 to Source 1.

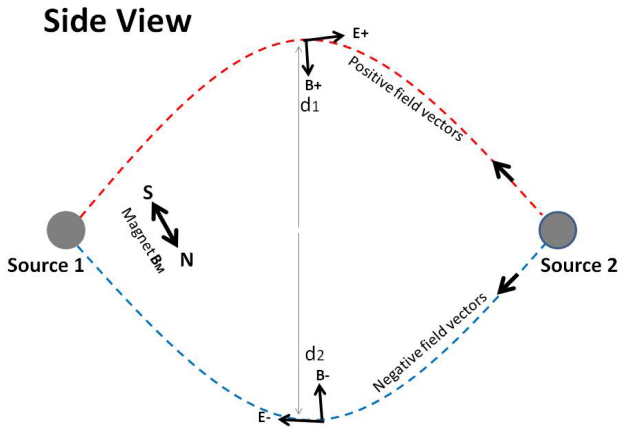

Figure 3. Measuring TEM waves propagating from Source 2. Two MQs, as described in Figure 1, Source 1 and Source 2, were positioned at 10 m distance. Source 1 was connected to a 9 V battery and Source 2 was also connected to a 9 V battery. This resulted in TEM waves propagating between the two sources. A permanent magnet $\mathbf{B_M}$ was inserted within the flow of TEM waves, 1 m in front of Source 1. TEM waves propagating from Source 2 to Source 1 were diverted in the vertical plane. This resulted in that positive field vectors $\mathbf{E}^+$ and $\mathbf{B}^+$ were diverted the distance d_1 in the vertical plane. The negative field vectors $\mathbf{E}^-$ and $\mathbf{B}^-$ were diverted the distance d_2 to the opposite side in the vertical plane. This enabled separate measurement of TEM waves propagating from Source 2 to Source 1, respectively from Source 1 to Source 2.

Analysis: the experiments were performed blindly, randomly and repeated 3 times.

4. Results

Experiments 1-4 were made with the MQ connected to the signal generator. The purpose with these experiments was to verify plane TEM wave frequency and its origin. Initially the signal generator frequency was increased from 1 to 100 Hz in increments of 0.1 Hz. TEM wave amplitude close to the MQ was measured as a function of frequency. It was observed that the MQ received and emitted plane TEM waves from the object being measured at two distinct frequencies; 69.9 Hz and 91.9 Hz. The signal generator was adjusted to these two frequencies in Experiments 1-4. It was also observed that the MQ always received and emitted plane TEM waves from the earth (*i.e.* ground). Hence, the MQ did not generate TEM waves; its only function was to create resonance at the plane TEM wave frequency.

Experiment 1. The purpose with this experiment was to measure the frequency of TEM waves received from the Gravity Source. The method was to create resonance (*i.e.* low impedance) in an MQ, connected to a signal generator, and to measure the amplitude of transmitted and absorbed TEM waves as function of frequency. The purpose was also to measure the direction of TEM waves

Copyright © 2013 SciRes.

received from and transmitted to the Gravity Source. One MQ, connected to a signal generator, was positioned on a table and this was called Source 1. The signal generator frequency was 69.9 Hz and then changed to 91.9 Hz. The generator frequency was carefully adjusted to maximum TEM wave field vector amplitude. 1‰ deviation in frequency resulted in approximately 50% change in TEM wave field vector amplitude, which illustrates the demand for accuracy. The MQ was activated at the frequency 69.9 Hz for 48 hours in order for the experiment to stabilize. It was observed that the field vector amplitude increased approximately 10 times during 48 hours. It also continued to increase after 48 hours by approximately 10% daily. It produced plane TEM_1 waves propagating from Source 1 towards north (earth's rotational axis). It followed a diurnal, counter-clockwise circle with approximately 20 degrees cone angel. Its peak altitude was approximately 75 degrees and occurred at noon (in Sweden) and the direction was towards the geographical north +/− 5 degrees. Plane TEM_2 waves propagated from a source in the universe towards Source 1, aligned along and merged with TEM_1. It was possible to measure TEM_1 and TEM_2 separately by inserting a magnet, with magnetic field $\mathbf{B_M}$ 1 m in front of Source 1, as explained in **Figure 2** and in **Figure 3**. The procedure is also explained in Experiment 10. Measurements displayed electric field vectors $\mathbf{E}^+$ and $\mathbf{E}^-$ and magnetic field vectors $\mathbf{B}^+$ and $\mathbf{B}^-$ perpendicular to the direction from Source 1 to Source 2 and from Source 2 to Source 1. In each direction the field vectors $\mathbf{E}^+$ and $\mathbf{B}^+$ respectively $\mathbf{E}^-$ and $\mathbf{B}^-$ were perpendicular, *i.e.* separated 90 degrees as in any plane TEM wave, e.g. radio wave [3]. **E** and **B** in one direction were rotated 90 degrees relative to **E** and **B** in the opposite direction, as described in **Figures 2** and **3**. In each direction the amplitudes were identical, *i.e.* $\mathbf{E}^+ = \mathbf{E}^-$ and $\mathbf{B}^+ = \mathbf{B}$; however, they varied between the two directions. Positioning an electric or magnetic field close to the field vectors changed their positions, confirming their nature and polarity. The method is described in [7]. The experiment was repeated, using generator frequency 91.9 Hz, displaying similar results. It is proposed that Source 2 was the Gravity Source generating plane TEM waves with the frequency 69.9 Hz and 91.9 Hz. The experiment displayed that the MQ, Source 1, received TEM_2 waves from the Gravity Source and that it produced TEM_1 waves which propagated in the direction towards the Gravity Source.

Experiment 2. The purpose with this experiment was to measure the frequency of TEM waves received from and transmitted to the sun. The method was to create resonance (*i.e.* low impedance) in an MQ, connected to a signal generator, and to measure the amplitude of transmitted and absorbed TEM waves as function of frequency. The purpose was also to measure the direction of TEM waves received from and transmitted to the sun. Experiment 1 was repeated; however, in this case TEM_1 and TEM_2 waves to and from the sun were measured at 69.9 Hz and then at 91.9 Hz. Measurements displayed results similar to Experiment 1, and where the only differences were the direction of the TEM waves and their amplitudes. TEM_1 and TEM_2 waves were always directed to and from the sun during daytime. The amplitude of plane TEM waves to/from the sun were less than 5% of the plane TEM waves to/from the Gravity Source, indicating the huge influence of the Gravity Source.

Experiment 3. The purpose with this experiment was to measure the frequency of TEM waves received from and transmitted to the moon. The method was to create resonance (*i.e.* low impedance) in an MQ, connected to a signal generator, and to measure the amplitude of transmitted and absorbed TEM waves as function of frequency. The purpose was also to measure the direction of TEM waves received from and transmitted to the moon. Experiment 1 was repeated; however, in this case plane TEM_1 and TEM_2 waves to and from the moon were measured at 69.9 Hz and then at 91.9 Hz. Measurements displayed results similar to Experiments 1 and 2, and where the only differences were the direction of the TEM waves and their amplitudes.

Experiment 4. The purpose with this experiment was to measure the frequency of TEM waves received from and transmitted to a mass. The method was to create resonance (*i.e.* low impedance) in an MQ, connected to a signal generator, and to measure the amplitude of transmitted and absorbed TEM waves as function of frequency. The purpose was also to measure the direction of TEM waves received from and transmitted to a mass. Experiment 1 was repeated; however, in this case plane TEM_1 and TEM_2 waves to and from a nearby object (e.g. 10 kg iron) were measured at 69.9 Hz and then at 91.9 Hz. Measurements displayed results similar to experiments 1, 2 and 3. The amplitude of $\mathbf{E}^+ = \mathbf{E}^-$ and $\mathbf{B}^+ = \mathbf{B}^-$ were proportional to the object's mass and inverse proportional to the objects distance r to the MQ, Source 1.

Experiments 5-7 aimed at verifying the theoretical model, presented in Section 2. One MQ or many collocated MQs were positioned at Source 1. Source 2 was located at the distance r = 10 m and one or many MQs were positioned at Source 2. All MQs were connected to a 9 V battery each. It produced plane TEM_1 waves propagating from Source 1 to Source 2 and plane TEM_2 waves propagating from Source 2 to Source 1. Measurements displayed electric field vectors $\mathbf{E}^+$ and $\mathbf{E}^-$ and magnetic field vectors $\mathbf{B}^+$ and $\mathbf{B}^-$ perpendicular to the direction from Source 1 to Source 2 and from Source 2 to Source 1. In each direction the field vectors $\mathbf{E}^+$ and $\mathbf{B}^+$ respectively $\mathbf{E}^-$ and $\mathbf{B}^-$ were perpendicular, *i.e.* separated 90 degrees as in any plane TEM wave, e.g. radio wave [3]. In each

Copyright © 2013 SciRes.

direction the amplitudes were identical, *i.e.* $\mathbf{E}^+ = \mathbf{E}^-$ and $\mathbf{B}^+ = \mathbf{B}^-$. It was also observed that Source 1 and Source 2 received and emitted plane TEM waves from the Gravity Source and from the earth (*i.e.* ground). Hence, the energy in TEM_1 and TEM_2 originated from these sources. Consequently, the MQs did not generate TEM waves; their only function was to create resonance with low frequency plane TEM waves and to re-emit them.

Experiment 5. The purpose of this experiment was to validate the theoretical model Equations (2) and (6); $F(r) = \gamma \cdot S_1(r) \cdot S_2(r) = \xi \cdot n \cdot p / r^2$. $S_1(r)$ and $S_2(r)$ were measured as a function of n and p. The purpose was also to simulate variation of n by varying the voltage U on one MQ. One MQ was positioned at Source 1 and one MQ at Source 2. The amplitude of the field vectors E^+ were measured in both directions (*i.e.* TEM_1 from Source 1 to Source 2 and TEM_2 from Source 2 to Source 1).

Then the number n of MQs at Source 1 was increased to 4 in steps of 1. Subsequently the number p of MQs at Source 2 was increased to 4 in steps of 1. Measurements displayed that the amplitude of the electric and magnetic field vectors $\mathbf{E}^+$, $\mathbf{E}^-$, $\mathbf{B}^+$ and $\mathbf{B}^-$ were proportional to $n \cdot p$ in both directions. Subsequently the MQ at Source 1 was connected to a variable voltage source and the voltage U on Source 1 was varied from 0 to 40 V in steps of 5 V. Measurements displayed that the amplitude of the electric and magnetic field vectors $\mathbf{E}^+$, $\mathbf{E}^-$, $\mathbf{B}^+$ and $\mathbf{B}^-$ were proportional to U in both directions, see **Figure 4**.

Experiment 6. The purpose of this experiment was to validate the theoretical model Equations (2) and (6); $F(r) = \gamma \cdot S_1(r) \cdot S_2(r) = \xi \cdot n \cdot p / r^2$. $S_1(r)$ and $S_2(r)$ were measured as a function of r. One MQ was positioned at Source 1 and one MQ at Source 2. The distance r between Source 1 and Source 2 was varied, starting with r = 1 m, then increased to 10 m in steps of 1 m. The amplitude of the field vectors $\mathbf{E}^+$, $\mathbf{E}^-$, $\mathbf{B}^+$ and $\mathbf{B}^-$ were measured in both directions as a function of the distance r. Measurements displayed that the amplitudes of the electric and magnetic field vectors $\mathbf{E}^+$, $\mathbf{E}^-$, $\mathbf{B}^+$ and $\mathbf{B}^-$ were inverse proportional to the distance r in both directions, see **Figure 5**.

Experiment 7. The purpose of this experiment was to verify that there was a transfer of energy from $S_1(r)$ to $S_2(r)$ vice versa according to Equation (2). One MQ was positioned at Source 1 and one MQ at Source 2 and the distance between them was 10 m. The amplitude of the field vectors $\mathbf{E}^+$, $\mathbf{E}^-$, $\mathbf{B}^+$ and $\mathbf{B}^-$ were measured at different distances from Source 1 along the straight direction from Source 1 to Source 2, and measured in both directions. Measurements displayed that the amplitude of the sum of electric and magnetic field vectors $\mathbf{E}^+$, $\mathbf{E}^-$, $\mathbf{B}^+$ and $\mathbf{B}^-$ from both directions (*i.e.* $TEM_1 + TEM_2$) were constant at every position between Source 1 and Source 2. $\mathbf{E}^+$, $\mathbf{B}^+$, $\mathbf{E}^-$ and $\mathbf{B}^-$ were spaced 90 degrees in both directions, as in any plane TEM wave.

In the following Experiments 8 and 9 an MQ, connected to a 9 V battery, was positioned at Source 1. Source 2 was a mass in Experiment 8 and the sun in Experiment 9.

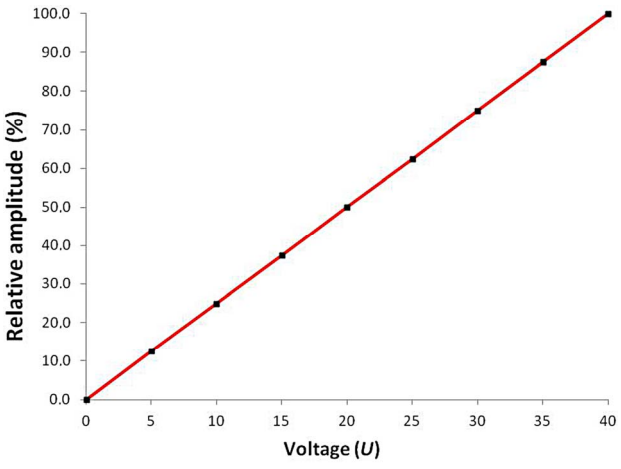

Figure 4. Field vector amplitude as function of voltage on one MQ. Two MQs, as described in Figure 1, Source 1 and Source 2, were positioned at 10 m distance. Source 2 was connected to a 9 V battery. The voltage *U* on Source 1 was varied from 0 - 40 V in steps of 5 V. The amplitude of the plane TEM_1 and TEM_2 wave's electric and magnetic field vectors ($\mathbf{E}^+$, $\mathbf{B}^+$, $\mathbf{E}^-$ and $\mathbf{B}^-$) was measured as a function of the voltage *U*. The amplitudes of all four field vectors were proportional to *U* and $\mathbf{E}^+ = \mathbf{E}^-$ and $\mathbf{B}^+ = \mathbf{B}^-$ in both directions. $\mathbf{E}^+$ amplitude in TEM_1 as function of *U* is displayed in Figure 4.

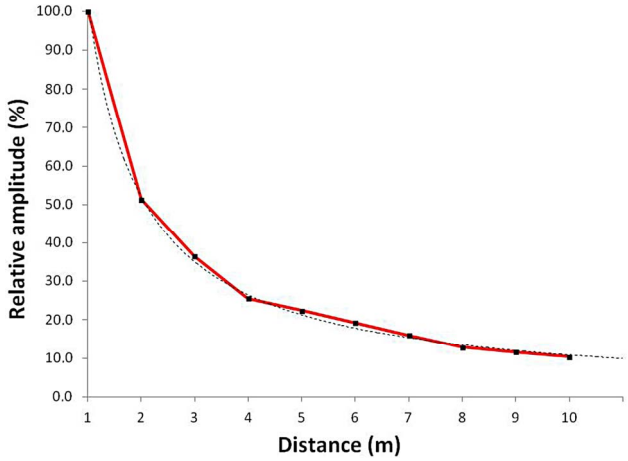

Figure 5. Field vector amplitude as a function of distance. Two MQs, described in Figure 1, were positioned at the distance *r*, which was initially 1 m and then increased to 10 m in steps of 1 m. The amplitude of TEM_1 and TEM_2 wave's electric and magnetic field vectors ($\mathbf{E}^+$, $\mathbf{B}^+$, $\mathbf{E}^-$ and $\mathbf{B}^-$) was measured as a function of the distance *r* in both directions. The amplitudes of all field vectors were proportional to1/r and $\mathbf{E}^+ = \mathbf{E}^-$ and $\mathbf{B}^+ = \mathbf{B}^-$ in both directions. $\mathbf{E}^+$ amplitude in TEM_1 as function of *r* is displayed in Figure 5. The dotted line represents the theoretical decline 1/*r*.

Experiment 8. The purpose of this experiment was to validate the theoretical model Equation (2), Equations (6) and (7); $F(r) = \gamma \cdot S_1(r) \cdot S_2(r) = \xi \cdot n \cdot p / r^2 \approx F_{Newton} = G \cdot m_1 \cdot m_2 / r^2$. $S_1(r)$ and $S_2(r)$ were measured as a function of the mass m_2. A mass, m_2, (Source 2) which consisted of iron was positioned 5 m from the MQ at Source 1. The mass m_2 was increased from 0 to 10 kg in increments of 1 kg. Measurements displayed plane TEM_1 waves propagating from Source 1 to the mass m_2 and plane TEM_2 waves propagating from the mass m_2 to Source 1. The amplitude of the field vectors $\mathbf{E}^+$, $\mathbf{E}^-$, $\mathbf{B}^+$ and $\mathbf{B}^-$ were measured, in both directions, as a function of the mass m_2. Measurements displayed that the amplitude of the electric and magnetic field vectors $\mathbf{E}^+$, $\mathbf{E}^-$, $\mathbf{B}^+$ and $\mathbf{B}^-$ were proportional to the mass m_2 in both directions, see **Figure 6**. It was also observed that the mass m_2 received and emitted plane TEM waves to and from the Gravity Source and the earth (*i.e.* ground).

Experiment 9. The purpose with this experiment was to show that Equation (2), $F(r) = \gamma \cdot S_1(r) \cdot S_2(r)$, was only valid at steady state and to demonstrate how this steady state was achieved. Measurements were performed outside Stockholm, Sweden during the daytime. Source 1, consisting of one MQ, was positioned on a table. Measurement started by activating Source 1 (*i.e.* the MQ was connected to a 9 V battery). Measurements were performed 2 m in front of Source 1 and roughly in the direction of the sun. Measurements displayed plane TEM_1 waves propagating from Source 1 in direction towards the sun (Source 2) and plane TEM_2 waves propagating in the opposite direction. The amplitude of the field vectors $\mathbf{E}^+$, $\mathbf{E}^-$, $\mathbf{B}^+$ and $\mathbf{B}^-$ were measured as a function of time (both TEM_1 and TEM_2). Measurements displayed that the amplitude of TEM_1 electric and magnetic field vectors $\mathbf{E}^+$, $\mathbf{E}^-$, $\mathbf{B}^+$ and $\mathbf{B}^-$ increased approximately six times the initial amplitude within 16 minutes. Then they remained stable displaying no change in amplitude, see **Figure 7**.

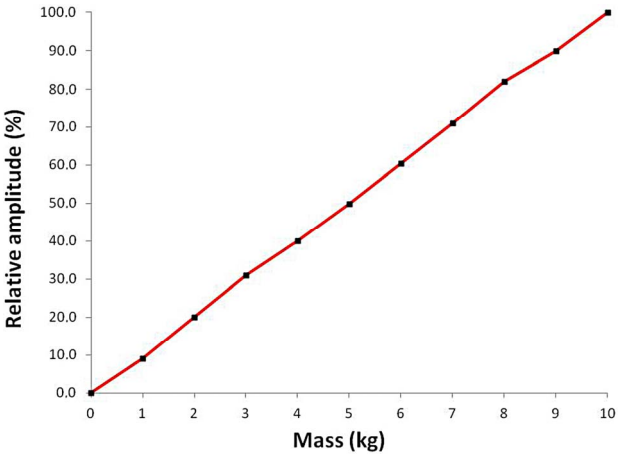

Figure 6. Field vector amplitude as a function of mass. One MQ (Source 1) was positioned 5 m from a mass which consisted of iron (Source 2). The mass was changed from 0 - 10 kg in steps of 1 kg. The amplitude of TEM_1 and TEM_2 wave's electric and magnetic field vectors ($\mathbf{E}^+$, $\mathbf{B}^+$, $\mathbf{E}^-$ and $\mathbf{B}^-$) was measured as a function of mass *m*. The amplitudes of all four field vectors were proportional to *m* in both directions and $\mathbf{E}^+ = \mathbf{E}^-$ and $\mathbf{B}^+ = \mathbf{B}^-$. $\mathbf{E}^+$ amplitude in TEM_1 as function of the mass *m* is displayed in Figure 6.

Measurement was also performed on plane TEM waves to and from the Gravity Source (after 48 hours). TEM wave amplitude of the Gravity Source was more than 20 times larger than the TEM wave amplitude towards the sun, indicating its large influence. Note that TEM wave amplitude from the Gravity Source continued to increase after 48 hours by approximately 10% daily. Hence, it is reasonable to assume that the influence from the Gravity Source was very large.

Experiment 10. The purpose of this experiment was to introduce a method which facilitated separate measurement of TEM waves travelling in opposite direction, as described in **Figures 2** and **3**. Experiments 1-9 were enhanced in the following way; a static magnetic field $\mathbf{B}_M$ (*i.e.* a 1 μT magnet) was inserted at the centre of the plane TEM_1 and TEM_2 waves, 1 m from Source 1, see **Figures 2** and **3**. It was observed that in Experiment 1,

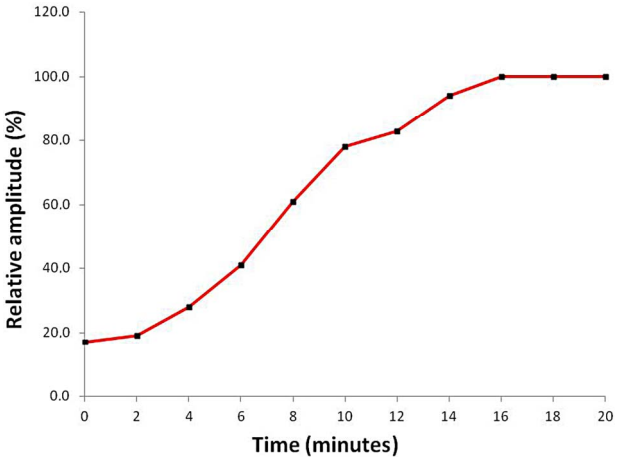

Figure 7. Field vector amplitude towards the sun as a function of time. One MQ, Source 1, was positioned on a table. The sun constituted Source 2. Measurements displayed plane TEM_1 waves propagating from Source 1 in direction towards the sun and plane TEM_2 waves propagating in direction from the sun to the MQ, Source 1. The amplitude of the plane TEM_1 and TEM_2 waves electric and magnetic field vectors ($\mathbf{E}^+$, $\mathbf{B}^+$, $\mathbf{E}^-$ and $\mathbf{B}^-$) was measured as a function of time. The amplitudes of field vectors were $\mathbf{E}^+ = \mathbf{E}^-$ and $\mathbf{B}^+ = \mathbf{B}^-$ at all times. After 16 minutes the amplitude was constant during an 8 hour measured period. The direction of plane TEM_1 waves and plane TEM_2 waves followed the position of the sun. After 16 minutes the length of TEM_1 field vectors were approximately 2 m at $U = 9$ V, indicating that the electric and magnetic field strength was significant and thus the field divergence divE was significant and easy to measure.

Copyright © 2013 SciRes.

TEM_1 was diverted much further than TEM_2, which provided a way to measure the plane TEM waves to and from the Gravity Source separately and to make a relative comparison between TEM_1 and TEM_2 amplitudes. It was also observed that in Experiment 9, TEM_1 was diverted much further than TEM_2, during the initial 8 minutes. It facilitated a way to measure the plane TEM waves to and from the sun separately and to make a relative comparison between TEM_1 and TEM_2 amplitudes.

Experiment 11. The purpose with this experiment was to measure extremely low frequency TEM waves received from the Gravity Source. The method was to create resonance (*i.e.* low impedance) in an MQ, connected to a signal generator, and to measure the amplitude of the absorbed TEM wave. One MQ, connected to a signal generator, was positioned on a table and this was called Source 1. The signal generator frequency was changed from 0.1 Hz to 1 Hz in steps of 0.01 Hz. The generator voltage was 0.5 mV RMS. It was observed that the MQ created resonance at 0.74 Hz and received plane TEM_2 waves from the direction of the Gravity Source. It was also observed that the MQ radiated 0.74 Hz plane TEM_1 waves to every type of matter, Source 2, in its vicinity. The amplitude of TEM_1 was proportional to the mass of Source 2. Furthermore, the amplitude of TEM_1, at Source 1, decreased linearly with the distance to Source 2. It was also observed that the amplitude of TEM_1 along the straight line between Source 1 and Source 2 decreased linearly with the distance from Source 1. It was not possible to observe any TEM_2 waves propagating from matter, Source 2, to the MQ, Source 1. It was concluded that the Gravity Source radiated plane TEM waves at 0.74 Hz and that this energy was absorbed by matter and probably re-emitted uniformly. The amplitude of the 0.74 Hz TEM wave, absorbed by matter, was significantly higher than the amplitude of 69.9 Hz and 91.9 Hz TEM waves propagating to the same matter (approximately 10 times larger).

It was observed in Experiments 1-11 that vertically propagating plane TEM waves (e.g. to/from the earth) resulted in that magnetic field vectors were oriented north to south caused by influence from the geomagnetic field. Otherwise the magnetic field vectors were oriented vertically, also the result of influence from the geomagnetic field. Consequently, the plane TEM waves were polarized which explains the efficiency of the measurement method used in Experiments 1-11.

5. Discussion

Experiments 2 and 9 displayed that gravity between the electronic device MQ (**Figure 1**) and the Gravity Source was much larger than gravity between the electronic device MQ and the sun. From Section 4 and 5 follows that gravity between the electronic device MQ and the Gravity Source was significant. It is proposed that the MQ within the atom (atomic MQ) behaves similar to the electronic device MQ. Consequently, the atomic MQ was exposed to two different gravity components, gravity between the atomic MQ and all other atomic MQs in the universe and gravity between the atomic MQ and the Gravity Source. It is proposed that the former is called gravitational gravity and the latter is called inertial gravity. The inertial gravity results in that the universe rotates (spirals) around the Gravity Source. Exposing the MQ to force accelerates the MQ relative to all other MQs and the Gravity Source. It can be illustrated with an MQ travelling through space, far away from planets and stars. It is primarily influenced by TEM waves from and to the Gravity Source. Its reference frame is the Gravity Source or more precisely TEM energy at MQ proximity. Its energy state relative to its reference frame (*i.e.* TEM energy generated by the Gravity Source) is changed when the MQ is accelerated and hence $\delta \mathrm{F} = \eta \cdot \mathrm{MQ} \cdot a$. a is the acceleration created by the quantified force δF on the inertial mass quantum $\eta \cdot \mathrm{MQ}$. A mass on earth experiences two reference frames. The first is the earth and its gravity and the second is the Gravity Source and its gravity. Hence, this mass m can be described as inertial mass, $m_i = \eta \cdot \sum \mathrm{MQ}$ and gravitational mass, $m_g = \beta \cdot \sum \mathrm{MQ}$ according to Equations (6) and (7). η and β are constants. This explains why, according to classical mechanics, the gravitational mass is proportional to the inertial mass. It is proposed that mass does not exist. Mass is only the observation of electromagnetic energy (*i.e.* TEM waves originating from the Gravity Source) operating on electric and magnetic fields, *i.e.* $\sum \mathrm{MQ}$ in atoms In that case Einstein's mass-energy equivalence may relate to the MQ, $\mathrm{E} = mc^2 = \zeta \cdot \sum \mathrm{MQ}$, where ζ is a constant.

The atom is in traditional physics described by its particles, quarks, gluon, graviton, baryon, proton, electron etc. and by its forces, the strong interaction, the weak interaction, electromagnetism and gravity, described in the Standard Model [8,9]. The present paper describes the atomic MQ (mass quantum) as an atomic entity creating gravity and inertia. The MQ consists of a static electric field in parallel with a magnetic field.

In its simplest form the MQ may consist of only two charges, a positive and a negative elementary charge forming an electric dipole. This dipole absorbs plane TEM waves from the Gravity Source with the frequency 0.74 Hz and this induces an electric and magnetic field with the frequency 0.74 Hz. Hence, this dipole consists of a static electric field and an almost static magnetic field. Consequently, the dipole can be regarded as an electromagnetic dipole which also creates resonance with plane TEM waves (gravity waves) at 69.9 Hz and 91.9 Hz. This dipole is called MQ in the present paper and it

Copyright © 2013 SciRes.

is the atom's elementary entity and also the atom's mass quantum.

The dipole (MQ) has electric and magnetic fields, electric and magnetic dipole moments, it produces gravity (mass) and it produces inertia (inertial mass). The force on one dipole (MQ) in the atom from all other dipoles (MQs) in the atom is entirely electromagnetic, *i.e.* caused by electromagnetic fields. The fields operating on the dipole consist of the vector sum of electric fields (Coulomb field) from all dipole's charges, the vector sum of electric dipole moments from all dipoles, the vector sum of induced electromagnetic fields (at 0.74 Hz) from all dipoles and the vector sum of induced electromagnetic dipole moments (at 0.74 Hz) from all dipoles.

The (induced) magnetic force (at 0.74 Hz) dominates within the atom's nucleus. It is proposed that this magnetic force represents what is commonly called gluon and the strong interaction. The electric force (Coulomb force) is strong within a dipole and between adjacent dipoles. Hence, the electric force can contribute to the strong interaction. However, within the atom's nucleus the electric force is normally smaller than the magnetic force. The force from electric and magnetic dipole moments is probably small. It is proposed that the electric force and the dipole moments normally represent what is commonly called the weak interaction and electromagnetism. The conclusion is that the atom can be described by configurations of MQs (dipoles) and elementary charges and by electromagnetic fields creating two forces; the magnetic force and the electric force. In addition the atomic MQs create resonance with gravity waves (TEM waves) and re-emit them. The flow of gravity waves between two MQs creates mutual force of attraction, *i.e.* gravity. Thus gravity is an electromagnetic force.

Positioning two MQs (dipoles) side-by-side; however, in opposite directions, results in strong magnetic and electric forces which fuses the MQs. MQs can be added forming a matrix. Such configuration can be described as a quark and various configurations can be described as various types of quarks.

Amalgamated quarks result in baryons, e.g. neutron. A proton is created when a positive elementary charge is added to one MQ in a neutron. An electron is created when a negative elementary charge is added to one MQ in a small configuration of MQs (e.g. a dipole with one positive charge and two negative charges). The sum of these configurations of MQs is the atom.

Consequently, the atom may consist of only positive and negative elementary charges configured into MQ, electron, quark, neutron, proton etc. Hence, the universe may consist of only positive and negative elementary charges and different configurations of these charges. All forces in the universe are electromagnetic forces induced by the position and motion (*i.e.* velocity and acceleration) of these elementary charges and their configurations, according to the laws of electromagnetism. The Gravity Source may consist of rotating charges and its generated TEM waves are the main provider and carrier [6] of energy within the universe. This model enables description of phenomena within the universe (e.g. dark energy, dark matter, expanding space, black hole, gravitational lensing and redshift) based on the laws of electromagnetism.

Equation (2) $\mathrm{F}(r)=\gamma\cdot\mathrm{S}_1(r)\cdot\mathrm{S}_2(r)$ describes the mutual force of attraction when the positions of the two sources are static relative to each other. When one source rotates relative to the other a force perpendicular to r is introduced and this force and the labor performed are minimized when the source's rotational axis is directed towards the other source. Experiment 1 displayed that the direction towards the Gravity Source was to the north, aligned to the earth's rotational axis; however, with a small misalignment. It is known that the Milky Way galaxy and its Galactic Centre contains the astronomical radio source Sagittarius A*. It has also been proposed that the Galactic Centre contains a super massive black hole. The earth's rotational axis is oriented towards the Galactic Centre; however, with a small misalignment [10,11]. Data from the WMAP mission display that distribution of energy in universe is anisotropic and may be aligned relative to the earth's rotational axis [12]. This anisotropic distribution of energy has recently (21 March 2013) been confirmed by data released from the Planck mission. Perhaps the earth's rotational axis and the Milky Way are oriented towards a concentration of mass in the universe and this concentration of mass is the Gravity Source. The universe expands and perhaps the Milky Way and the earth moves in direction from the Gravity Source, *i.e.* in the direction of the earth's geographical south? Compiling the present findings with known galaxy filaments may provide improved understanding of the universe.

It is proposed that there are three quanta. The positive and the negative elementary charges are the Charge Quantum. The atomic dipole is the Mass Quantum. The gravity wave and photon is the carrier of energy. The photon consists of electromagnetic energy superpositioned on gravity waves [6]. The gravity wave is the Energy Quantum. All three can be included in (modified) quantum physics. The fundament of modified quantum physics may comprise Charge Quantum, Energy Quantum and Mass Quantum operating on the laws of electromagnetism.

6. Conclusions

The study proposes that gravity is created by plane TEM (transverse electromagnetic) waves, which is the solution to Maxwell's equations $\operatorname{curl}\mathbf{H}=\boldsymbol{i}+\partial\mathbf{D}/\partial t$ and

Copyright © 2013 SciRes.

$\mathrm{curl}\,\mathbf{E} = -\partial\mathbf{B}/\partial t$ [3]. The gravitational force or mutual force of attraction between two synchronized plane TEM waves travelling in opposite direction is proportional to the scalar product of their Poynting vectors [4] according to Equation (2).

It is proposed that a gravitational singularity called the Gravity Source emitted plane TEM waves to elementary entities, or more precisely, to mass quanta, MQs, within the atom's nucleus. It is proposed that the MQ contained intrinsic, merged electric and magnetic fields or electromagnetic dipoles or one electric dipole. These almost static merged fields created resonance with the plane TEM wave's almost static field vectors. The received plane TEM waves were re-emitted as plane TEM waves and distributed to, in principle, every MQ in the universe and where the amplitude decreased linearly with the distance to the MQ. The content of these plane TEM waves remained unchanged. Simultaneously every MQ in the universe received plane TEM waves from, in principle, every other MQ in the universe. The plane TEM wave amplitude was inverse proportional to the distance between the MQs. Energy emitted by the Gravity Source was partly re-emitted to the Gravity Source. Hence, every MQ was also exposed to gravity from the Gravity Source.

The mutual force of attraction between two MQs is described by Equation (3). The mutual force of attraction between two masses (*i.e.* the sum of contributions from many MQs) is described by Equation (6), which is approximately equal to the Newtonian geometric law of gravity according to Equation (7).

The plane TEM wave frequency was measured in Experiments 1-4 using a device, MQ, which created resonance at a predetermined frequency; it received and re-emitted plane TEM waves at one particular frequency. It consisted of an internal alternating electric field $\mathbf{E}_i$ with frequency 0.74 Hz, 69.9 Hz or 91.9 Hz, merged with an internal static magnetic field $\mathbf{B}_i$.

Experiment 1. This experiment confirmed the existence of the Gravity Source generating plane TEM waves with the frequency 69.9 Hz and 91.9 Hz. The direction towards the Gravity Source was to the north and followed a diurnal, counter-clockwise circle with approximately 20 degrees cone angle. It was assumed that the diurnal change of direction was caused by the rotation of the earth and where the earth's axis was misaligned 10 degrees relative to the direction towards the Gravity Source.

Experiment 2. This experiment displayed that plane TEM wave's amplitude to/from the Gravity Source was at least twenty times the plane TEM wave's amplitude to/from the sun, confirming its large influence.

Experiments 2-4. These experiments confirmed that the sun, the moon, the earth and an object (e.g. iron) positioned in close proximity to the MQ, produced and received synchronized and mutually coupled plane TEM waves with frequency 69.9 Hz and 91.9 Hz. It indicated that these objects produced 69.9 Hz and 91.9 Hz plane TEM waves and that these plane TEM waves were synchronized to the Gravity Source's plane TEM waves.

Experiment 5. The purpose of this experiment was to validate the theoretical model Equation (2) and Equation (6); $\mathrm{F}(r) = \gamma \cdot \mathrm{S}_1(r) \cdot \mathrm{S}_2(r) = \xi \cdot n \cdot p/r^2$. $\mathrm{S}_1(r)$ and $\mathrm{S}_2(r)$ were measured as a function of n and p. n respectively p MQs were positioned at a distance r. Results displayed that $\mathbf{E}^+$, $\mathbf{B}^+$, $\mathbf{E}^-$ and $\mathbf{B}^-$ amplitudes were proportional to $n \cdot p$ confirming Equations (2) and (6) and also Equations (3)-(5). This was simulated by varying the voltage U on Source 1, resulting in proportional change in field vector amplitude and within the measurement accuracy as displayed in **Figure 4**.

Experiment 6. The purpose of this experiment was to validate the theoretical model Equation (2) and Equation (6); $\mathrm{F}(r) = \gamma \cdot \mathrm{S}_1(r) \cdot \mathrm{S}_2(r) = \xi \cdot n \cdot p/r^2$. $\mathrm{S}_1(r)$ and $\mathrm{S}_2(r)$ were measured as a function of r. In this experiment the distance r between MQs was varied, displaying that field vector amplitudes $\mathbf{E}^+$, $\mathbf{B}^+$, $\mathbf{E}^-$ and $\mathbf{B}^-$ were proportional to $1/r$ confirming Equations (2)-(6). Measured data was in good agreement with the theoretical decline $1/r$, displayed in **Figure 5**. (Note that field vectors decreased with $1/r$ while energy decreased as $1/r^2$).

Experiment 7. Plane TEM waves propagating between two MQs displayed that the sum of TEM_1 and TEM_2 field vector amplitudes were constant all the way from one MQ to the other MQ. It indicated the mutual coupling between synchronized plane TEM_1 and TEM_2 waves propagating in opposite direction. It is proposed that there was a transfer of energy between the two TEM waves. This transfer of energy and the back reaction force that the plane TEM waves created on its source created mutual force of attraction or gravity according to Equation (2). Consequently, Experiment 7 supports the theoretical model.

Experiment 8. The purpose of this experiment was to validate the theoretical model Equation (2), Equation (6) and Equation (7); $\mathrm{F}(r) = \gamma \cdot \mathrm{S}_1(r) \cdot \mathrm{S}_2(r) = \xi \cdot n \cdot p/r^2 \approx \mathrm{F}_{\mathrm{Newton}} = \mathrm{G} \cdot m_1 \cdot m_2/r^2$. $\mathrm{S}_1(r)$ and $\mathrm{S}_2(r)$ were measured as a function of the mass m_2.This experiment proved that an object (mass) produced gravity proportional to its mass m, confirming Equations (6) and (7). This experiment showed that a mass produced plane TEM waves identical the Gravity Source, the sun, the moon and also the electronic device used in Experiments 1-7. This indicates that the mass, the sun and the moon contained similar type of mechanism of intrinsic nature and similar to the function of the electronic device called MQ. It is proposed that the mass, the sun and the moon contained an elementary entity or mass quantum which created resonance and

Copyright © 2013 SciRes.

re-emitted gravity TEM waves originating from the Gravity Source. It is proposed that the mass quantum consisted of an intrinsic electric field or dipole merged with a magnetic field or dipole.

Experiment 9. The purpose with this experiment was to show that Equation (2), $F(r)=\gamma\cdot S_1(r)\cdot S_2(r)$, was only valid at steady state and to demonstrate how this steady state was achieved. It took approximately 16 minutes to stabilize the TEM_1 waves propagating from Source 1 (the MQ) to Source 2 (the sun) and the TEM_2 waves propagating from Source 2 to Source 1. The field vectors reached their maximum amplitude after approximately 16 minutes. The round trip to the sun was 16.6 minutes at the speed of light. It can be explained as follows. The MQ at Source 1 was switched on at time t = 0 minutes. After 8.3 minutes (t = 8.3) TEM_1 waves reached the sun creating the force $F(r)=\gamma\cdot S_1(r)\cdot S_2(r)$ at the sun. Then it took another 8.3 minutes (t = 16.6) before the influenced TEM_2 waves reached Source 1. The two synchronized TEM_1 and TEM_2 waves created mutual force of attraction between Source 1 and Source 2, and full gravity (at t = 16.6). The experiment confirmed the mutual exchange of energy between the two sources according to Equation (2) and also that plane TEM waves (off course) propagated with the speed of light.

Experiment 10 displayed that it was possible to separate TEM_1 waves from TEM_2 waves and that it was possible to measure the two directions separately.

Experiment 11 displayed that investigated matter contained some type of mechanism that absorbed plane TEM waves at 0.74 Hz, originating from the Gravity Source. Hence, TEM waves at 0.74 Hz were absorbed by matter and its atoms. Consequently, the absorbed TEM wave energy must induce electric and magnetic fields with the frequency 0.74 Hz within atoms.

The conclusion is that the universe contained a gravitational singularity called the Gravity Source. It generated plane TEM waves with the frequency 69.9 Hz and 91.9 Hz. Atomic mass quanta, MQ, consisting of intrinsic, merged static electric and magnetic fields or dipoles created resonance with these plane TEM waves. They were then re-emitted to other atomic MQs as plane TEM waves with the frequency 69.9 Hz and 91.9 Hz. Atomic MQs in the universe were synchronized to the Gravity Source which resulted in that received and emitted plane TEM waves were synchronized, causing exchange of energy and mutual force of attraction, which is called gravity. The atom consisted of many MQs. This resulted in an equation called the electromagnetic law of gravity, Equation (6). It was compared with the Newtonian geometric law of gravity, Equation (7). In addition the Gravity Source radiated plane TEM waves at 0.74 Hz, which was absorbed by matter and the absorbed plane TEM wave amplitude was linear to the mass, indicating an intrinsic atomic mechanism.

The following offers a possible explanation to the origin of the Gravity Source. It is proposed that the Gravity Source consisted of a kernel of charge rotating at three speeds (*i.e.* T = 1/0.74 s, T = 1/69.9 s and T = 1/91.9 s), constituting a gigantic electromagnetic generator. It emitted photons and their plane TEM waves with frequency 0.74 Hz, 69.9 Hz and 91.9 Hz.

Experiments 1-11 can also be summarized as follows. Gravity consisted of extremely low frequency plane TEM waves. Using state of the art measurement technique would require unrealistically long antennas. The method was to create plane TEM wave spatial divergence, which was created with the electronic device called MQ and polarization created by the geomagnetic field. The plane TEM wave spatial divergence created TEM wave field vector divergences div**E** and div**B** which were measured with a charge meter. This innovative measurement technique enabled unbundling of gravity.

It is proposed that the present study unifies gravity, described by Equation (6), with electromagnetic theory and quantum physics. Hence, this electromagnetic theory of gravity supplements Newtonian geometric theory of gravity, relativistic metric theory of gravity, Newton's second law of motion and Einstein's mass-energy equivalence.

We have developed a stable, reliable source of continuous-wave squeezed vacuum at 1064 nm, using a subthreshold monolithic lithium niobate optical parametric oscillator. Quantum-noise reduction below the vacuum noise level in a bandwidth of 30 MHz with a maximum of 5.5 ± 0.2 dB at 2 MHz is demonstrated. The reconstruction of the Wigner function of a continuous-wave, strongly squeezed-vacuum state is obtained.
© 1995 Optical Society of America

1. INTRODUCTION

Squeezed states of light have been successfully demonstrated in several different schemes, for both phase and amplitude quadratures of the electromagnetic field.[1] Among these schemes, the optical parametric oscillator (OPO) operating both below and above threshold has been verified to be a very good squeezing generator. In addition to the demonstration of a high degree of squeezing,[2–4] these devices have been used in several applications such as sub-shot-noise interferometry and spectroscopy, noise reduction in optical amplification, and back-action-evading measurements.[5–8] It has also been suggested that the solution of many challenging problems in quantum mechanics, such as quantum nondemolition measurements, noiseless amplification, and Schrödinger cats, can be pursued with OPO's.[9–11] For most of these experiments and proposals, OPO's with good stability and low loss are essential.

To realize a compact, stable, low-loss system for the generation of squeezed states of light, we employ a monolithic resonator. The monolithic resonator is a simple device that consists of a nonlinear crystal coated on both faces with reflecting dielectric coatings. Such a design ensures good mechanical stability and small losses. Furthermore, because of the short length of the cavity, the linewidth of such a resonator is broad compared with those at discrete cavities, which implies a broad bandwidth in the noise reduction. The performance of monolithic resonators has been successfully tested for second-harmonic generation and frequency downconversion and for the generation of nonclassical light such as twin beams and bright squeezing in second-harmonic generation.[12–14]

In this paper we combine these techniques to build a compact continuous-wave source of squeezed vacuum at 1064 nm. Our research is partially motivated by the possible application of such a squeezed-light source in planned gravitational wave interferometers and ultrasensitive polarimeters, which will operate at this wavelength.[15,16] In addition to the measurement of broadband squeezing, we applied the technique of optical homodyne tomography[17,18] to reconstruct, for the first time to our knowledge, the Wigner function of a strongly squeezed state in the continuous-wave regime.

The paper is organized as follows. In Section 2 we describe the experimental setup and characterize the OPO. In Section 3 we present the measurements of squeezing and the reconstruction of the Wigner function. Conclusions and future prospects are given in Section 4.

2. EXPERIMENTAL SETUP AND CHARACTERIZATION OF THE OPO

A general overview of the experimental setup is shown in Fig. 1. A frequency-doubled diode-pumped Nd:YAG laser (Lightwave Electronics Model 122) pumps a monolithic degenerate type-I OPO whose output is analyzed in a balanced homodyne detector.

The OPO is a 7.5-mm-long standing-wave resonator consisting of a $LiNbO_3$ crystal doped with 5% MgO. The end faces of the crystal are polished spherically, with 10-mm radii of curvature. One end of the crystal is coated with a high reflector at both 1064 and 532 nm; the other side is the output coupler with transmission $T = 2.1\%$ at 1064 nm and high transmission at 532 nm. With this configuration, the nonresonant pump double passes the resonator to enhance the nonlinear coupling, so that the threshold is reduced. The faces perpendicular to the crystal c axis are coated with gold for electro-optic modulation. The resonator is embedded in an aluminum oven whose temperature is actively controlled to a few millikelvins. The measured finesse of the OPO is 265, which, considering the free spectral range of 9 GHz, gives a linewidth of $2\Gamma = 34$ MHz (FWHM).

Crucial for the suitability of a resonator for the generation of strong squeezing is its escape efficiency $\rho = T/(T + A)$, where T is the transmission of the output coupler and A is the total internal round-trip loss of the resonator. The value of ρ is equal to the maximum achievable degree of squeezing. For a monolithic resonator, it is not easy to measure the propagation losses A and the output coupler transmission T separately. A

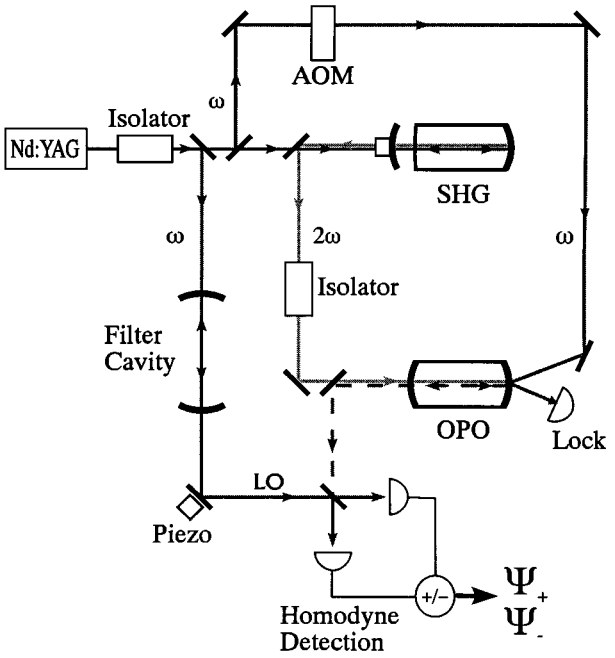

Fig. 1. Experimental scheme for the generation of squeezed vacuum with a monolithic $LiNbO_3$ resonator. AOM, acousto-optic modulator; SHG, second-harmonic generator; LO, local oscillator; piezo, piezoelectric mirror actuator.

direct way to determine the escape efficiency consists of measuring the conversion efficiencies for resonant second-harmonic generation or for parametric downconversion. For both processes the maximum conversion efficiency is equal to ρ. In previous experiments we measured maximum conversion efficiencies of 82% and 84% for frequency doubling and downconversion, respectively, at pump powers near 110 mW.[13,19] Correcting these values for the imperfect mode-matching results in an escape efficiency ρ of 88%. Assuming perfect detection efficiency, the best degree of squeezing possible with this resonator is 9.5 dB.

A basic requirement for our system is temporal stability of the squeezing. This condition can be achieved by active stabilization, whereby the laser frequency is locked to the OPO cavity resonance and the frequency-doubling cavity is locked to the laser frequency. For the stabilization of the laser frequency a probe beam at 1064 nm is frequency shifted by 180 MHz with an acousto-optic modulator and is injected through the high-reflector end of the monolithic standing-wave cavity into a higher-order transverse mode, such that the laser frequency (the subharmonic of the OPO's pump frequency) coincides with the resonator's TEM_{00} mode. Thus degenerate operation of the OPO is ensured. An error signal for the feedback to the laser is generated by a modified Pound–Drever technique,[20] in which the OPO crystal is modulated at 14.5 MHz, and the ensuing amplitude modulation of the probe wave is measured in reflection by a rf photodetector (see Fig. 1).

In fact, the high frequency stability of the laser and the OPO and the large OPO linewidth allow us to keep the laser frequency in resonance manually for several minutes. Most measurements shown here were therefore done without active stabilization of the laser.

The frequency-doubling cavity is independently locked to the laser frequency with a similarly generated error signal controlling the cavity length by means of a piezoelectric mirror actuator.

The squeezed vacuum at the output of the OPO is combined with a strong local oscillator in a balanced homodyne detector.[21] As photodetectors we used passivated Epitaxx ETX500 InGaAs photodiodes with the covers removed. We measured the quantum efficiency to be 97%, using a Laser Instrumentation thermopile for calibration. The local oscillator is split off from the laser source and is filtered by a high-finesse cavity to reduce the excess amplitude noise of the diode-pumped Nd:YAG laser at frequencies of a few megahertz. The filter cavity is 50 cm long, with a bandwidth of 140 kHz. Figure 2 shows the spectral densities $\Psi_{\pm}$ of the photocurrents $i_{\pm}$ from the plus and the minus junctions of the homodyne detector for the beams before and after the filter cavity. A comparison of the traces shows that the excess noise of the laser is strongly suppressed by the filter cavity, so that the local oscillator is shot-noise limited at frequencies ≥ 1 MHz. The suppression of a strong coherent modulation applied to the local oscillator is better than 20 dB. The shot-noise level, determined by comparison of Ψ_+ and Ψ_- when the open port of the beam splitter has vacuum input, is accurate to 0.3 dB for a wide range of frequencies. When the balancing of power in the two detectors is optimized for a particular frequency, the accuracy is of the order of 0.2 dB. With a local oscillator power of 2 mW the shot-noise level is 14 dB above the electronic noise level of the detectors at lower frequencies and 5 dB for frequencies above 24 MHz.

The alignment as well as the mode matching of the pump into the OPO were optimized by operation of the OPO above threshold, as described in Ref. 19. Further optimization of the pump alignment and the OPO temperature was done by measurement of the parametric amplification of a small signal at 1064 nm injected into the high-reflector port of the cavity. With pump powers near the threshold power of 28 mW, parametric gain as high as 170 was observed.

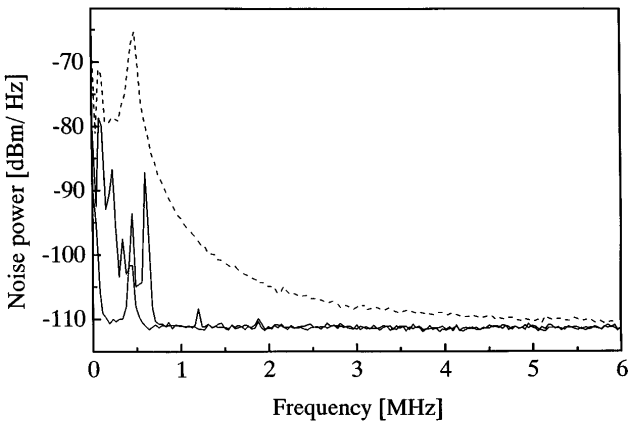

Fig. 2. Spectral density of the amplitude noise of the diode-pumped Nd:YAG laser as a function of frequency. Shown are Ψ_+ before the filter cavity (top, dashed trace) and Ψ_+ after the filter cavity (middle, solid trace). The bottom trace shows Ψ_- for both cases. The peak at 500 kHz is due to the relaxation oscillation of the laser. The second peak at 600 kHz in the trace of Ψ_+ after the filter cavity is the frequency modulation used for locking the cavity. The resolution bandwidth was 10 kHz.

3. MEASUREMENTS OF SQUEEZING

A. Squeezing Spectrum

The squeezed vacuum from the OPO is detected by a measurement of the photocurrent fluctuations i_- from the balanced homodyne detector. The resulting current is sent to a spectrum analyzer, where the spectral density Ψ_- is recorded. The maximum noise enhancement S_+ (antisqueezing) and reduction S_- (squeezing) correspond to the fluctuations of the quadrature components $\hat{x} = (\hat{a} + \hat{a}^\dagger)$ and $\hat{p} = (\hat{a} - \hat{a}^\dagger)/i$ of the electric-field operator $\hat{E}$. For a pump power P and an analysis frequency Ω, the spectra are given by[2,22]

$$S_\pm(\Omega, P) = \pm \frac{4\sqrt{P/P_{\text{th}}}}{(\Omega/\Gamma)^2 + (1 \mp \sqrt{P/P_{\text{th}}})^2}, \tag{1}$$

where $\Gamma = 17$ MHz is the cavity linewidth (HWHM) and $P_{\text{th}} = 28$ mW is the threshold power of the OPO. The measured spectral densities of the photocurrents are related to the spectra by

$$\Psi_\pm(\Omega, P) = \Psi_0[1 + \xi\rho S_\pm(\Omega, P)], \tag{2}$$

where Ψ_0 is the spectral density for a vacuum-state input, ρ is the escape efficiency of the resonator, and ξ is the detection efficiency; the last includes propagation losses after the OPO, homodyne efficiency, and detector quantum efficiency.

Because we used broadband detectors that were calibrated between 1 and 30 MHz, we were able to record the whole spectrum of squeezing and antisqueezing by keeping the phase of the local oscillator constant at either minimum or maximum noise level. After subtracting the electronic noise and normalizing the squeezing and the antisqueezing to the shot-noise level, we obtained the traces shown in Fig. 3. The observation of squeezing at still higher frequencies was limited only by the bandwidth of the photodetectors employed in our detection scheme. The theoretical spectra are in good agreement with the experimental data, as shown by the curves presented in Fig. 3, where we used the total efficiency $\delta\xi$ and P/P_{th} as fit parameters.
